(Dated: August 2, 2017)

We present a systematic \textit{ab initio} investigation of the longitudinal and transverse spin relaxation times of magnetic single adatoms deposited on metallic substrates. Our analysis based on time-dependent density functional theory shows that the longitudinal time, $T_\parallel$, is of order femtosecond while the transverse time, $T_\perp$, is of order picosecond, i.e., $T_\perp \gg T_\parallel$. This comes as a consequence of the different energy scales of the corresponding processes: $T_\parallel$ involves spin-density excitations of order eV, while $T_\perp$ is governed by atomic spin-excitations of order meV. Comparison to available inelastic scanning tunneling spectroscopy $dI/dV$ experimental curves shows that the order of magnitude of $T_\parallel$ agrees well with our results. Regarding $T_\parallel$, the time scale calculated here is several orders of magnitude faster than what has been measured up to now; we therefore propose that an ultrafast laser pulse measuring technique is required in order to access the ultrafast spin-dynamics described in this work.

PACS numbers:

I. INTRODUCTION

Single adatoms deposited on substrates offer an exceptional scenario for studying magnetism at the atomic scale, given that these tiny objects can develop a large magnetic moment of several Bohr magnetons\cite{11,12} as well as a large magnetic anisotropy energy barrier of few meV\cite{13,14} both extremely desirable properties for potential applications in spintronic devices. Interestingly, the possibility of tuning and engineering these and other properties by the suitable combination of adatom and substrate material (possibly including coating layers) provides plenty of room for research in this area.

In order to achieve the ultimate goal of a technologically applicable magnetic single adatom, however, not only the static properties need to be adequate but also the dynamical ones, and in particular the ones related to the spin, i.e., the spin-dynamics. For example, fast spin-dynamics can be useful when the goal is to transfer magnetic information from or to the adatom, while slow spin-dynamics are desirable if the aim is to store magnetic information. In comparison to the static case, the study of spin-dynamics of single adatoms is much more recent and has only hatched out after the advent of spin-polarized scanning tunneling microscopy (STM) and inelastic electron tunneling spectroscopy (IETS). These experimental techniques, occasionally used in combination with X-ray magnetic circular dichroism (XMCD)\cite{15} and electron paramagnetic resonance (EPR)\cite{16} allow to monitor the dynamical regime by, e.g., measuring atomic spin-excitations\cite{17,18} and quasiparticle interferences\cite{19}, accessing spin relaxation times\cite{20,21} and even resolving highly dynamical processes like the reading and writing of magnetic information into a single adatom\cite{22}.

From the theoretical point of view, spin-dynamics of single adatoms have also attracted a great deal of attention in the past few years. In this context, time-dependent density functional theory\cite{23,24,25,26} (TDDFT) has proven to be a powerful tool for characterizing the spin-excitation spectrum and, more generally, giving insight into the connection between what is measured experimentally and the underlying electronic structure (see, e.g., Refs. 25-27). Alongside, model Hamiltonians have also been used to analyze, among other aspects, the role of symmetry on the switching rate of the magnetic moment\cite{28,29}.

In this paper, we present an \textit{ab initio} study based on density functional theory (DFT) and TDDFT of two relaxation processes of single adatoms, namely the longitudinal and transverse spin relaxations characterized by the relaxation times $T_\parallel$ and $T_\perp$, respectively. Physically, $T_\parallel$ characterizes the relaxation of the size of the adatom’s spin magnetic moment while $T_\perp$ describes its damped precessional motion. Employing \textit{ab initio}-derived expressions, we systematically provide hard numbers for $T_\parallel$ and $T_\perp$ for a series of $3d$ and $4d$ transition metal adatoms deposited on two metallic substrates, namely Ag(100) and Cu(111). Our analysis shows that, while $T_\parallel$ is of the order of femtosecond, $T_\perp$ ranges from few to thousands picoseconds, i.e., $T_\perp \gg T_\parallel$. Noteworthily, these time scales are settled by the corresponding energy scales of the associated processes; continuous spin-conserving single-particle excitations of energy eV in the case of $T_\parallel$, atomic spin-flip spin-excitations of energy meV in the case of $T_\perp$. In comparison to available experimental measurements, the relaxation times $T_\perp$ extracted from IETS $dI/dV$ curves show overal the same order of magnitude as the ones calculated in our work, and agree remarkably well in specific cases such as Fe on Cu(111)\cite{30}. Regarding $T_\parallel$, the time resolution of the currently available measuring techniques ranges from few nanoseconds to hundreds of picoseconds\cite{31,32}, hence not enough to monitor the femtosecond regime predicted here. However, considering
the technological developments within this field, access to the fs time scale of magnetic adatoms could be realized in the near future, thus giving access to the spin-dynamics described in this work.

The paper is organized as follows. Sec. II summarizes the technical details of the formalism used throughout the work. In Sec. III we present DFT calculations of ground state properties of several 3d and 4d transition metal adatoms deposited on Ag(100) and Cu(111). In Sec. IV we extend the analysis to the dynamical regime; in particular, we calculate longitudinal (Sec. IV A) and transverse (Sec. IV B) relaxation times within the TDDFT framework. Conclusions and a summary of the main results are provided in Sec. V. In Appendices A and B we derive the connection between TDDFT and phenomenological models for the longitudinal and transverse dynamics, respectively. Finally, Appendix C contains a short summary of the Bloch-Redfield formalism in order to allow comparison of our TDDFT-based work to other theoretical analyses.

