INTRODUCTION

Coronaviruses (CoVs) are single-chain, enveloped RNA viruses. They do not contain the RNA polymerase enzyme; however, they encode this enzyme in their genome. They are defined as CoV due to the protrusions on their surface (Latin: corona=crown). Coronaviruses belong to the Orthocorona-virinae sub-family and are classified as four types (alpha, beta, gamma, and delta CoVs) and multiple subspecies. Coronavirus 2019 is within the beta-coronavirus 2b strain. The genomes of the beta-coronaviridae were
shown to be closely related to the bat SARS-like coronavirus\(^2\). This type of virus may be found in humans, bats, pigs, cats, dogs, remnants, and winged animals\(^3\). Coronaviruses are a large virus family that may lead to self-limited, mild, and common infections like the common cold, and also more severe infections like Severe Acute Respiratory Syndrome (SARS)\(^4\) and Middle East Respiratory Syndrome (MERS)\(^5\). These viruses may lead to clinical conditions with various degrees of respiratory, enteric, hepatic, nephritic, and neurological involvement.

Pneumonia cases with unknown etiology and of suggested viral origin were reported in Wuhan, Hubei, China on 31 December 2019. The virus was shown in workers of the seafood wholesale market where different animal types are sold. The patients exhibited fever, dyspnea, cough, and, radiologically, bilateral pneumonic infiltrations\(^6\). Death usually occurred in individuals who were elderly or who had comorbid systemic diseases (hypertension, diabetes mellitus, cardiovascular diseases, cancer, chronic pulmonary diseases, and other immune-suppressive conditions)\(^7,8\).

The pathophysiology of the high pathogenicity of this unusual highly contagious SARS-CoV2 could not be fully understood yet. Inflammation plays an important role in infectious diseases. Accumulating evidence has shown the importance of inflammation in the progression of viral pneumonia, including in coronavirus disease 2019 (COVID-19) cases\(^8\). Pro-inflammatory cytokines have been shown to increase in sera of patients with pulmonary inflammation\(^9\). The white blood cell (WBC) count, neutrophil, lymphocyte count, neutrophil/lymphocyte ratio (NLR), and platelet/lymphocyte ratio (PLR) are markers of systemic inflammation\(^10,11\). These markers are useful predictors for the prognosis and follow-up of patients with viral pneumonia. NLR is a very useful, rapid, and inexpensive indicator, the significance of which has been shown in bacterial pneumonia\(^12\) and viral infections\(^13\).

This retrospective, single-center study was conducted to investigate the complete blood count parameters, NLR, PLR, C-reactive protein (CRP), and the other infection bio-markers and biochemical data of a total of 80 COVID-19 positive and negative cases.

**METHODS**

A total of 80 patients who had been hospitalized at the medical clinic between 01 April 2020 and 25 April 2020 and tested for COVID-19 with real-time reverse transcription-polymerase chain reaction (rRT-PCR) were enrolled in the study. The nasal and pharyngeal swabs of all patients were obtained. Isolated patient samples that were obtained with VNAT viral transport and brought to the molecular virology laboratory were examined using the Biospedy (Bioeksen, Turkey) rRT-PCR kit provided by the Ministry of Health of Turkey. The patients whose rRT-PCR results were positive were regarded as COVID-19 (+), and those whose rRT-PCR results were negative twice with a 48-hour interval were regarded as COVID-19 (-). Hospital records (demographic, clinical, and laboratory data) of the cases above 18 years were analyzed retrospectively. The patients were divided into two groups, i.e., COVID-19 (+) and COVID-19 (-). Neutrophil, lymphocyte, platelets, MPV, hemoglobin, and CRP values of all patients were recorded, and the NLR and PLR values were calculated. The reports from the thoracic computed tomographies were obtained from the data management system. Serum urea, creatinine, total cholesterol, triglyceride, low-density lipoprotein (LDL)-cholesterol, high-density lipoprotein (HDL)-cholesterol, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and albumin were analyzed using the kinetic alkaline picrate method with the Architect C 16000 (Abbott) device at the biochemistry laboratory of the hospital. Complete blood count parameters were investigated with the Celldyn 3700 device. Ethics committee approval was obtained from the Ministry of Health of the Turkish Republic and the Sakarya University Medical School (No: 715224737050.01.04/131; April 04, 2020).

