ABSTRACT
The combination of galaxy–galaxy lensing and galaxy clustering data has the potential to simultaneously constrain both the cosmological and galaxy formation models. In this paper, we perform a comprehensive exploration of these signals and their covariances through a combination of analytic and numerical approaches. First, we derive analytic expressions for the projected galaxy correlation function and stacked tangential shear profile and their respective covariances, which include Gaussian and discreteness noise terms. Secondly, we measure these quantities from mock galaxy catalogues obtained from the Millennium-XXL simulation and semi-analytic models of galaxy formation. We find that on large scales ($R > 10 h^{-1}$ Mpc), the galaxy bias is roughly linear and deterministic. On smaller scales ($R \lesssim 5 h^{-1}$ Mpc), the bias is a complicated function of scale and luminosity, determined by the different spatial distribution and abundance of satellite galaxies present when different magnitude cuts are applied, as well as by the mass dependence of the host haloes on magnitude. Our theoretical model for the covariances provides a reasonably good description of the measured ones on small and large scales. However, on intermediate scales ($1 < R < 10 h^{-1}$ Mpc), the predicted errors are $\sim 2$–$3$ times smaller, suggesting that the inclusion of higher order, non-Gaussian terms in the covariance will be required for further improvements. Importantly, both our theoretical and numerical methods show that the galaxy–galaxy lensing and clustering signals have a non-zero cross-covariance matrix with significant bin-to-bin correlations. Future surveys aiming to combine these probes must take this into account in order to obtain unbiased and realistic constraints.

Key words: gravitational lensing: weak – galaxies: statistics – cosmology: theory – large-scale structure of Universe.

1 INTRODUCTION
Since the first pioneering attempt to measure the galaxy–galaxy lensing (hereafter GGL) signal by Tyson et al. (1984), there have been significant technological developments in deep and wide-field astronomy, which have led to the emergence of GGL as one of the most promising probes for simultaneously constraining both the cosmological and galaxy formation models.

The first robust detection of the GGL signal was made by Brainard, Blandford & Smail (1996) using 90 arcmin$^2$ of imaging data from the 5 m Palomar telescope. They showed that whilst the tangential shear profile around individual galaxies was too weak to be measured, the stacked signal around all lens galaxies could be detected with high signal-to-noise. Since then there has been a rapid explosion in the field: the addition of the Wide-Field Camera to the Hubble Space Telescope enabled a number of key GGL studies (dell’Antonio & Tyson 1996; Griffiths et al. 1996; Hudson et al. 1998; Leauthaud et al. 2012). The improvement of ground-based facilities such as the Canada–France–Hawaii Telescope has also led to significant developments (Wilson et al. 2001; Hoekstra, Yee & Gladders 2004; Parker et al. 2007; van Uitert et al. 2011; Hudson et al. 2015; Velander et al. 2014). However, perhaps the most prolific work in this area comes from the analysis of the data from the Sloan Digital Sky Survey (hereafter SDSS; Guzik & Seljak 2001, 2002; McKay et al. 2001; Hirata et al. 2004; Sheldon et al. 2004, 2009a,b; Mandelbaum et al. 2005, 2006a,b,c, 2013; Johnston et al. 2007; Nakajima et al. 2012). All these works have revealed that the GGL signal is a complex function depending on a number of galaxy properties, such as luminosity, colour, spectral type, etc. The key importance of GGL is that it enables one to make a direct link from galaxy properties to the underlying dark matter distribution.

* E-mail: l.marian@sussex.ac.uk
Indeed, these works have also constrained the mass, density profiles, ellipticity of the dark matter haloes hosting the lens galaxies.

One of the first to realize that cosmic shear could help to simultaneously constrain galaxy formation and cosmology, through directly measuring the bias, was Schneider (1998). Schneider’s approach of using aperture mass filters was implemented by Hoekstra et al. (2002) who directly measured galaxy bias, establishing that it was a complicated function of scale. This approach was further theoretically developed for the halo occupation distribution framework by Guzik & Seljak (2001) and later by Seljak et al. (2005) and Yoo et al. (2006). More recent work has been performed by Cacciato et al. (2009, 2013) who have combined the results from GGL and galaxy clustering (hereafter GC) studies, along with measurements of the galaxy luminosity function (hereafter GLF) from SDSS to constrain the parameters of the conditional luminosity function (hereafter CLF) model – which fully specifies the link between a given dark matter halo and the galaxies it hosts, albeit with assumptions about the functional form of the CLF (Yang, Mo & van den Bosch 2003; van den Bosch et al. 2013). An interesting result to emerge from this work was that if one did not include the GGL measurements in the analysis, then equally good fits to the CLF model parameters could be obtained for either Wilkinson Microwave Anisotropy Probe 1 (WMAP1) or WMAP3 cosmology (Spergel et al. 2003, 2007). Including the GGL data broke this degeneracy and identified the WMAP3 parameters as the preferred cosmological model. See also the very recent works of Miyatake et al. (2013) and More et al. (2014).

Whilst there has been significant progress in attempting to understand and interpret the GGL signal (see also Baldauf et al. 2010; Saghiha et al. 2012), our understanding of how to perform a robust likelihood analysis with such data sets has been lacking. For example, in the recent development of the CLF framework (Cacciato et al. 2013; More et al. 2013; van den Bosch et al. 2013), the GGL and GLF measurements were taken to have diagonal covariance matrices, and the GC covariance matrix was obtained from jackknife estimation. Moreover, these probes were assumed to have zero cross-covariance. This is clearly a simplification that future large data set analyses should improve on. A better analysis of the errors was performed by Leauthaud et al. (2012) who used numerical simulations to estimate the covariance matrices of the GGL and GC measurements, while Mandelbaum et al. (2013) used the jackknife approach. The very recent works of Miyatake et al. (2013) and More et al. (2014) also had an improved error analysis. However, again in their analyses the cross-covariance of the two measurements was assumed to be negligible.