II. COMPUTATIONAL DETAILS

We have performed DFT calculations using the Korringa-Kohn-Rostoker Green function (KKRGF) approach, employing the atomic sphere approximation with full charge density including spin-orbit coupling (SOC). Exchange and correlation (XC) effects have been taken into account using the local spin-density approximation with the parametrization by Vosko, Wilk and Nusair. We have modeled the two surfaces Ag(100) and Cu(111) using a slab composed of 24 layers and augmented by two vacuum regions of 21.1 Å thickness each, employing the lattice constants \( a = 5.46 \) Å and \( a = 4.83 \) Å, respectively. The vertical distance from adatom to the surface layer has been calculated using the structural relaxation scheme implemented in the QUANTUM-ESPRESSO package, considering the convergence criterion whereby forces are \( < 10^{-4} \) Ry a.u.\(^{-1} \) and employing norm-conserving pseudopotentials, a \( 4 \times 4 \) two-dimensional unit cell, \( \Gamma \) point calculation and a cutoff energy of 80 Ry. In all cases, the distance between adatom and substrate was reduced by approximately 15% with respect to the ideal value. Hence, for the sake of comparison, we adopted the same distance for all adatoms in the DFT and TDDFT calculations using the KKRGF method. Noteworthily, this method allows a real-space treatment of the adatoms through an embedding technique. Following this scheme, we have employed converged real-space clusters of 43 and 55 sites for the Ag(100) and Cu(111) surfaces, respectively.

III. GROUND STATE PROPERTIES

In this section we analyze two ground state properties, namely the spin magnetic moment, denoted by \( m_0 \), and electronic density of states (DOS) of several 3d and 4d transition metal adatoms deposited on the metallic substrates Ag(100) and Cu(111). Let us begin with Fig. 1 where the calculated \( m_0 \) is depicted. This figure shows that all the considered adatoms develop large magnetic moments of more than \( 2 \) \( \mu_B \). Furthermore, \( m_0 \) acquires non-integer values, indicating the itinerant character of the adatom’s \( d \)-electrons induced by the hybridization with the electrons of the metallic substrate. This feature is confirmed by the DOS, which is displayed in Fig. 2 for the specific case of 3d adatoms deposited on Ag(100). This figure shows that the \( d \)-state peaks, so-called virtual bound states, are substantially broadened (between \( \sim 0.1 \) eV and \( \sim 1 \) eV depending on the adatom), which is a well-known consequence of hybridization with the substrate. A further property indicated by Fig. 1 is that the first of the atomic Hund’s rules is closely fulfilled, i.e. the half filled \( d \)-shell elements develop the largest magnetic moments, case of Cr and Mn for 3d, Mo and Tc for 4d. Finally, Fig. 1 shows that the choice of metallic substrate and surface orientation does not substantially affect the spin magnetic moment developed by the adatom, indicating that the symmetry of the sub-
strate plays a minor role in this context. These ground state properties are consistent with the original works by Dederichs and co-workers, as well as with more recent studies.

IV. SPIN-SUSCEPTIBILITIES AND RELAXATION TIMES

In this section, we analyze dynamical properties of the magnetic adatoms studied in the previous section, paying special attention to relaxation times and their connection to the electronic structure. For this, let us consider the linear response of a ferromagnetic system to an externally applied time-dependent perturbation,

$$\delta m(\mathbf{r}; t) = \int d\mathbf{r}' \int dt' \chi(\mathbf{r}, \mathbf{r}'; t-t') \delta V(\mathbf{r}', t').$$

(1)

Above, $\delta m = (\delta m_x, \delta m_y, \delta m_z, \delta n)$ and $\delta V = (\delta B_x, \delta B_y, \delta B_z, \delta V)$, with $\delta m_i$ and $\delta B_i$ respectively the components of the spin magnetic moment and external magnetic field, while $\delta n$ and $\delta V$ are the charge density and external scalar field, respectively. In frequency space and defining atomic-like quantities by integrating out the magnetic field, while $\delta n$ takes the simplified form

$$\delta m(\omega) = \chi(\omega) \delta V(\omega).$$

(2)

The quantity $\chi$ in the above equations is a 4×4 tensor that couples in general all components of the spin and charge responses with each other. If SOC is weak, however, the full response decouples into a longitudinal and transverse part. This approximation is justified for the systems investigated here since the off-diagonal sectors of the susceptibility tensor are small in comparison to the systems investigated here since the polarizability of such elements is very weak.

Above, $\chi^{L}(\omega)$ denotes the longitudinal spin-susceptibility. This quantity is determined by excitations between electrons with the same spin state, given that it involves the Pauli matrix $\sigma_z$ that is diagonal in spin basis. On the other hand, the change of the transverse spin components can be compactly described using the circular combinations $m_{\pm} = m_x \pm i m_y$ and $B_{\pm} = B_x \pm i B_y$, yielding for the + component

$$\delta m_{+}(\omega) = \chi^{L}(\omega) \delta B_{+}(\omega).$$

(3)

Above, $\chi^{+}(\omega)$ denotes the transverse spin-susceptibility which, contrary to $\chi^{L}(\omega)$, is determined by transitions that flip the spin state of the electrons due to the transverse Pauli spin matrices involved, which are off-diagonal in spin space.

In the following, the analysis is divided in two subsections: Sec. IV A deals with the longitudinal response while Sec. IV B deals with the transverse component.

