We demonstrate a technique that allows to fully control the bandwidth of entangled photons independently of the frequency band of interest and of the nonlinear crystal. We show that this technique allows to generate nearly transform-limited biphotons with almost one octave of bandwidth (hundreds of THz) which corresponds to correlation times of just a few femtoseconds. The presented method becomes an enabling tool for attosecond entangled-photons quantum optics. The technique can also be used to generate paired photons with a very high degree of entanglement.

The development of methods for the generation of entangled photon pairs (biphotons) with a specific bandwidth has been of great interest in recent years. Narrow bandwidth of frequency correlations is important for the design of efficient atom-photon interfaces [1] in quantum networks [2], for long distance quantum communications [3], or to enable direct measurements of temporal correlations with current photodetectors [4, 5].

On the other hand, some applications such as quantum optical coherence tomography [6] and nonlinear microscopy [7] require wide bandwidths. Wide bandwidths are a requisite for the generation of biphotons with very short correlation times [8] and when high fluxes of biphotons are desired [9]. A bandwidth of hundreds of THz can generate biphotons with a few femtoseconds of correlation time. These short temporal biphotons are of particular interest in the fields of quantum metrology [10] and for some protocols for timing and positioning measurements [11]. The narrow temporal correlation embedded in the biphoton can be transmitted over large distances thanks to the strong correlations of the entangled photons that allow to remotely compensate for chromatic dispersion [12].

Spontaneous parametric down conversion (SPDC) is the most convenient source for the generation of entangled photon pairs. When an intense laser beam illuminates a nonlinear material, with a certain small probability a pump photon might split into two lower energy photons. In analogy with a classical pulse, the temporal correlation width of the biphoton is determined by its spectral bandwidth and spectral phase [13]. The bandwidth of the SPDC pairs is determined by the type of phase-matching (type-I, type-II), the length and the dispersive properties of the nonlinear material, the geometry of the SPDC configuration (collinear or non-collinear) and by the spectral and spatial characteristics of the pump beam. By changing any of these parameters it is possible to modify the bandwidth and therefore the temporal correlations of the SPDC photons. For example, by choosing a particular material (PPLN) and pumping it at a specific wavelength (λ = 1885 nm), an ultra broad bandwidth of ~ 1080 nm has been recently reported [14]. However, from this experiment no conclusion can be drawn about the biphoton’s temporal length because the spectral correlations were not measured. In contrast, the group of Silberberg achieved to produce a bandwidth of 100 nm that yielded a biphoton with 23 fs of correlation time [7].

An alternative approach to modify the SPDC bandwidth is to use chirped quasi-phase matched crystals [15]. A frequency correlation bandwidth of ~ 300 nm at a central wavelength of 812 nm has been achieved. Nevertheless, when this technique is used to obtain narrow temporal biphotons, compensation of the spectral phase is required as the biphotons are not transform limited.

In this Letter, we demonstrate experimentally a technique to increase the SPDC bandwidth in order to generate ultrashort near transform-limited biphotons. It employs angular dispersion (pulse-front tilt) to modify the effective group velocity and group velocity dispersion of the interacting waves. Differently from other approaches, the method is not based on the choice nor on the engineering of the nonlinear material and it works in any frequency band and in any nonlinear crystal of interest. That offers two advantages: First, the wavelength can be chosen in the region where single-photon detectors exhibit high detection efficiency; second, advantage can be taken of materials with high nonlinear coefficient that naturally do not provide the desired bandwidth.

Angular dispersion is a powerful enabling tool in many different areas of optics. It can be used to introduce negative group velocity dispersion in a beam propagating in free space [16], it is a key element in many techniques for pulse compression, it enables the generation of femtosecond second harmonic waves [17, 18], and it has made possible the observation of temporal solitons [19], where the natural dispersion of the material would have made such observation impossible. In quantum optics, angu-
lar dispersion enables to tailor the frequency correlations of entangled photons and allows to generate frequency-uncorrelated and frequency-correlated pairs of photons, quantum states that are not easily produced in most experimental configurations currently used.

Let us consider collinear SPDC where the downconverted photons copropagate along the direction of the pump beam. The state of the downconverted photons at the output of the medium may be written as

$$|\psi\rangle = \int dq_s dq_i d\Omega_s d\Omega_i \Phi(\Omega_s, \Omega_i, q_s, q_i) |\Omega_s\rangle |\Omega_i\rangle,$$

where $$\Omega_j$$ ($$j = s, i$$) denote the signal and idler photons’ angular frequency detunings from the central angular frequency $$\omega_j^0$$, i.e., $$\omega_j = \omega_j^0 + \Omega_j$$, and $$q_j$$ are the corresponding transverse wavenumber vectors. The spectral and spatial properties of the down-converted photons are described by the joint spectrum

$$\Phi(\Omega_s, \Omega_i, q_s, q_i) \propto E_\omega(\Omega_s + \Omega_i) E_q(q_s + q_i) \times \text{sinc}\left(\frac{\Delta k L}{2}\right) \exp\left(i \frac{sk L}{2}\right),$$

where $$E_\omega$$ and $$E_q$$ are the spectral and transverse wavenumber distributions of the pump beam at the input face of the nonlinear crystal of length $$L$$, respectively. $$\Delta k = k_p - k_s - k_i$$ is the phase-mismatch along the longitudinal direction with $$k_j = (\omega_j n_j)^2 / c^2 - |q_j|^2$$, and $$s_k = k_s + k_i$$. $$n_j$$ is the index of refraction and $$c$$ the speed of light.