If upcoming surveys such as Dark Energy Survey (DES), The Javalambre-Physics of the Accelerated Universe Astrophysical Survey (J-PAS), Euclid and Large Synoptic Survey Telescope (LSST) are to optimally constrain the cosmological model, then it is inevitable that they must also jointly constrain the model of galaxy formation. The best way to do this will be to combine the GGL, GC and GLF measurements. This will require not only accurate models for the signals themselves, but also accurate modelling of the covariance and cross-covariance matrices of these probes.

In this paper, we develop an analytical framework to compute both the covariance and cross-covariance of GC and GGL. Our work builds upon the analysis of the earlier work of Jeong, Komatsu & Jain (2009) for GGL and that of Smith & Marian (2014, 2015) for the GC signal. We then use the semi-analytic galaxy catalogues and dark matter distribution from the Millennium-II (hereafter MXXL) simulation (Angulo et al. 2012) to directly measure these observables and their associated auto- and cross-covariances, for several bins in luminosity. Unlike the CLF approach, semi-analytic models (hereafter SAM) make no direct assumption on how galaxies populate dark matter haloes. Instead, they attempt to model the relevant physical processes for galaxy formation and evolution, and how these are affected by environment and assembly history. Thus, the non-linearity and stochasticity of galaxy bias are predictions, not assumptions in our study.

The paper is structured as follows. In Section 2, we present the necessary theoretical expressions for modelling the stacked tangential shear profiles and projected GC signals. In Section 3, we present expressions for their associated auto- and cross-covariances. In Section 4, we provide an overview of the MXXL simulation and the SAM galaxy catalogues that we use. In Section 5, we present the measurements of the GGL and GC signals for a set of luminosity bins, and compare them with the predictions from the theory. In Section 6, we present our results for the GC and GGL covariance and cross-covariance matrices. In Section 7, we summarise our findings and draw our conclusions.

2 THEORETICAL PREDICTIONS FOR THE GGL AND GC SIGNALS

In this section, we present theoretical expressions for the stacked tangential shear signal of a population of galaxy lenses and the signal for the projected galaxy correlation function.

2.1 Overview of required lensing ingredients

In the flat-sky approximation, the complex shear is written in terms of the convergence as (Bartelmann & Schneider 2001)

\[ \gamma(\theta) = \frac{1}{\pi} \int \kappa(\theta') D(\theta - \theta') \, d\theta' , \]

(1)

where the lensing kernel is defined to be

\[ D(\theta) \equiv (\theta_x^2 - \theta_y^2 - 2\theta_x\theta_y) / |\theta|^4 , \]

(2)

with \( \theta_x \) and \( \theta_y \) being the Cartesian components of the Euclidean vector \( \theta = (\theta_x, \theta_y) \). These equations can be written in Fourier space as

\[ \gamma(l) = \frac{1}{\pi} \kappa(l) D(l) , \quad \text{with} \quad D(l) = \frac{l_x^2 - l_y^2 + 2l_xl_y}{|l|^2} , \]

(3)

where \( l_x \) and \( l_y \) are the Cartesian components of the vector \( l \); \( \gamma(l) \) and \( D(l) \) are the Fourier transforms of \( \gamma(\theta) \) and \( D(\theta) \), respectively.

From equation (3), the complex shear can also be written using the polar coordinates of the Fourier vector \( l \) as

\[ \gamma(l) = \gamma_r(l) + i\gamma_i(l) = \kappa(l) [\cos(2\phi_l) + i\sin(2\phi_l)] \]

(4)

The tangential shear at position \( \theta \) with respect to position \( \theta_0 \) (where \( \theta \) and \( \theta_0 \) are defined with respect to the same origin) is

\[ \gamma_r(\theta; \theta_0) = -\gamma_r(\theta) \cos(2\phi_{\theta-\theta_0}) - \gamma_i(\theta) \sin(2\phi_{\theta-\theta_0}) \]

(5)

where \( \phi_{\theta-\theta_0} \) is the polar angle of the relative position vector \( \theta - \theta_0 \). Combining the last two equations, one can write

\[ \gamma_r(\theta; \theta_0) = -\int \frac{d^2l}{(2\pi)^2} \kappa(l) [\cos(2\phi_{\theta-\theta_0} - \phi_l) + \sin(2\phi_{\theta-\theta_0})] e^{i\bar{l} \cdot \theta} \]

(6)

Finally, we define the azimuthal average of the tangential shear as

\[ \gamma_{\Delta}(\theta; \theta_0) = \frac{1}{2\pi} \int_0^{2\pi} \frac{d\phi_{\theta-\theta_0}}{2\pi} \gamma_r(\theta; \theta_0) . \]

(7)
With the help of the very useful Bessel relation
\[
J_n(x) = \int_0^{2\pi} \frac{d\phi}{2\pi} e^{i\phi - i x \sin(\phi)},
\]
one obtains the following equation which will recur many times in this section:
\[
J_2(x) = -\frac{1}{\sqrt{2}} \int_0^{2\pi} \frac{d\phi}{2\pi} \cos(2(\phi - \phi')) e^{i x \cos(\phi - \phi')}.
\]
Therefore, the azimuthal average of the tangential shear is
\[
\langle \gamma_t(x) \rangle = \frac{1}{2\pi} \int_0^{2\pi} \frac{d\phi}{2\pi} J_2(\phi) e^{i x \phi}.
\]