A. Longitudinal component

The general expression for the adatom’s enhanced longitudinal spin-susceptibility (see Eq. (4)) within the TDDFT framework is given by

$$\chi^{L}(\omega) = \frac{\chi^{KS}(\omega)}{1 - U_{||} \cdot \chi^{KS}(\omega)},$$

(5)

where $U_{||}$ denotes the longitudinal XC kernel treated in the adiabatic local spin-density approximation, including the Coulomb term, while $\chi^{KS}(\omega)$ is the longitudinal KS spin-susceptibility. We note that neglecting the direct contribution of the substrate atoms to the magnetic spin-susceptibility is justified in the Ag and Cu substrates analyzed here since the polarizability of such elements is very weak.

In essence, $\chi^{L}(\omega)$ in Eq. (5) describes the ability of the system to continuously modify the size of its magnetic moment by an externally applied time-dependent magnetic perturbation along the magnetization direction. The dynamics of this process can be phenomenologically studied in terms of the longitudinal Bloch equation, which yields the following form for the enhanced spin-susceptibility (see Appendix A),

$$\chi^{BL}(\omega) = \frac{\chi^{KS}(\omega)}{1 - i\omega T_{||}}.$$  

(6)

Above, $\chi^{KS}(\omega)$ denotes the static spin-susceptibility, while $T_{||}$ corresponds to the longitudinal relaxation time mentioned in the introduction. Our aim is to establish a direct comparison between Eqs. (5) and (6). For this purpose, let us use the first-order Taylor expansion of the KS spin-susceptibility

$$\chi^{KS}(\omega) \approx \rho_{F} - in_{e,h},$$

(7)

with $\rho_{F} = \rho_{F,\uparrow} + \rho_{F,\downarrow}$ the DOS at the Fermi level and $n_{e,h} = \pi(\rho_{F,\uparrow} + \rho_{F,\downarrow})/2$ the density of electron-hole excitations of the same spin channel. By inserting $\chi^{KS}(\omega)$ of Eq. (7) into Eq. (5), $\chi^{L}(\omega)$ acquires a functional form in $\omega$ equal to that of $\chi^{BL}(\omega)$ in Eq. (6). This then allows to obtain an expression for the longitudinal relaxation time in terms of basic electronic properties (see Appendix A for details):

$$T_{||} = \frac{U_{||} n_{e,h}}{U_{||} \rho_{F} - 1}.$$  

(8)

The above expression is one of the main results of the present work. First of all, it shows that the longitudinal relaxation time is settled by the magnitude of electron-hole excitations weighted by the XC kernel (see the denominator of Eq. (8)), both quantities of order eV, hence settling the time scale of $T_{||}$ as fs. Secondly, it shows that $T_{||}$ diverges as $U_{||} \rho_{F} \rightarrow 1$ (see the unitless denominator in the equation), i.e. as the system approaches the magnetic
transition point. This feature reveals that weakly magnetic adatoms or even non-magnetic adatoms close to the transition point can host long-living longitudinal excitations\cite{22}. In the following, we first focus on quantitatively analyzing the ingredients of Eq. (8) and subsequently turn to $T_{\parallel}$ itself.

In order to compute reliable values for the kernel $U_{\parallel}$, we make use of the static limit of Eq. (5), from which

$$U_{\parallel} = \rho_F^{-1} - \chi_{\parallel}^{-1}(0).$$

We note that $\chi_{\parallel}(0)$ can be calculated by a standard ground state DFT calculation with a static magnetic field $\Delta B$ via $\chi_{\parallel}(0) = \Delta m/\Delta B$, with $\Delta m$ the corresponding self-consistent change of the magnetic moment\cite{22}. In Fig. 3 we show the calculated values of $\rho_F$ and $U_{\parallel}$ for several 3$d$ and 4$d$ adatoms deposited on Ag(100). The most important message exposed by this figure is the large variation of $U_{\parallel}$ among different elements; while $U_{\parallel} \lesssim 0.5$ eV for most 4$d$ elements, $U_{\parallel} \gtrsim 1.5$ eV for various 3$d$ elements, reaching a maximum of one order of magnitude difference between Ru and Cr. A second important feature revealed by Fig. 3 is the distribution of $U_{\parallel}$ within each d-shell, whereby it is smallest at the ends of the row — case of Ti and Co among 3$d$, Nb and Ru among 4$d$ — and highest in the middle of the row — case of Cr and Mn among 3$d$, Mo and Tc among 4$d$ —, yielding an approximate inverted V-shape. We note that $\rho_F$ in Fig. 3 shows the opposite behavior, i.e. it is minimum for Cr and maximum for Co and Ru. This is consistent with Eq. (9), although we note strong deviations from the $U_{\parallel} \propto \rho_F^{-1}$ relationship (see in particular the case of Cr), revealing the importance of the term $\chi_{\parallel}^{-1}(0)$ in Eq. (9).