To illustrate the principle behind the proposed method, let us consider the scheme shown in Fig. 1. In contrast to typical collinear SPDC configurations, the nonlinear crystal is placed between two optical elements that introduce angular dispersion, e.g., a pair of prisms or diffraction gratings. Angular dispersion $$\epsilon$$ causes the front of the pulse to be tilted by an angle $$\xi$$ given by

$$\tan \xi = -\lambda_0 \epsilon,$$

where $$\lambda_0$$ is the central wavelength of the pulse and angular dispersion $$\epsilon = m / (d \cos \beta_0)$$, where $$m$$ is the grating’s diffraction order, $$d$$ is the groove spacing and $$\beta_0$$ is the output diffraction angle.

The introduction of angular dispersion modifies the spatial distribution of the pump $$E_q$$ and the phase-mismatch $$\Delta k$$ of the joint spectrum of Eq. 2. If the gratings introduce opposite angular dispersion in such a way that $$\tan \xi_s = -\tan \xi_p / \alpha_p$$ and $$\alpha_p \alpha_s = 1$$, it is possible to modify $$\Delta k$$ only, and to effectively modify the group velocity and the group velocity dispersion of the pump, signal and idler photons. Here $$\alpha_j \equiv \cos \theta_j / \cos \beta_j$$ with $$\theta_j$$ and $$\beta_j$$ being the incidence and diffraction angles of the pump beam at grating $$Gr_1$$, respectively.

The effects of angular dispersion on the SPDC spectrum can be better understood by expanding $$\Delta k$$ in a Taylor series about the central frequencies $$\omega_j^0$$. For a quasi-continuous-wave pump, the frequency detunings of the downconverted photons must be anticorrelated in order to satisfy energy conservation, i.e., $$\Omega_s = -\Omega_i$$, and $$\Delta k$$ becomes

$$\Delta k \approx (N_s' - N_i') \Omega_s - \frac{1}{2} (g_s' + g_i') \Omega_s^2 + \ldots,$$

where $$N_j' = N_j + \tan \xi_j \tan \rho_j / c$$ and $$g_j' = g_j - [\tan \xi_j / c] k_j^0 / k_j$$ play the role of effective inverse group velocity and effective group velocity dispersion, respectively. The inverse group velocity $$N_j = (dk_j / d\omega_j)_{\omega_j^0}$$ and group velocity dispersion $$g_j = (d^2 k_j / d\omega_j^2)_{\omega_j^0}$$ are modified in the presence of the pulse-front tilt $$\xi_p$$ and Poynting-vector walk-off $$\beta_j$$. The new effective values of group velocity and group velocity dispersion depend on the angular dispersion experienced by the pump beam and allow us to control the SPDC bandwidth.

For example, let us consider type-II SPDC where the polarizations of the downconverted photons are mutually orthogonal. If tilt $$\xi_p$$ is chosen such that the effective group velocities are equal, $$N_s' = N_i'$$, the lowest non-zero term in phase mismatch $$\Delta k$$ is of the second order which results in an increase of the bandwidth. We obtain a type-II process where the dependence of the bandwidth on the length of the nonlinear crystal goes as $$1 / \sqrt{L}$$ instead of the typical $$1 / L$$ [13]. The value of the pulse tilt that maximizes the bandwidth is

$$\xi_{II} = \tan^{-1}\left(\frac{c(N_i - N_s)}{\tan \rho_s - \tan \rho_i}\right).$$

On the other hand, in a type-I process the polarizations and the group velocities of the signal and idler photons are equal. The bandwidth is increased if the tilt is chosen such that $$g_s' = g_i' = 0$$. In such a case, the first non-zero term in $$\Delta k$$ is of the 4th order and the dependence of the bandwidth on the length of the crystal goes as $$1 / L^{1/4}$$. The tilt that maximizes the bandwidth is

$$\xi_l = \tan^{-1}\left(\frac{c^2 g_j k_j^0}{2}\right),$$

where $$k_j^0 = k_j (\omega_j^0, q_s = q_i = 0)$$.

To demonstrate the feasibility of the proposed technique, an experiment was performed (see Fig. 1). A
2 mm thick, type-II BBO crystal flanked with two gratings Gr1 and Gr2 was pumped by the second harmonic (Radiantis Blue Stream, 40% efficiency in the picosecond regime) of a picosecond Ti:sapphire laser (Coherent Mira 900-P) tuned at 810 nm. The downconverted photons were separated by a polarizing beamsplitter and fed into monochromators Mono1 and Mono2 (Jobin Yvon MicroHR). Single-photon detectors (Perkin-Elmer SPCM-AQR-14-FC) measured single counts and coincidence counts coincidences counted coincidence counts within a 3 ns window. The joint spectrum was broadened by measuring the number of coincidences while the two monochromators scanned the plane from 760 nm to 860 nm.