2.2 Estimator for the stacked tangential shear

In GGL, the signal of individual lenses is very weak, so in order to improve the signal-to-noise of this probe, one has to stack several lenses. Suppose there is a population of \(N_g\) lens galaxies at positions \(x_i\) in a chosen coordinate system. Also suppose the total area of the survey to be \(S = \Omega_k\). The number density of these lenses can be written as a sum over their positions:
\[
n_g(x) = \sum_{i=1}^{N_g} \delta(x - x_i),
\]
where \(x\) is a 2D vector in the survey area. Using the above equation, an estimator for the tangential shear of such a lens population at an arbitrary position \(\theta\) with respect to the location of the galaxy centres \(x_i\) is (Jeong et al. 2009)
\[
\hat{\gamma}_t(\theta) = \frac{1}{N_g} \sum_{i=1}^{N_g} \gamma_t(x_i + \theta; x_i).
\]
We define the fluctuation in the number density of lenses as \(n_g(x) = \bar{n}_g[1 + \delta_g(x)]\), where the mean angular density of lens galaxies is \(\bar{n}_g = N_g/\Omega_k\). At this point, we also introduce the definitions of the convergence and galaxy density auto- and cross-power spectra, which shall be used throughout this paper:
\[
\langle \kappa(l) \kappa(l') \rangle = (2\pi)^2 \int d\theta x \kappa(l) \kappa(l') C_{\kappa\kappa}(l);
\]
\[
\langle \delta_g(l) \delta_g(l') \rangle = (2\pi)^2 \int d\theta x \delta_g(l) \delta_g(l') C_{\delta_g\delta_g}(l);
\]
\[
\langle \delta_g(l) \kappa(l') \rangle = (2\pi)^2 \int d\theta x \delta_g(l) \kappa(l') C_{\delta_g\kappa}(l).
\]

Since the tangential shear with respect to an origin \(\theta\) vanishes on average \(\langle \gamma_t(\theta|0) \rangle = 0\), the ensemble average of the estimator in equation (12) is
\[
\langle \hat{\gamma}_t(\theta) \rangle = \frac{1}{N_g} \int_{\Omega_k} d^2x \langle n_g(x) \gamma_t(x + \theta; x) \rangle
\]
\[
= \frac{1}{\Omega_k} \int d^2x \langle \delta_g(x) \gamma_t(x + \theta; x) \rangle
\]
\[
= \langle \delta_g(0) \gamma_t(\theta; 0) \rangle
\]
\[
= -\int \frac{d^2l}{(2\pi)^2} C_{\delta_g\kappa}(l) \cos[2(\phi_k - \phi_t)] e^{i l \cdot \phi_t}.
\]

In the above we have also used the homogeneity of the Universe, which makes the ensemble average of two cosmological fields to be invariant under translations. We shall take advantage extensively of this property throughout this work. With equation (9), we arrive at the azimuthally-averaged expression for the ensemble average of the stacked shear estimator:
\[
\langle \hat{\gamma}_t^e(\theta) \rangle = \int \frac{d^2l}{(2\pi)^2} C_{\delta_g\kappa}(l) J_2(l\theta).
\]

Our goal is to compare theory predictions with estimates from simulations, so we must take into account that the measured tangential shear is bin averaged and not just azimuthally averaged. We introduce the bin area:
\[
A(\theta) = \int_0^{2\pi} d\phi \int_{\theta_{\text{min}}}^{\theta_{\text{max}}} d\theta \theta = \pi (\theta_{\text{max}}^2 - \theta_{\text{min}}^2),
\]

with \(\theta_{\text{min}}\) and \(\theta_{\text{max}}\) being the lower and upper bounds of the radial bin \(i\). The bin-averaged stacked tangential shear estimator is defined by
\[
\langle \hat{\gamma}_t^e(\theta_i) \rangle = \frac{1}{A(\theta)} \int_{A(\theta)} d^2\phi \langle \hat{\gamma}_t^e(\theta) \rangle = \frac{2\pi}{A(\theta)} \int_{\theta_{\text{min}}}^{\theta_{\text{max}}} d\theta \theta \langle \hat{\gamma}_t^e(\theta) \rangle.
\]

2.3 The projected galaxy correlation function

We define the estimator for the projected galaxy correlation function to be
\[
\hat{w}_{gg}(R) = \frac{1}{2\pi} \int_0^{2\pi} d\phi R \int_{-\kappa_{\text{max}}}^{\kappa_{\text{max}}} d\kappa \hat{\xi}_{gg}(R),
\]
where \(\hat{\xi}_{gg}\) is an estimator for the 3D galaxy correlation function, \(\kappa_{\text{max}} = 100 h^{-1}\) Mpc, their contribution to \(\hat{w}_{gg}\) is of \(\sim\)10 per cent on the largest scales that we consider and less otherwise (Baldauf et al. 2010). The galaxy correlation function can be written in terms of its Fourier transform, the galaxy power spectrum:
\[
\hat{\xi}_{gg}(R) = \int \frac{d^3k}{(2\pi)^3} \mathcal{P}_{gg}(k) e^{i k \cdot R}
\]
\[
= \int_0^{\kappa_{\text{max}}} \frac{dk}{(2\pi)^3} e^{i k \cdot R} \int_0^\infty dk e^{i k \cdot R} \mathcal{P}_{gg}(k)
\]
\[
\times e^{-i k \cdot R} e^{i k \cdot R \cos(\phi_k - \phi_t)},
\]

where the second line follows from expressing the wavevector \(k\) in cylindrical coordinates, with components \(k_z, \phi_k, k_r\), \(k_r\) is the component along the line of sight and the magnitude \(k\) is defined in the standard way \(k = \sqrt{k_r^2 + k_z^2}\). The expectation of the projected
galaxy correlation function estimator may therefore be written as
\[
\langle \hat{w}_{eg}(R) \rangle = \int_0^{\infty} \frac{dk}{(2\pi)^2} k J_0(k R) \int_{-\infty}^{\chi_{\text{max}}} dk_p \mathcal{P}_{eg}(k) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi} \times \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi} \times \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi},
\]

where \( j_0 \) is the zeroth-order spherical Bessel function. Note that we can also obtain an expression for the ensemble average of our projected correlation function estimator in spherical coordinates, choosing a particular frame where \( r \parallel e_z \),
\[
\langle \hat{w}_{eg}(R) \rangle = 4 \chi_{\text{max}} \int_0^{\infty} \frac{dk}{(2\pi)^2} k J_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi} \times \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi} \times \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi}.
\]

where in the last equality we took advantage of the fact that the result did not depend on our particular choice of frame, and switched back to cylindrical coordinates. Whilst equations (23) and (24) are expected to yield the same result, the evaluation of the latter should be more accurate since it involves a single Bessel function integral.