The inverse of the static spin-susceptibility $\chi_{\parallel}^{-1}(0)$ is closely connected to the magnetic equation of state, i.e. the dependence of the energy $E$ as a function of the magnetic moment $m$, via\cite{25}

$$\chi_{\parallel}^{-1}(0) = \frac{\partial E(m)}{\partial m^2} \bigg|_{m=m_0} < 0.$$

In essence, the magnetic equation of state informs about how stable the magnetic solution is in comparison to the non-magnetic one. We have calculated $E(m)$ for the set of adatoms considered in Fig 3 by employing DFT for fixed magnetic field\cite{25}. The results are shown in Fig. 4 which reveals that the energy difference between the magnetic and non-magnetic state,

$$\Delta E = E(m=0) - E(m=m_0),$$

is of the order of eV and can largely vary for different adatoms. Importantly, our calculations show that 3$d$ adatoms overall have a substantially larger $\Delta E$ than 4$d$ adatoms; for Cr, for instance, $\Delta E \sim 3$ eV, while for Ru $\Delta E \sim 0.25$ eV. Therefore, DFT predicts most 3$d$ adatoms to be magnetically more stable than 4$d$ ones, as expected. Furthermore, given that Eq. (10) together with Eq. (9) relates the XC kernel to the second derivative of the equation of state at $m_0$, one can establish an approximate connection between the depth of the minimum of $E(m)$ and the value of $U_{\parallel}$, as it is visible from the comparison of Figs. 4 and 3, the deeper the minimum, the larger $U_{\parallel}$.

We note that following the above procedure, one can also extract the kernel in the non-magnetic ground state, i.e. the so-called Stoner XC parameter $I_{\chi,xc}\cite{26}$. This can be achieved by considering the curvature of $E(m)$ not at $m = m_0$ but at $m = 0$, as well as using the non-magnetic DOS in Eq. (4) instead of the magnetic one. As it is clearly visible from Fig. 4, the curve is very different at $m = 0$ and $m = m_0$. Furthermore, $\rho_F$ can also strongly vary from a magnetic to a non-magnetic calculation. As a consequence, the distribution of $I_{\chi,xc}$ along the transition metal series first reported by Janak in Ref. \cite{49} is very different to that of $U_{\parallel}$ illustrated in Fig. 3.

Having analyzed the properties of $\rho_F$ and $U_{\parallel}$, we next focus on the longitudinal relaxation time $T_{\parallel}$. The values calculated from Eq. (8) are plotted in Fig. 5 for 3$d$ and 4$d$ adatoms deposited on Ag(100) and Cu(111). $T_{\parallel}$ is of the order of a few fs in all cases, being overall slightly larger for 4$d$ than 3$d$ adatoms, while the choice of substrate does not substantially affect it. Within each d-shell, $T_{\parallel}$ is largest at the ends of the row while it is minimum for the half filled elements, thus resembling the behavior of $\rho_F$ (compare Figs. 3 and 5). Ru on Ag(100) has the highest value of $T_{\parallel} \approx 50$ fs, mainly as a consequence of the denominator of Eq. (8) being closer to zero than in other elements. In contrast, Cr and Mn have $T_{\parallel} \sim 1$ fs in both substrates, i.e. nearly two orders of magnitude less than the aforementioned example. As a general feature, we note that the order of magnitude of $T_{\parallel}$ is settled by the energy scale of the problem; all quantities involved in Eq. (8) are of the order of eV, whose corresponding
time scale is fs. Therefore, the longitudinal relaxation of the spin analyzed in this work is extremely fast. The physical reason is the large exchange splitting dominating the relaxation process, which makes it energetically very expensive to modify the length of the moment due to the high energies involved.

1. Connection to experimental measurements

Let us next consider the experimental scenario regarding the measurement of the longitudinal spin relaxation time. For this, we first note that in a experiment, several different mechanisms can contribute to this relaxation process, whose overall relaxation time is generally denoted as $T_1$. In this context, $T_\parallel$ calculated here is a particular contribution to $T_1$, which may include further contributions depending on the physical processes taking place. To the best of our knowledge, the first experimental technique that measures $T_1$ in magnetic single adatoms was developed by Loth and co-workers[19]. Within this STM-based technique, the spin relaxation time was measured by monitoring the decay of electrons in excited states after the application of an all-electronic pump-probe scheme[19]. It is noteworthy that this scheme has so far only been applied to adatoms deposited on semi-insulating substrates, which are close to the atomic limit. The original work by Loth and co-workers measured $T_1 \sim 90$ ns for a Fe-Cu dimer on Cu$_2$Ni/Cu(100)[19]. A subsequent work by Rau and co-workers measured $T_1 \sim 200$ µs for a single Co atom on MgO/Ag(100)[5]. Lastly, Baumann and co-workers reported $T_1 \sim 90$ µs for a single Fe atom on MgO/Ag(100)[14] while in a recent work of Paul and co-workers on the same system[50], the value of $T_1$ was enhanced up to the ms regime by fine tuning external conditions such as the height of the STM tip. To conclude, we note that the reported time resolution of the measuring technique employed in the above experiments ranges between few ns to hundreds of ps.

All the above measured values of the spin relaxation time are several orders of magnitude larger than the values of order fs that we have calculated in this work for $T_\parallel$ (see Fig. 5). Let us first note that all of the above experiments are performed under externally applied static magnetic fields that range between 1 T and 10 T. This, in turn, breaks the degeneracy of the spin ground states[19], a situation that is commonly modeled by a shifted discrete energy diagram as the one shown in Fig. 6(a). We note that excitations within such a diagram are not allowed to change the length of the spin moment (spin quantum number $S$ in this context), but only its projection (magnetic quantum number $S_z$). Therefore, the main spin relaxation process contributing to $T_1$ within such an scheme involves transitions between the two non-degenerate states with same $S$ but opposite $S_z$ (see Fig.
cess the dynamics encoded into \( T \). The initially non-degenerate two ground states of maximum \( S_\parallel \) become non-degenerate by energy \( \sim \) meV under externally applied magnetic fields of 1-10 T. Transitions between these two states then determine \( T_\parallel \), which take place via quantum tunneling. (b) schematically describes the excitations contributing to \( T_\parallel \) considered in this work. These take place in a continuum energy landscape of order eV and are driven by direct spin-conserving electron-hole transitions.

