It has been suggested that rotating black holes could serve as particle colliders with arbitrarily high center-of-mass energy. Astrophysical limitations on the maximal spin, back-reaction effects and sensitivity to the initial conditions impose severe limits on the likelihood of such collisions.

PACS numbers: 97.60.Lf,04.70.-s

Bañados, Silk and West (henceforth BSW) \cite{Bañados:2001} recently observed that collisions of point particles falling from rest into rotating (Kerr) black holes (BHs) may have arbitrarily large center-of-mass (CM) energies close to the event horizon if the BH is maximally spinning and one of the particles has orbital angular momentum close to the value $L=L_{\text{scat}}$ corresponding to marginally bound geodesics.

An important practical limitation on the achievable CM energies occurs because, as pointed out by Thorne \cite{Thorne:1974}, the dimensionless spin of astrophysical BHs should not exceed $a/M = 0.998$. For $a/M = 0.998$, Eq. (14) in BSW yields maximum CM energies of about $10\mu$ for particles of rest mass $\mu$.

Even in the idealized scenario of being given an extremal BH, back-reaction effects make high-energy scattering very unlikely. Neglecting gravitational radiation, upon absorption of a pair of colliding particles of mass $\mu$ the dimensionless spin must be reduced by $\epsilon \equiv 1-a/M \sim \mu/M$. After this first collision, Eq. (14) in BSW predicts that the new maximum allowed CM energy would be $E_{\text{CM}} \lesssim 10^{12}(\mu/\text{1 MeV})^{3/4} (M/100M_\odot)^{1/4}$ GeV, orders of magnitude below the Planck scale for typical values of the parameters. The collision of (say) a single electron pair would reduce the spin of a $100M_\odot$ BH enough to inhibit any further Planck-scale collisions. A hypothetical dark matter particle would need a mass $\mu \gtrsim 10^8$ TeV to allow for more than one Planck-scale event.

The estimates in BSW neglect gravitational radiation, which will significantly affect geodesics with $\delta = 1-L/L_{\text{scat}} \ll 1$ (notice that in the critical case $L = L_{\text{scat}}$ it takes an infinite amount of proper time for a particle to reach the horizon). For small $\delta$, the particle orbits around the marginally bound circular geodesic of a Schwarzschild BH $N \sim -(\sqrt{2}\pi)^{-1} \log \delta$ times. For near-extremal Kerr BHs we get $N \sim -(2\pi \sqrt{2})^{-1} \log(8\sqrt{7}\delta)$. This simple analysis suggests that for $\delta \ll 1$ the radiation should be peaked at frequencies corresponding to marginally bound quasi-circular orbits with orbital frequency $\Omega_{\text{hm}}$ and that the total radiated energy $E_{\text{tot}} \sim N \sim -\log \delta$.

In Fig. 1 we confirm these conclusions by a numerical calculation of the energy radiated by particles of mass $\mu \ll M$ plunging from rest into a Schwarzschild BH (see \textsuperscript{3} for details and notation).

In conclusion, frame dragging effects in Kerr BHs can in principle accelerate particle to high energies, but (1) astrophysical restrictions on the spin severely limit the maximum CM energies in the collisions; (2) just as radiative losses constrain the performance of particle accelerators, gravitational radiation and back-reaction constrain the maximum CM energy for collisions around Kerr BHs; (3) the exponential sensitivity of whirling orbits to initial conditions requires significant fine-tuning to get sensible cross sections for the highest-energy collisions.