Finally, we may apply the Limber approximation to simplify equation (23). In this approximation, it is only modes that are transverse to the line of sight which contribute to the power spectrum integral, and so the second integral in equation (22) becomes
\[
\int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi} \times \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi} \times \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi}.
\]

Using this relation in equation (22), we find that the Limber-approximated ensemble average of the projected galaxy correlation function estimator is therefore
\[
\langle \hat{w}_{eg}(R) \rangle = \int_0^{\infty} \frac{dk}{2\pi} k J_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi} \times \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi} \times \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ j_0(k R) \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ e^{i k \chi}.
\]

\[3 \text{ SIGNAL COVARIANCE MATRICES}\]

In this section, we compute the auto- and cross-covariance matrices of the stacked tangential shear signal and the projected galaxy correlation function.

\[3.1 \text{ The covariance matrix of the stacked tangential shear estimator}\]

The definition of the covariance of the estimator in equation (12) is
\[\text{Cov}\left[ \hat{\gamma}_{i}^{\theta}(\theta_1, \theta_2) \right] = \langle \hat{\gamma}_{i}^{\theta}(\theta_1) \hat{\gamma}_{i}^{\theta}(\theta_2) \rangle - \langle \hat{\gamma}_{i}^{\theta}(\theta_1) \rangle \langle \hat{\gamma}_{i}^{\theta}(\theta_2) \rangle.
\]

The bin-averaged estimate of the GGL covariance is defined according to equation (17) as
\[\text{Cov}\left[ \hat{\gamma}_1^{\theta}(\theta_1, \theta_2) \right] = \frac{1}{\Omega_i} \int_{A_i} d\theta_i d\theta_j \text{Cov}\left[ \hat{\gamma}_1^{\theta}(\theta_1, \theta_2) \right].
\]

In Appendix A1 we provide the complete details of the derivation of the covariance of the stacked tangential shear profiles. The main result is (cf. equation A14)
\[\text{Cov}\left[ \hat{\gamma}_{i}^{\theta}(\theta_1, \theta_2) \right] = \frac{1}{\Omega_i} \int_{A_i} d\theta_i d\theta_j \left\{ C_{\gamma g}(l) + C_{\delta g}(l) \left( \frac{\sigma^2}{\bar{n}_g} \right) \left[ \delta_{D}(\theta_1 - \theta_2) \right] \right\},
\]

where \( \sigma^2 / 2 = \sigma_{\gamma g}^2 = \sigma_{\delta g}^2 \) is the variance per shear component in the measurement of one source galaxy and \( \bar{n}_g \) is the mean angular density of the source galaxies.

\[3.2 \text{ The covariance matrix of the projected galaxy correlation function estimator}\]

The azimuthally-averaged covariance of the projected correlation function estimator can be written as a projection of the covariance of the estimator for the 3D galaxy correlation function, which we denote \( \hat{\gamma}_{eg} \). Hence,
\[\text{Cov}[\hat{w}_{eg}](R_1, R_2) = \frac{1}{V_1} \int_{0}^{2\pi} \frac{d\phi_{R_1}}{2\pi} \int_{0}^{2\pi} \frac{d\phi_{R_2}}{2\pi} \int_{-\chi_{\text{max}}}^{\chi_{\text{max}}} d\chi \ x_{\max} \left[ \mathcal{P}_{eg}(k R_1) \mathcal{P}_{eg}(k R_2) \left( \frac{\sqrt{k_{\perp}^2 + k_z^2}}{\Omega_i} \right) \frac{2(1 + \alpha)}{\bar{n}_g} \left[ w_{eg}(R_1) + 2x_{\max}(1 + \alpha) \right] \right] \delta_{D}(R_1 - R_2) \frac{1}{2\pi R_1},
\]

where \( \alpha \) is a constant quantifying how dense the random catalogue used to estimate the correlation function is relative to the galaxy data (see Appendix A2 for more details). Note that in the above \( \bar{n}_g \) is the mean galaxy volume density, whereas in Section 3.1 the same notation is used for the mean angular density of lens galaxies. As in the case of the ensemble-averaged projected galaxy correlation function estimator, here too we apply the Limber approximation to simplify the above result. The Limber-approximated covariance is
given by

\[
\text{Cov}^L[\hat{w}_g(R_1, R_2)] = \frac{1}{V \chi_{\text{max}}} \int_0^{\chi_{\text{max}}} \frac{dk}{2\pi} J_0(k R_1) J_0(k R_2) 
\times \mathcal{P}_g(k) \left[ \mathcal{P}_g(k) + \frac{2(1 + \alpha)}{\bar{n}_g} \right] + \frac{2}{\bar{n}_g} \left[ w^T_{tg}(R_1) + 2 \chi_{\text{max}}(1 + \alpha)^2 \right] \cdot
\]

(31)

Note that the survey volume can be expressed as \( V_r = 2 \chi_{\text{max}} A_s \),
where \( A_s \) denotes the transverse area of the survey. If \( \chi_{\text{max}} \to \infty \),
then we also have \( V_r \to \infty \) and the Limber-approximated covariance becomes

\[
\text{lim}_{\chi_{\text{max}} \to \infty} \text{Cov}^L[\hat{w}_g(R_1, R_2)] = \frac{2}{A_s} \int_0^{\chi_{\text{max}}} \frac{dk}{2\pi} J_0(k R_1) J_0(k R_2) 
\times \mathcal{P}_g(k) \left[ \mathcal{P}_g(k) + \frac{2(1 + \alpha)}{\bar{n}_g} \right] + \frac{2}{\bar{n}_g} \left[ w^T_{tg}(R_1) + 2 \chi_{\text{max}}(1 + \alpha)^2 \right] \cdot
\]