We note that their energy separation is of order meV, hence much smaller than the excitations of order eV involved in the change of the spin magnetic moment size considered for our calculation of \( T_\parallel \), as schematically depicted in Fig. 6(b). On top of that, given that direct transitions between the two non-degenerate states of Fig. 6(a) are virtually inexistent, spin relaxation in these conditions is driven by quantum tunneling processes, which are intrinsically much slower than the direct transitions considered in this work. These two considerations explain why the spin relaxation time measured under the mentioned experimental conditions is several orders of magnitude larger than the values of \( T_\parallel \) obtained in this work.

It is apparent that, in order to experimentally access the dynamics encoded into \( T_\parallel \), a measuring scheme based on ultrafast techniques that modify the length of the spin magnetic moment is required. Considering the technological developments within STM measuring techniques\( ^{22,23} \), accessing the fs time scale of magnetic adatoms seems to be a reasonable goal for the near future by, e.g., using ultrafast laser pulses, a breakthrough that would allow to monitor the ultrafast spin-dynamics analyzed in this work.

**B. Transverse component**

Unlike the longitudinal component, the transverse spin-susceptibility and associated spin-excitations of single adatoms have been thoroughly studied from first principles in, e.g., Refs. \( ^{22,27} \). The general form for the adatom’s enhanced transverse spin-susceptibility (see Eq. \( ^{11} \)) in the TDDFT scheme is

\[
\chi_\pm(\omega) = \frac{\chi_\parallel^{KS}(\omega)}{1 - U_\perp \chi_\parallel^{KS}(\omega)}. \tag{12}
\]

Above, \( U_\perp \) is the transverse XC kernel treated in the adiabatic local spin-density approximation\( ^{31} \), while \( \chi_\parallel^{KS} \) denotes the transverse KS spin-susceptibility. Despite the formal similarity between Eq. \( ^{5} \) for \( \chi_\parallel(\omega) \) and Eq. \( ^{12} \) for \( \chi_\pm(\omega) \), the underlying physics behind both expressions is very different. While the former contains excitations that modify the spin density, the latter describes damped precessional motion of the spin moment\( ^{24} \). This motion, in turn, is described by the imaginary part of the enhanced spin-susceptibility of Eq. \( ^{12} \), \( \text{Im} \chi_\pm(\omega) \), which gives access to the density of transverse spin-excitations of single adatoms\( ^{22,24} \).

The characteristic form of the spin-excitation hosted by \( \text{Im} \chi_\pm(\omega) \) is illustrated in Fig. 7 and is characterized by two main quantities. The first one is its resonance frequency, \( \omega_{\text{res}} \), a fundamental property related to the magnetic anisotropy energy that is ultimately determined by SOC\( ^{24} \). The second main quantity is the width of the spin-excitation, \( \Gamma \), which is proportional to the hybridization of the adatom’s electrons with the substrate\( ^{22,23} \) (see also Ref. \( ^{52} \) for model Hamiltonian point of view). As shown in Ref. \( ^{25} \), the main contribution of the hybridization to \( \Gamma \) is proportional to the electron-hole excitations of opposite spin channel, \( n_{e-h} = \pi(\rho F, \rho F, \pm) \):

\[
\Gamma \approx \frac{n_{e-h}^{\prime}}{\text{Re}Q} \omega_{\text{res}}, \tag{13}
\]

with \( Q = \partial \chi_\pm^{KS}(\omega)/\partial \omega \big|_{\omega = 0} \). We note that the order of magnitude of \( \omega_{\text{res}} \) ranges between \( 10^{-2} - 1 \) meV while \( n_{e-h}^{\prime}/\text{Re}Q \) is a unitless fraction that is typically of order unity.

Importantly, a finite width corresponds to a finite damping of the precessing magnetic moment and is thus directly linked to the transverse spin relaxation time (see Appendix B and Eq. \( ^{13} \)):

\[
T_\perp = \frac{2}{\Gamma} \propto (n_{e-h}^{\prime})^{-1}. \tag{14}
\]

We note that, while \( T_\parallel \) in Eq. \( ^{8} \) is directly proportional to the density of spin-conserving electron-hole excitations,
n_{e,h}, T_{\perp} above is inversely proportional to the spin-flip counterpart $n'_{e,h}$.

Using the TDDFT formalism developed in Refs. 22–24, we have calculated $T_{\perp}$ from the spin-excitation width for various 3d and 4d magnetic adatoms deposited on the metallic substrates Ag(100) and Cu(111); calculated values are shown in Fig. 5. One notes that the variation of $T_{\perp}$ among adatoms is somewhat larger than that of $T_{\parallel}$, shown in Fig. 5. This is a consequence of the large variation of the width $\Gamma$ of atomic spin-excitation, which can range from $10^{-2}$ meV to few meV, i.e. nearly three orders of magnitude change. This, in turn, can be linked to the electronic DOS at the Fermi level via Eq. 13 adatoms where the DOS peak of the $d$ states lies close to the Fermi level, case of Ti, V, Fe and Co in Fig. 2 tend to be much more hybridized than those where only the tail of the DOS peak lies at the Fermi level, case of Cr and Mn in Fig. 2. In this way, Cr and Mn acquire large relaxation times of $T_{\perp} \sim 10^{-1}$–$10^{-2}$ ps, while strongly hybridized adatoms such as Co, Nb and Ru have $T_{\perp} \sim 10^{-1}$–$10^{-2}$ ps.