**STATISTICAL ANALYSIS**

Data analysis was performed by using statistical software (SPSS, version 10.0 [SPSS Inc, Chicago, IL]). Normally distributed data were compared by one-way analysis of variance, and non-normally distributed data were compared via the Mann-Whitney U test. Categorical associations were evaluated by using the \(\chi^2\) test and multiple logistic regression. The goodness of fit was determined by using the Nagelkerke \(R^2\) and Hosmer-Lemeshow goodness-of-fit test. The performance of NLR was assessed using receiver operating characteristic (ROC) curve analysis and by calculating the area under the curve (AUC) of the ROC curves. Statistical significance was defined as \(P \leq 0.05\).
RESULTS

Of the total 80 patients, 39 (49%) were females and 41 (51%) were males. COVID-19 was determined to be positive in 54 out of the 80 cases (67.5%). The mean age (SD) was 53 (18) years for COVID-19 (+) patients and 60 (14) for COVID-19 (-) patients, and the difference was not statistically significant (F=3.029; P=0.086). Similarly, there was no difference between the groups concerning gender (χ²=0.400 P=0.527). Fever was present in 41% of COVID-19 (+) cases. There was a significant difference between the groups concerning HDL-cholesterol values (F=4.984; P=0.031). The rates of fever, lactate, and ferritin levels were significantly higher in COVID-19 (+) cases compared to COVID-19 (-) cases (Mann-Whitney U=390.0, P=0.040; 202.5, P=0.046; 396.0, P=0.008, respectively). The rate of total bilirubin level were significantly lower in COVID-19 (+) cases (Mann-Whitney U=152.0, P=0.040). While the NLR, PLR, and CRP values were significantly higher (Mann-Whitney U 477.5, P=0.021; 508.0, P=0.046; 448.5, P=0.012, respectively), the lymphocyte count was significantly lower (Mann-Whitney U 419.0, P=0.004) in COVID-19 (+) cases compared to COVID-19 (-) cases. There was no difference between COVID-19 (+) and (-) cases concerning WBC, neutrophil, platelet count, MPV, and procalcitonin. The demographic and laboratory characteristics of patients infected with and without COVID-19 are shown in Table - I. The mean neutrophil/lymphocyte ratio and fever in COVID-19 (+) and (-) cases are displayed in Figure 1. The effect of NLR on the diagnosis of COVID-19 was analyzed by ROC curve and AUC and was found to be significant (AUC:0.660; P=0.021, 95% CI 0.538 to 0.783) (Fig.2). Sensitivity, specificity, positive predictive value, negative NPV, LR+, LR- values, and the disease prevalence for NLR ≥ 2.4 were 69.01%, 65.40%, 80%, 50%, 1.98, 0.48 and 67.5%, respectively. The effect of fever on the diagnosis of COVID-19 was analyzed by

ROC curve and AUC and was found to be significant (AUC:0.722; P=0.001, 95% CI 0.606 to 0.838). Sensitivity, specificity, positive predictive value, negative NPV, LR+, LR- values, and the disease prevalence for fever ≥ 36.8 were 66.67%, 76.92%, 86%, 43%, 2.98, 0.43 and 67.5%, respectively.

We built a logistic regression model including NLR ≥ 2.4, temperature≥ 36.8, and serum total bilirubin as free predictors of a Covid-19 positive diagnosis. According to our model, the odds ratio for a covid-19-positive result was 20.3 and 10.5 when NLR was ≥2.4 and temperature was >36.8 (B=3.011, Standart Error=1.324, Wald=5.170, Odds ratio=20.3, P=0.023 for NLR; B=2.356, Standart Error=1.079, Wald=4.768, Odds ratio=10.5, P=0.029 for fever and B=7.726, Standart Error=3.141, Wald=6.049, Odds ratio=0.0, P=0.014 for serum total bilirubin). The decrease of total serum bilirubin was significant for a covid-19-positive result, but without affecting the odds ratio. Nagelkerke R² was 65%.

**DISCUSSION**

In the present study, we reported the cohort of 54 COVID-19 (+) cases and 26 COVID-19 (-) cases confirmed with laboratory tests. NLR and fever were found to be significantly higher in COVID-19 cases. Total bilirubin levels were found to be lower in COVID-19 cases. There was no difference between COVID-19 (+) and (-) cases concerning age and gender.

Fever is among the most important clinical manifestations of CoV infections. In a study reported in the Lancet, fever was detected in 83% of the cases with COVID-19 pneumonia; this rate was found to be 43.8% in another study. The rate of fever was found to be 41% in our study. If the definition of case surveillance is mainly focused on the detection of fever, patients may be overlooked in the absence of fever, since fever was not detected in about half of the patients at the beginning. We determined a significant difference between COVID-19 (+) and (-) cases concerning fever. The risk of COVID-19 was found to be 10.5-fold greater when the fever was ≥36.8 degrees. Fever and CRP are not only systemic markers of inflammation but also mediators of inflammatory factors. CRP was found to be high in COVID-19 patients in a previous study. We also found CRP to be significantly high in our study.