Therefore, the Limber covariance is well behaved in the limit where \( \chi_{\text{max}} \to \infty \). Finally, using the definitions in equations (16) and (17), we write the expression for the bin-averaged, Limber-approximated covariance of the projected galaxy correlation function estimator:

\[
\text{Cov}^L[\hat{w}_g(R_1, R_2)] = \frac{2}{V \chi_{\text{max}}} \int_0^{\chi_{\text{max}}} \frac{dk}{2\pi} J_0(k R_1) J_0(k R_2) 
\times \mathcal{P}_g(k) \left[ \mathcal{P}_g(k) + \frac{2(1 + \alpha)}{\bar{n}_g} \right] + \frac{2}{\bar{n}_g} \left[ w^T_{tg}(R_1) + 2 \chi_{\text{max}}(1 + \alpha)^2 \right] \cdot
\]

(32)

### 3.3 The cross-covariance of the stacked tangential shear and the projected galaxy correlation function estimators

In this section, our goal is to compute the cross-covariance of the estimators for the stacked tangential shear and projected galaxy correlation functions, defined by equations (12) and (20). To this avail, we follow the same procedure as before, and define the cross-covariance as:

\[
\text{Cov}[\hat{w}_g(R_1), \hat{\gamma}_t^g(R_2)] = \langle \hat{w}_g(R_1) \hat{\gamma}_t^g(R_2) \rangle - \langle \hat{w}_g(R_1) \rangle \langle \hat{\gamma}_t^g(R_2) \rangle,
\]

(33)

where \( R_1 \) and \( R_2 \) are two 2D position vectors. To simplify this calculation, we shall use the angular correlation function instead of the projected correlation function. This is justified by the fact that our lenses are in a thin redshift slice, in which case the two correlation functions are equivalent. In Appendix A3 we provide complete details of the derivation of the cross-covariance matrix.

The final expression is given by (cf. equation A39)

\[
\text{Cov}[\hat{w}_g(\theta_1), \hat{\gamma}_t^g(\theta_2)] = -\frac{1}{\Omega_r} \int \frac{d\ell}{(2\pi)^2} C_{ug}(\ell) \left[ C_{ug}(\ell) + \frac{1}{\bar{n}_g} \right] \times \cos[2(\phi_2 - \phi_1)] [e^{i\ell(\phi_2 - \phi_1)} + e^{i\ell(\phi_1 - \phi_2)}].
\]

Just like before, we are interested in the cross-covariance matrix of the bin-averaged measurements. In a similar fashion to the analysis of the previous sections, we see that under binning the above

\[
\text{Cov} \left[ \hat{w}_g(\theta_1), \hat{\gamma}_t^g(\theta_2) \right] = \frac{2}{\Omega_r} \int \frac{d\ell}{(2\pi)^2} J_0(\theta_1) J_0(\theta_2) \left[ C_{ug}(\ell) + \frac{1}{\bar{n}_g} \right] \times C_{ug}(\ell) \left[ C_{ug}(\ell) + \frac{1}{\bar{n}_g} \right].
\]

(34)

Equation (34) represents the bin-averaged cross-covariance of the estimator for the angular galaxy correlation function and the stacked tangential shear estimator. As expected, it has no dimensions.

### 4 The MXXL Simulation

The MXXL is the largest simulation in the Millennium series, with a volume of \( V = 3 \ h^{-1} \text{Gpc}^3 \) and \( 6720^3 \) dark matter particles of mass \( m_p = 6.9 \times 10^9 \ h^{-1} \text{M}_\odot \). The cosmological model corresponds to a flat \( \Lambda \) cold dark matter universe with the matter density parameter \( \Omega_m = 0.25 \), the dimensionless Hubble parameter \( h = 0.73 \), the amplitude of matter fluctuations \( \sigma_8 = 0.9 \), the primordial spectral index \( n_s = 1 \) and a constant dark energy equation of state with \( w = -1 \). For a complete description of the MXXL, we refer the reader to Angulo et al. (2012).

Halo and subhalo catalogues were stored for 63 snapshots. The smallest object in these catalogues has a mass \( \sim 1.4 \times 10^{11} \ h^{-1} \text{M}_\odot \). Merger trees were built by identifying for each subhalo in each snapshot the most likely descendant in the next snapshot. The trees were then used to build a galaxy catalogue with the SAM galaxy formation code L-GALAXIES (Springel et al. 2005).

The L-GALAXIES code corresponds to a set of differential equations that couple with the above-mentioned merger trees and that encode the key physical mechanisms for galaxy formation. Processes such as gas cooling, star formation, feedback from SN and AGN, galaxy mergers, black hole formation and growth, and generation of metals are all implemented in a self-consistent manner. We refer the interested reader to Guo et al. (2011), Henriques et al. (2012) and references therein for specific details on the method, and to Angulo et al. (2014) for details on the implementation in the MXXL simulation. Here, we just highlight that the galaxy population of a given halo does not depend on its mass alone, as commonly assumed in many models, but also on the details of the halo assembly history and environment. For each galaxy, the full star formation history is stored, and when coupled with population synthesis models and an assumed initial stellar mass function, it allows us to compute the expected luminosity for each of the five SDSS filters.

In Fig. 1, we present the luminosity function for the five SDSS bands. We find that all of the luminosity functions show qualitatively similar behaviour: a steep fall-off at bright magnitudes and a turn-over followed by a power-law-like tail at intermediate and faint magnitudes. We also see that for a given magnitude band, there are greater abundances of galaxies at red wavelengths than at blue. This is qualitatively consistent with observational results from the SDSS (Blanton et al. 2003). For the faintest magnitudes, we notice artefacts produced by the finite mass resolution of the MXXL simulation. We elaborate on this next.

In the upper-left panel of Fig. 2, we present the relative abundance of central, satellite and orphan galaxies as a function of their red-band absolute magnitude. ‘Central’ galaxies reside at the centres of the main halo (subhalo), and are therefore the main galaxies of the friends-of-friends (FoF) haloes. ‘Satellite’ galaxies inhabit satellite subhaloes within the FoF haloes. ‘Orphan’ galaxies are satellite galaxies whose dark matter subhalo has been stripped down below the resolution limit of the simulation. The figure clearly shows
that the brightest galaxies \( (M_r \leq -18) \) are mostly centrals. The satellites with a resolved dark matter subhalo are sub-dominant for all magnitude bins, but dominate among satellite galaxies with \( M_r < -20 \). These features depend on the mass resolution of the simulation (see Fig. B1 for an analogous figure constructed from the higher resolution Millennium simulation). With a much higher mass resolution, central galaxies would dominate at any luminosity and there would be no orphan galaxies.