To conclude, let us note that the trend of $T_{\perp}$ within each $d$-shell row is opposite to that shown by $T_{\parallel}$ (see Fig. 5). This comes as a consequence of the dependence on the density of electron-hole excitations, with $T_{\parallel} \propto n_{e,h}$ (see Eq. 5) and $T_{\perp} \propto (n'_{e,h})^{-1}$ (see Eq. 13). In fact, $T_{\parallel}$ and $T_{\perp}$ can be formally related to each other considering the relation between the spin-conserving and spin-flip electron-hole contributions, namely $\rho_F^2/2 = n_{e,h} + n'_{e,h}$. From Eq. 5 for $T_{\parallel}$ and Eq. 13 for $T_{\perp}$ one can then infer the following expression:

$$\frac{\rho_F^2}{2} \simeq T_{\parallel} \frac{U_F - 1}{U_{\parallel}} + 2T_{\perp}^{-1} \frac{ReQ}{\omega_{res}}. \quad (15)$$

The unifying concept behind the above relationship between $T_{\parallel}$ and $T_{\perp}$ is the hybridization of substrate electrons with the $d$-states of the transition metal adatoms, which in essence gives rise to a finite total $\rho_F$. However, despite the formal relationship, the fact that $T_{\parallel}$ and $T_{\perp}$ in Eq. 15 have fundamentally different prefactors makes the time scale of the two relaxation constants differ by nearly three orders of magnitude.

1. Connection to experimental measurements and a comment on nomenclature

Next, we consider several experimental measurements of spin-excitation lifetimes of different single adatoms and connect them to our work. The lifetime of an atomic spin-excitation can be experimentally accessed from the width of the step observed in IETS $dI/dV$ measurements, which provides a measure of $\Gamma$. Given that the energy resolution of this technique is $10^{-1}$ meV, the longest lifetimes that can be inferred following this procedure are of order 10 ps (see Eq. 14). These type of experiments can measure adatoms deposited on both metallic and semi-insulating substrates; as a general trend, the latter induce a larger lifetime than the former due to a far smaller electronic hybridization. We begin by considering Ref. 17, where Khajetoorians and co-workers estimate the spin-excitation lifetime of a Fe adatom deposited on metallic Cu(111) to be 0.2 ps, in very good quantitative agreement with our calculated value $T_{\perp} = 0.15$ ps for the same system (see Fig. 5). Noteworthy, when the same atom is deposited on metallic Pt(111), the measured lifetime is increased by nearly an order of magnitude. We note that we have found a similar variation between the two substrates considered in this work for the elements Ti, V, Cr and Mo, as it can be checked in Fig. 8. Focusing next on the semi-insulating Cu$_2$Ni/Cu(100) substrate, a lower bound of ~10 ps has been experimentally estimated for Fe, Cr, Mn and Ni adatoms, although it is possible that the actual lifetimes are substantially larger. In fact, our calculations on Cr and Mn, which are the elements with smallest hybridization and thus the ones closest to the semi-insulating limit, show that $T_{\perp}$ can reach up to 10$^3$ ps (see Fig. 8); hence, it is not unlikely that the lifetimes of the aforementioned adatoms on Cu$_2$Ni/Cu(100) could be of the same order of magnitude. Last, it is worth noting the case of Co on MgO, which, despite being a semi-insulating substrate, yields a relatively short spin-excitation lifetime of ~0.5 ps, i.e. a common value for adatoms deposited in metallic substrates analyzed in this work (see Fig. 7).

To conclude this section, we note that the convention followed in the standard literature to denote the transversal relaxation time is $T_2$ (see, e.g., Refs. 47,54). We have noticed, however, that the relaxation time associated to atomic spin-excitations has in some cases been named as a $T_1$-like term; see, e.g., the review by Delgado and Fernández-Rossier. The authors of this review use $T_2$ to denote another relaxation mechanism named as adiabatic decoherence. We have included a brief discussion on this nomenclature issue in Appendix C.
V. CONCLUSIONS

In conclusion, we have presented a systematic ab initio investigation of longitudinal and transverse spin relaxation times of magnetic single adatoms deposited on metallic substrates. Our analysis has yielded as a main result the fact that the longitudinal spin relaxation process of single adatoms is much faster than the transverse one, i.e., $T_\perp \gg T_\parallel$. This, in turn, comes as a consequence of the energy scale of the corresponding processes: eV for $T_\parallel$, meV for $T_\perp$. Importantly, the two processes are triggered by different mechanisms: while $T_\parallel$ is driven by spin-conserving excitations that change the spin-density, $T_\perp$ depends on the atomic spin-flip spin-excitations that induce the precessional motion. The comparison of our results with available experimental measurements shows that the relaxation times extracted from inelastic scanning tunneling spectroscopy $dI/dV$ curves show over the same order of magnitude as $T_\parallel$ and agree remarkably well in specific cases such as Fe on Cu(111) \cite{A2}. Regarding the measurement of $T_\parallel$, we have argued that, although currently available techniques cannot monitor the femtosecond regime of magnetic single adatoms, it is reasonable that this can be achieved in the near future e.g. by employing STM-integrated ultrafast laser schemes \cite{A3,A4}, thus giving access to the ultrafast spin-dynamics described in this work.