Figure 2 shows the experimental results. Fig. 2(a) depicts the joint spectral density for tilt ξ_p = 0° when the gratings were removed. The typical frequency anti-correlation of the SPDC photons can be observed. Fig. 2(b) corresponds to the situation with tilt ξ_p max = 38° that maximizes the bandwidth. This was accomplished by taking grating Gr1 with a groove spacing d = 1/1200 mm and diffraction angle β_p = 52°. In order to satisfy tan ξ_s = -tan ξ_p/ξ_s and α_p α_s = 1, grating Gr2 had d = 1/600 mm and β_s = 18°.

A more quantitative comparison between the cases with and without pulse-front tilt is plotted in Fig. 3. The graphs in the upper row correspond to the spectra of signal single counts measured after one of the monochromators: (a) without tilt and (b) with tilt ξ_p = 38°. The spectra of idler photons are not shown for being alike. The squares are experimental data and the solid lines are the theoretical prediction.

Figures 3(c) and (d) depict the profile of the number of coincidence counts along the antidiagonal (straight line at -45°) of Fig. 2 without tilt and with tilt, resp. The variable Λ_− = (Λ_s − Λ_j)/√2, where Λ_j is the detuning from the central wavelength, is associated with this antidiagonal. Without tilt, the FWHM bandwidth was measured to be ΔΛ_− ~ 7.5 nm (Fig. 3(c)). Applying a tilt ξ_p = 38°, the bandwidth broadened to ΔΛ_− ~ 52 nm (Fig. 3(d)). The sevenfold increase of the bandwidth is achieved without any modification of the nonlinear crystal or the working wavelength, only by introducing angular dispersion into the pump beam and the downconverted photons. It is this independence of the material properties and of the working wavelength which makes the method proposed here so promising for controlling the bandwidth of the SPDC photons.

The application of this method for the generation of entangled photons with very narrow temporal correlations can be seen in Fig. 4. In general, temporal biphoton Ψ(t_1,t_2) (t_j is the clicking time of j-th detector) is given by the amplitude and phase of the joint spectrum Φ(Ω_s,Ω_l). Fig. 4 shows the spectral density (a), spectral phase (b) and temporal shape (c) of a biphoton for the case of 2-mm thick Type-I BBO SPDC at 810 nm. Type-I phase matching was chosen because of its naturally broader spectrum. In the case without tilt, the spectral phase follows a quadratic dependence. In the case with tilt in the region where the spectral density varies, the spectral phase is almost constant due to its fourth-order dependence on the frequency. This is the fact that makes possible to generate nearly transform-limited biphotons. The mentioned increase of bandwidth translates into ultrashort biphotons with a temporal correlation of a few femtoseconds. This contrasts with other methods where the increase of the bandwidth is not directly accompanied by a decrease of the correlation time [15, 23].

Figure 4(c) was obtained by performing a Fourier transform of Eq. 2 both numerically and analytically. The dashed and solid lines correspond to the case ξ_p = 0° and ξ_p = ξ_p max = 16.2°, resp. The FWHM bandwidth of the spectral density obtained without tilt is 96 nm.

![Figure 2](image1.png)  
![Figure 3](image2.png)
entanglement can be achieved using broadband SPDC photons. For entangled photons of the form $\Phi(\Omega_s, \Omega_i) \propto \exp\left\{ -\frac{(\Omega_s + \Omega_i)^2}{B_p^2} \right\} \exp\left\{ -\frac{(\Omega_s - \Omega_i)^2}{B_c^2} \right\}$, the entropy of entanglement $22$ depends on the ratio between the bandwidth of the pump beam $B_p$ (typically $2\pi$ MHz) and the bandwidth of the biphoton $B_c$. For a bandwidth of $\Delta \lambda = 31 \text{ nm}$ ($B_c \sim 2\pi$ $16.4$ THz) at $1064$ nm $24$, one has values of $B_c/B_p \sim 3.3 \times 10^6$ and $E \sim 21$ ebits. The method presented here allows to reach values of $\Delta \lambda > 500$ nm ($B_c > 2\pi$ $420$ THz), therefore allowing typical ratios greater than $8.4 \times 10^7$ and $E > 26$ ebits.

In conclusion, a scheme to broaden the bandwidth of the SPDC photons was experimentally demonstrated. The method is based on the introduction of angular dispersion (pulse-front tilt) into the pump and downconverted photons which allowed us to demonstrate a sevenfold increase of the original bandwidth without changing the nonlinear crystal or the frequency band. The potentiality of the proposed method to generate ultrashort nearly transformed-limited biphotons, and with a high degree of entanglement, has also been discussed. The described method can allow biphotons to enter the realm of attosecond quantum optics, since it allows the generation of entangled photons with correlation times below one femtosecond.