The upper-right panel of Fig. 2 shows how the mass of the host haloes evolves with the galaxy luminosity. Independent of the brightness of satellite and orphan galaxies, the haloes hosting them are quite massive \( (M_{\text{vir}} \in [3 \times 10^{13}, 10^{14}] M_\odot) \), whereas the haloes inhabited by central galaxies display a substantial decrease in mass with decreasing luminosity. This drop in halo mass spans more than two orders of magnitude, starting at \( M \sim 2 \times 10^{13} h^{-1} M_\odot \).

The bottom-left panel of Fig. 2 shows the average distance of the galaxies from the central galaxy, as a function of magnitude. By definition, the distance of central galaxies is zero. Satellite galaxies are on average most distant from the halo centre: the brightest have a separation of \( \sim 0.9 h^{-1} \) Mpc, and the faintest of about \( 0.6 h^{-1} \) Mpc. On the other hand, orphan galaxies are on average within \( [0.4, 0.6] h^{-1} \) Mpc from the halo centre, which is a consequence of tidal forces being stronger closer to the halo centre where tidal disruption and mass-loss happen.

Finally, the bottom-right panel of Fig. 2 presents the evolution of the host subhalo mass with luminosity. For centrals, this is in fact the same as shown in the upper-right panel; the other two types follow the same trend as the centrals. Note that the subhalo mass associated with the orphan galaxies is defined to be the mass of the last subhalo tracked before it fell below the mass resolution of the simulation. We can see that there are no strong differences among different types which is a consequence of the fact that the \( r \)-band magnitude mostly traces the total amount of mass in stars, which in turn depends primarily on the total amount of gas available for star formation and thus on the mass of the host dark matter structure.
In this paper, we shall use only the red band, since most of the GGL and GC studies to date have focused on this band. We shall only consider galaxies with $M_r < -19$, split into four absolute-magnitude bins, with each bin spanning a single unit of magnitude, except for the brightest bin for which we take all galaxies with $M_r < -22$. We have ensured that above the chosen limit $M_r < -19$, our results are qualitatively insensitive to the finite mass resolution of the MXXL by explicitly comparing the GGL and GC signals with those derived from the higher-resolution Millennium simulation.

5 RESULTS I: CLUSTERING AND LENSING MEASUREMENTS IN MXXL

5.1 Methodology for estimating the projected correlation functions

In order to estimate the GGL and GC signals and their covariance from the MXXL data, we divide the simulation box into 216 subcubes of volume $V_{sub} = [500\ h^{-1}\ Mpc]^3$. Each subcube therefore contains $\approx 1.4 \times 10^9$ dark matter particles, as well as galaxies from the catalogues described in Section 4. For our analysis, we assume both the Born and Limber approximations, which allow us to perform all of the computations at the fixed redshift $z = 0.24$. For each of the subcubes, we measure the projected matter–matter, galaxy–matter, and galaxy–galaxy correlation functions. In order to handle the huge data volume, we have developed a fast K-D tree code in C++ with MPI parallelization. Our algorithm is similar to that described by Moore et al. (2001) and Jarvis, Bernstein & Jain (2004). However, rather than invoking an approximate scheme for binning the pair counts as is done in these algorithms, we place every particle exactly into the correct radial bin. We have carefully tested that our code obeys the pair counting scaling $DD \propto R^{3/2}$ and that it reproduces exactly the answer obtained from a brute-force pair summation code.

For the particular problem of computing the correlation functions in the MXXL simulation, we count particles in logarithmic bins of the transverse distance $R$, and linear bins of the line-of-sight distance $\chi$. Since the subcubes do not have periodic boundary conditions, we also cross-correlate the data with a random catalogue to account for boundary effects on the pair counts. With the pair counts for the $(R, \chi)$ bins, the 3D correlation function can be estimated by using the unbiased and minimum-variance (in the limit of no-clustering) estimator of Landy & Szalay (1993):

$$\hat{\xi}(R, \chi) = \frac{(D_1D_2 - D_1R - D_2R + RR)}{RR},$$

(35)

where $D_1$ and $D_2$ represent the first and second data catalogues, and $R$ is the random catalogue. $D_1D_2$, $D_1R$, $D_2R$ and $RR$ represent the respective pair counts. For auto-correlations, $D_1 = D_2$, while for cross-correlations e.g. of galaxies and matter, they differ. Note that this estimator perfectly matches the one we defined in equations (A15) and (A18), since we took the weights there to be constant. The ratio of the number of data particles to the number of particles from the random catalogue represents the $\alpha$ from equation (A15). Some details of how we estimate these correlations are as follows. In order to obey computing time constraints, we limit the random catalogues to $10^6$ particles. To maintain a value as low as possible for $\alpha$, we subsample both the matter and the galaxy data. The number of subsamples is 32, and for each of them we generate a random catalogue. The rate of sampling for matter is $1/4000$, which gives us about 350,000 dark matter particles per subsample, while for each luminosity bin we randomly select no more than 150,000 galaxies. These values correspond to $\alpha \sim 0.3$ for matter and $\alpha \sim 0.15$ for galaxies in each luminosity bin. The only exception is the first luminosity bin, containing the brightest galaxies, which has only about 20,000 galaxies per subscale, and is therefore not subsampled. The matter particles and galaxies from every subsampled subcube are correlated with the random catalogue generated for that subsample. Thus, for all the subcubes, the $i^{th}$ subsample is correlated with the $i^{th}$ random catalogue. We have checked that given the number of data particles, the number of random particles is sufficiently large not to yield significant errors in the measured projected correlations.