VI. ACKNOWLEDGMENTS

The authors are very grateful to F. Guimarães for fruitful discussions on the LLG model. This work has been supported by the Impuls und Vernetzungsfonds der Helmholtz-Gemeinschaft Postdoc Programme and funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (ERC-consolidator grant 681405 DYNASORE). The authors gratefully acknowledge the computing time granted by the JARA-HPC Vergabegremium and provided on the JARA-HPC Partition part of the supercomputer JURECA at Forschungszentrum Jülich.

Appendix A: Longitudinal Bloch equation

The Bloch equation for the longitudinal change of the magnetization under the effect of a time-dependent perturbation $H_1(t)$ along the longitudinal direction can be written as \cite{A7}

$$\frac{dm_z(t)}{dt} = \frac{\chi_0^{BI} H_1(t) - m_z(t)}{T_\parallel},$$

(A1)

with $\chi_0^{BI}$ a static spin-susceptibility. The above equation describes how $m_z(t)$ comes back to equilibrium with a characteristic relaxation time $T_\parallel$ after being perturbed by $H_1(t)$. Using $f(t) = \int d\omega f(\omega)e^{-i\omega t}$ for both $m_z(t)$ and $H_1(t)$ we can write Eq. (A1) in frequency domain,

$$m_z(\omega) = m_z(\omega T_\parallel + 1) = \chi_0 H_1(\omega) \Rightarrow m_z(\omega) \equiv \chi_0^{BI} H_1(\omega) = \frac{\chi_0^{BI}}{1 - i\omega T_\parallel},$$

(A2)

where $\chi_0^{BI}$ is the enhanced spin-susceptibility. The real and imaginary parts of the above equation read

$$\begin{align*}
\text{Re} \chi^{BI}(\omega) &= \frac{\chi_0^{BI}}{1 + (\omega T_\parallel)^2}, \\
\text{Im} \chi^{BI}(\omega) &= \frac{\chi_0^{BI} \omega T_\parallel}{1 + (\omega T_\parallel)^2}.
\end{align*}$$

(A3)

A4)

Next, we consider the Taylor expansion of the KS spin-susceptibility (see Eq. (7) in the main text),

$$\chi^{KS}_\parallel(\omega) \approx \rho_F - i n_{e,h} \omega.$$ (A5)

The first-order expansion coefficient $n_{e,h} = \pi(\rho_F^{2,\uparrow} + \rho_F^{2,\downarrow})/2$ has been calculated in the Supplemental Material of Ref. \cite{A5}. Inserting $\chi^{KS}_\parallel(\omega)$ of Eq. (A5) into the definition of the TDDFT enhanced spin-susceptibility $\chi(\omega)$ (see Eq. (5) of the main text), the imaginary part $\text{Im} \chi_\parallel(\omega)$ can be cast in the following way,

$$\text{Im} \chi_\parallel(\omega) = \frac{n_{e,h} \omega}{(1 - U_\parallel \rho_F)^2} \cdot \frac{1}{1 + U_\parallel n_{e,h} \omega} = \frac{\omega T_\parallel}{(1 - U_\parallel \rho_F) U_\parallel} \cdot \frac{1}{1 + (\omega T_\parallel)^2}.$$ (A6)

where in the last step we used the expression for the static spin-susceptibility $\chi_\parallel(0) = \rho_F^2/(1 - U_\parallel \rho_F)$ and we defined

$$T_\parallel = \frac{U_\parallel n_{e,h}}{1 - U_\parallel \rho_F},$$ (A7)

which is the result quoted in the main text in Eq. (8).

Appendix B: Transverse relaxation within the Landau-Lifshitz-Gilbert equation

We consider the Landau-Lifshitz-Gilbert (LLG) equation describing the damped precessional motion of a magnetic moment placed in a static external magnetic field that has been perturbed by a time-dependent transverse magnetic field:

$$\frac{dm}{dt} = -\gamma m \times B^\text{ext} + \eta \frac{m}{m_0} \times \frac{dm}{dt},$$ (B1)

with $B^\text{ext} = B_0 \hat{z} + b(t)$ and $b(t) = \theta(t) \Delta B(\hat{x} + \hat{y})$, i.e. for $t < 0$ the static field points in the $z$-direction while for
Inserting the above expressions into the linearized equations \([B2]\) and \([B3]\) we obtain in frequency space
\[
-i\omega m_x(\omega) = +\gamma m_0 b_y(\omega) + (i\eta \omega - \gamma B_0) m_y(\omega), \tag{B12}
\]
\[
-i\omega m_y(\omega) = -\gamma m_0 b_x(\omega) + (\gamma B_0 - i\eta \omega) m_x(\omega). \tag{B13}
\]

The above can be simplified by considering the circular components \(m_\pm = m_x \pm im_y\), yielding
\[
-i\omega m_\pm(\omega) = \gamma_\pm \left(B_0 m_\pm(\omega) - m_0 b_\pm(\omega)\right), \Rightarrow \Lambda_\pm(\omega)m_\pm(\omega) = b_\pm(\omega), \tag{B14}
\]
with \(b_\pm(\omega) = b_x \pm ib_y\), \(\gamma_\pm = \pm i\gamma/(1 \pm \ii \eta)\) and
\[
\Lambda_\pm(\omega) = \frac{1}{\gamma_\pm m_0}(i\omega + \gamma_\pm B_0). \tag{B15}
\]