The decrease of total serum bilirubin was significant for covid-19-positive results but without affecting the odds ratio. Also, AST levels were significantly higher in COVID-19 cases; however, this increase was not observed for ALT. This was compatible with a study in China. This elevation may be related to viral load and changes in the liver synthesis capacity. Other causes of changes in liver function include ACE2-mediated direct viral infection of hepatocytes or critically-ill status and immune-mediated injury.

Thrombocytopenia is another pathological finding that could be detected in a complete blood count.
Thrombocytopenia was detected in our study, consistent with the previous study; furthermore, PLR was significantly high. The platelet count, dynamic changes during treatment, and PLR were a source of concern in severe COVID-19 pneumonia cases. It was interpreted that PLR could serve as a novel indicator of the degree of cytokine storm.

In a study conducted in China, no difference was found between severe and moderate cases concerning the WBC count in the correlation analysis, and lymphopenia was reported to develop when the WBC count was normal. Consistent with the previous study, we detected lymphopenia when the WBC and the neutrophil count were normal in hospitalized COVID-19 cases.

A decrease was determined in the peripheral blood lymphocyte count of critically ill COVID-19 patients. Immune cells infiltrate the lungs and lead to unexplained severe lung infections. In a study, the lymphocyte count was found to be <1.0x10^9/L. We found the lymphocyte value as 1.3x10^9/L, consistent with the previous studies.

The human immune response is created by lymphocytes triggered by viral infections. Systemic infections suppress cellular immunity. The novel coronavirus may mainly act on lymphocytes, especially T lymphocytes. The total lymphocytes, CD4+ T cells, CD8+ T cells, B cells, and NK cells decreased in COVID-19 patients, and severe cases had lower levels of these cells than mild cases. Therefore, CoV-induced inflammation-related lymphopenia increased NLR. In the only study conducted before ours, the optimal threshold of 3.3 for NLR showed a superior prognostic possibility of clinical symptoms for change from mild to severe. Our study was among the first studies in the literature. We found NLR to be high and the likelihood of COVID-19 was 20-fold greater when NLR was ≥2.4.

The results of rRT-PCR can be obtained in hours; hence the diagnosis and treatment may be delayed. The shortcomings of the PCR method due to false positive/false negative results from insufficient sampling, insufficient laboratory facilities due to the pandemic, samples collected too early or too late, and the binding sites of primer/probe couples used in the rRT-PCR lead to some difficulties in the diagnosis. However, NLR is a rapid, inexpensive, and useful indicator that could be estimated via the complete blood count. The clinical use of NLR has been shown in bacterial pneumonia and viral infections. The surveillance of NLR and lymphocyte subsets is helpful in the early screening of critical illness, diagnosis, and treatment of COVID-19.

The COVID-19 pandemic may spread rapidly from human-to-human. The clinical characteristics of the disease vary among patients. The severity of the condition may be related to the number of immune cells.

CONCLUSION

In conclusion, we found that NLR was significantly elevated in COVID-19 patients. We also provided a cut-off for this readily available test and showed that patients with NLR ≥2.4 were 20.5 times more likely to have COVID-19 compared to patients whose NLR was ≤2.4. Similarly, the likelihood of COVID-19 was 10.5-fold greater when fever was ≥36.8 °C. This study indicates that high fever and NLR are independent biomarkers for COVID-19 patients. Our findings may also help in the early diagnosis of COVID-19.

Authors contribution

AN, CV & SY did data collection and manuscript writing; AN, TK & HC conceived, designed, and did the statistical analysis & editing of the manuscript; AT did the review and final approval of the manuscript; AN takes responsibility and is accountable for all aspects of the work, ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.
RESULTADOS: Os níveis de NLR e febre foram maiores nos casos de COVID-19 (+) (P = 0,021; P = 0,001,respectivamente). Não houve diferença entre homens e mulheres em relação a positividade para COVID-19 (P = 0,527). Os níveis totais de bilirrubina foram menores nos casos de COVID-19 (+) (P = 0,040). Quando a análise ROC foi realizada para NLR nos casos COVID-19 (+), o valor da AUC foi de 0,66 (P = 0,021), sensibilidade 69,01%, especificidade 65,40%, LR +: 1,98 e LR -: 0,48 , PPV: 80,43 e NPV: 50,00 quando o NLR era > 2,4. The risk of COVID-19 was found to be 20.3-fold greater when NLR was ≥ 2.4 in the logistic regression (P=0.007).

CONCLUSÃO: NLR é um preditor independente para o diagnóstico de COVID-19. Também concluímos que aferições de febre e bilirrubina total podem ser úteis para o diagnóstico de COVID-19 nesta população.