We found that it was crucial to correct the projected correlation functions for the integral constraint, otherwise the results exhibited a strong dependence on the projection length $\chi_{max}$. This owes to the fact that the total density of objects in each subcube is not guaranteed to reach the universal mean.

We implement the integral constraint in the estimates of the 3D galaxy correlation function in a similar fashion to the procedure described in Landy & Szalay (1993). To begin, we define the ‘geometric factor’:

$$G_p(R_i, \chi_j) \equiv \frac{RR_{ij}}{\sum_{i,j} RR_{ij} dV_{ij}},$$

(36)

where $RR_{ij}$ is the number of random pairs for the bin $(R_i, \chi_j)$ and $dV_{ij}$ is the cylindrical volume of the respective bin, i.e. $dV_{ij} = \pi(R_{ij}^2 - R_i^2) \Delta \chi_j$, with $\Delta \chi_j \equiv \chi_{j+1} - \chi_j$. Thus, $G_p(R_i, \chi_j)$ is the number of pairs possible in the bin $ij$ relative to the total number of pairs in the survey volume. It is normalized to unity over the survey volume, i.e. $\sum_i G_p(R_i, \chi_j) dV_{ij} = 1$. The integral constraint is defined by the equation:

$$\sum_{i,j} (1 + \hat{\xi}_{ij}) G_p(R_i, \chi_j) dV_{ij} \equiv 1 + \xi_{Vs},$$

(37)

where $\hat{\xi}_{ij}$ is the estimator introduced in equation (35) at the respective bin. The integral-constraint-corrected estimator for the projected galaxy correlation function is given by

$$\hat{w}_{cor}(R_i) = \frac{\sum_{j=1}^{N_{\chi}} \left[ \frac{1 + \hat{\xi}_{ij}}{1 + \xi_{Vs}} - 1 \right] \Delta \chi_j}{N_{\chi}},$$

(38)

where $N_{\chi}$ is the number of bins in $\chi$. We apply this to all of the measurements.

Finally, we mention the choice of bins: we have 25 logarithmic bins in $R$, spanning the interval $[0.04, 54] h^{-1} \ Mpc$, and 10 linear bins in $\chi$, with a chosen $\chi_{max}$ of $100 h^{-1} \ Mpc$. We checked that the number of line-of-sight bins is sufficiently large to obtain an accurate estimation of the projected correlation function.

To summarize: the projected correlation functions are estimated through the following steps: (i) use the tree code to evaluate the 3D pair counts for each $(R, \chi)$ bin, and for every subsample; (ii) build the Landy–Szalay estimator for the 3D correlation function from the pair counts and determine the integral constraint factor; (iii) add the line-of-sight bins to obtain the projected correlation functions, i.e. compute $\hat{w}_{cor}$ following equation (38); (iv) calculate the average of the subsamples.

5.2 Galaxy and matter correlation functions

Fig. 3 presents the projected matter–matter, galaxy–matter, and galaxy–galaxy correlation functions – red, green and blue solid lines, respectively – from the 216 subcubes of the MXXL. Each line corresponds to the estimate from one subcube, and each panel presents one magnitude bin, starting with the brightest galaxies in the
5.3 Galaxy bias and cross-correlation coefficient

We may obtain the galaxy bias parameter either from the galaxy–galaxy or galaxy–matter projected correlation functions through

\[ b_{gg}(R) = \sqrt{\frac{w_{gg}(R)}{w_{mm}(R)}} \],

(39)

\[ b_{gm}(R) = \frac{w_{gm}(R)}{w_{mm}(R)}. \]

(40)

Fig. 4 presents the two bias estimates for all magnitude bins and averaged over all 216 subcubes of the MXXL simulation. There are several points worth noticing in these figures. First, on large scales, we see that both \( b_{gg} \) and \( b_{gm} \) appear to be constant and qualitatively consistent with one another. We also note that the bias is relatively similar for the fainter bins, but it increases sharply for the brightest galaxies. This luminosity dependence of the bias in SAM models is consistent with earlier studies (see Smith 2012, and references therein), and can be understood from Fig. 2. There we see that it is only for the brightest magnitude bin that the host haloes of both the central and satellite galaxies are very massive. For the fainter bins, the mass of the host haloes decreases with luminosity in the case of central galaxies, while remaining relatively constant in the case of the satellites. Thus, the bias of the latter is boosted. This explanation is consistent with the picture where an individual galaxy inherits the bias of the halo hosting it.

On smaller scales, we notice that \( b_{gm} > b_{gg} \); the scale where this transition occurs decreases with increasing absolute magnitude, ranging from \( R \sim 1 h^{-1} \) Mpc for the brightest galaxies to \( R \sim 0.07 h^{-1} \) Mpc for the faintest bin. The fact that \( b_{gm} > b_{gg} \) can be qualitatively understood from the following reasons. The 3D galaxy–galaxy correlations in SAM models obey an exclusion condition, which is that individual galaxies cannot come closer than the separation of the sum of their individual subhalo virial radii. On scales smaller than this, the correlation function drops to \(-1\). Whereas for the galaxy–matter cross-correlation function, no such exclusion is present and one simply probes the density profile of matter around galaxies – which is known to be cuspy (Hayashi & White 2008). However, in projection these effects are less significant, but nevertheless still operate and lead to the shape shown in Fig. 4. The transition scale varies with magnitude because the halo mass of central galaxies decreases with increasing absolute magnitude (cf. Fig. 2).

The cross-correlation coefficient can be defined as

\[ r_{gm}(R) \equiv \frac{w_{gm}(R)}{\sqrt{w_{gg}(R)w_{mm}(R)}} \equiv \frac{b_{gm}(R)}{b_{gg}(R)}. \]

(41)

Note that this is not the same as is usually understood in statistics, where the cross-correlation coefficient of two variables \( X \) and \( Y \) is constrained to be \(|r| \leq 1\). Equation (41) is defined in terms of correlation functions, and hence provided \( R \neq 0 \) it is not required to obey the condition \(|r| \leq 1\). Indeed, if either the galaxy–galaxy or matter–matter correlation functions cross zero, which they most certainly do, then \( r \) is formally divergent. Nevertheless, the diagnostic
properties of $r$ are key: if the galaxy bias were linear and deterministic, then $r = 1$, and measurements of either $w_{gm}$ or $w_{gg}$ may be directly related to the underlying matter distribution, modulo an amplitude factor. However, any departure from unity indicates that the bias is either non-linear or stochastic, or both (for more discussion, see Dekel & Lahav 1999; Seljak & Warren 2004).