It is apparent from Eq. \((B14)\) that the transverse spin-susceptibility can be obtained from the inverse of \(\Lambda_\pm(\omega)\) defined above. After some algebra and picking the minus sign in Eq. \((B15)\) one obtains
\[
\chi_\pm^{\text{LLG}}(\omega) = \left(\Lambda_\pm(\omega)\right)^{-1} = \frac{m_0 \omega_0}{B_0} \frac{-\eta \omega}{(\omega - \omega_0)^2 + (\eta \omega)^2}. \tag{B16}
\]

The density of spin-excitation in the LLG model are thus described by a skewed Lorentzian in \(\omega\):
\[
\text{Im} \chi_\pm^{\text{LLG}}(\omega) = \frac{m_0 \omega_0}{B_0} \frac{-\eta \omega}{(\omega - \omega_0)^2 + (\eta \omega)^2}. \tag{B17}
\]

The resonance frequency of the above function takes place at
\[
\frac{d}{d\omega} \text{Im} \chi_\pm^{\text{LLG}}(\omega) = 0 \Rightarrow \omega_{\text{res}} = \sqrt{1 + \eta^2}\omega_0, \tag{B18}
\]
while the FWHM amounts to
\[
\Gamma = 2\eta \omega_0 \frac{\sqrt{2 + 3\eta^2} + 2\sqrt{1 + \eta^2}}{1 + \sqrt{1 + \eta^2}} \approx 2\eta \omega_0. \tag{B19}
\]

We note that the above expression is exact in the \(\eta \to 0\) limit and involves only a \(\sim 10\%\) relative error for \(\eta = 1\), which is by far the maximum value that damping can get for single adatoms; for most of the elements analyzed in the main text we have \(\eta \lesssim 0.2\), so the approximation of Eq. \((B19)\) is indeed very good. Then, comparing Eq. \((B19)\) to Eq. \((B8)\) we arrive to the relation between the FWHM and the transverse relaxation time quoted in the main text:
\[
T_\perp = \frac{2}{\Gamma}. \tag{B20}
\]

**Appendix C: Basic expressions of the Bloch-Redfield formalism**

In this Appendix we provide a brief summary of the relaxation times in the context of Bloch-Redfield (BR)
The nonadiabatic contribution is given by

$$\frac{1}{T_1} \equiv \Gamma_{nm} = 2 \sum_{\alpha \beta} \Re (g_{\alpha \beta}(\omega_{mn})) S^\alpha_n S^m_n, \quad (C1)$$

where $n, m$ label the electronic eigenstates of the adatom, $\alpha, \beta$ label the eigenstates of the substrate, $\omega_{mn} = \epsilon_m - \epsilon_n$ with $\epsilon_i$ the eigenenergies, $g_{\alpha \beta}(\omega_{mn})$ is the substrate operator correlator and $S^\alpha_n$ the matrix elements of the adatom’s spin operator. Note that the term $\Gamma_{nm}$ in Eq. $(C1)$ corresponds to the scattering rate from state $n$ to $m$, hence $T_1$ is associated to population transfer between different states. $T_2$, in turn, is termed as the decoherence time and describes the decay rate of off-diagonal matrix elements of the reduced density operator. It can be separated into two different contributions, namely the nonadiabatic one, $\gamma_{nm}^{\text{nonad}}$, and the adiabatic one, $\gamma_{nm}^{\text{ad}}$:

$$\frac{1}{T_2} = \gamma_{nm}^{\text{nonad}} + \gamma_{nm}^{\text{ad}}. \quad (C2)$$

The nonadiabatic contribution is given by

$$\gamma_{nm}^{\text{nonad}} = \frac{1}{2} \left( \sum_{n' \neq n} \Gamma_{nn'} + \sum_{n' \neq m} \Gamma_{mn'} \right). \quad (C3)$$

while the adiabatic one reads

$$\gamma_{nm}^{\text{ad}} = \frac{1}{2} \sum_{\alpha \beta} \Re (g_{\alpha \beta}(0)) \left( S^m_n - S^n_n \right) \left( S^m_n - S^n_n \right). \quad (C4)$$

Noteworthily, the relaxation time of an atomic spin-excitation in the BR theory is described by $\gamma_{nm}^{\text{nonad}}$ of Eq. $(C3)$. The most important aspect to note for our purpose here is that $\gamma_{nm}^{\text{nonad}}$ in Eq. $(C3)$ involves a population transfer $\Gamma_{nn'}$, while $\gamma_{nm}^{\text{ad}}$ in Eq. $(C4)$ does not. As a consequence, $\gamma_{nm}^{\text{nonad}}$ and hence the spin-excitation lifetime is regarded as a $T_1$-like term (see Eqs. (69) and (70) of Ref. [30]), even though it formally describes the decay rate of off-diagonal matrix elements of the density operator rather than diagonal ones. Meanwhile, $\gamma_{nm}^{\text{ad}}$ is named the pure decoherence contribution. This, in our understanding, is how and why the relaxation time of an atomic spin-excitation is associated to $T_1$ instead of $T_2$ in this context.

We note that the above convention is not in line with the one adopted in the present work. From our point of view, given that an atomic spin-excitation can be related to the damped precessional (transversal) motion of the adatom’s magnetic moment, it is more natural to denote its lifetime by $T_2$ instead of with $T_1$.