Fig. 5 shows the cross-correlation coefficient as a function of the transverse scale $R$. We find that on large scales, the correlation coefficient approaches unity for the four magnitude bins that we have considered. This implies that, at least for the SAM galaxies in MXXL, the large-scale bias is linear and deterministic and that it describes both the galaxy–galaxy and galaxy–matter correlation functions. On small scales, we see that the correlation coefficient decreases sharply and then shoots up above unity. This is consistent with the non-linear scale-dependent bias presented in Fig. 4. Note that the small-scale clustering of galaxies is very sensitive to the
These discrepancies are attributed to the fact that HALOFIT underestimates the measured non-linear power spectrum on small scales. Consequently, also the convergence power spectrum on small scales.

Since the agreement between HALOFIT models and simulation measurements depends on both the mass resolution and the volume of the simulations – the closer the simulations’ specifications to those used for the calibration of the semi-analytical prescriptions, the better the agreement – we defer more sophisticated theory predictions to a future work and are satisfied for now that the original HALOFIT fitted formula HALOFIT (Smith et al. 2003) gives reasonable enough answers for our purpose here.

It is also interesting to note that the faintest galaxies yield high projected correlation functions around 1 h⁻¹ Mpc, most likely due to contributions from the satellite galaxies, which inhabit higher mass haloes and are therefore more biased.

5.4 Comparison of the measured and theoretical projected galaxy correlation function

In Fig. 6, we show again the projected galaxy correlation functions for the four magnitude bins, but this time we have averaged the data over the 216 MXXL subcubes. The error bars are plotted on the mean. The solid lines present the theoretical predictions. We evaluate the theory as follows: instead of a direct numerical evaluation of equation (26), which would require a model for \( P_{\text{gal}}(k) \), we determine the projected non-linear matter correlation function under the Limber approximation by replacing \( P_{\text{gal}}(k) \rightarrow P_{\text{mm}}(k) \). We then simply multiply this quantity by the measured bias, e.g. equation (39):

\[
w_{g\text{g}}^L(R) = b_{g\text{g}}(R)w_{\text{mm}}^L(R).
\]

In computing \( w_{\text{mm}}^L \), we use the non-linear matter power spectrum fitting formula HALOFIT (Smith et al. 2003).

In Fig. 6 we see that on small scales \( R \leq 0.1 \) h⁻¹ Mpc, the predictions underestimate the measured \( w_{\text{gal}}^L \) by roughly \( \sim 20 \) per cent. These discrepancies are attributed to the fact that HALOFIT underestimates the true non-linear matter power spectrum on small scales (Takahashi et al. 2012). The more recent work of Fosalba et al. (2015a,b) shows however that the revised HALOFIT of Takahashi et al. (2012) overpredicts the non-linear power spectrum and consequently also the convergence power spectrum on small scales. Since the agreement between HALOFIT models and simulation measurements depends on both the mass resolution and the volume of the simulations – the closer the simulations’ specifications to those used for the calibration of the semi-analytical prescriptions, the better the agreement – we defer more sophisticated theory predictions to a future work and are satisfied for now that the original HALOFIT of Smith et al. (2003) gives reasonable enough answers for our purpose here.

5.5 The stacked tangential shear of galaxies

As mentioned earlier, since the full particle data were not available for a large set of redshifts, we were not able to perform ray-tracing simulations. Instead, we use the Born approximation to make lensing observables from the MXXL data. In real terms, this means that the convergence is obtained as a weighted line-of-sight integration of the matter density fluctuations (Bartelmann & Schneider 2001):

\[
\kappa(\theta) = \frac{3H_0^2\Omega_m}{2c^2} \int_0^\infty dx \frac{\chi(x-\chi)}{x} \frac{\delta(x,\chi)}{a(\chi)},
\]

where we have assumed a flat space–time geometry and \( H_0 \) is the Hubble constant, \( c \) is the speed of light, \( \delta \) is the linear matter density perturbation and \( a \) is the expansion factor.

If we now reexamine equation (15), it can be proven that the azimuthally averaged tangential shear about a randomly selected point \( \theta_0 \), which we take to be \( \theta \), may be written in real space as (Schneider 2005)

\[
\gamma_{\theta,a}(\theta) = \kappa(\theta) - k_a(\theta). \]

If instead of random points we consider the centre of a lens galaxy as the reference point, then on averaging over all galaxies the above expression becomes (Guzik & Seljak 2001)

\[
\langle \gamma_{\theta,a}(R, z_i, z_s) \rangle = \frac{\Delta \Sigma(R, z_i)}{\Sigma_{\text{crit}}(z_i, z_s)},
\]

where we used the relation \( \theta = R/\chi(z_i) \) and the differential surface mass density is given by

\[
\Delta \Sigma(R, z_i) = \rho_m^0 \left[ \pi_{\text{gal}}(< R, z_i) - \bar{w}_{\text{gal}}(R, z_i) \right].
\]

In the above, \( \rho_m^0 \) is the comoving matter density of the Universe, and we have assumed that the circularly averaged tangential shear is sourced only by the matter associated with a single lens galaxy.
The critical surface density for lensing is given by

$$\Sigma_{\text{crit}}(z_1, z_2) = \frac{c^2}{4\pi G} \frac{D_A(z_2)}{D_A(z_1; z_2) D_A(z_1)},$$

where $D_A(z_1), D_A(z_2)$, and $D_A(z_1; z_2)$ represent the observer–source, observer–lens and lens–source angular diameter distances, respectively. To keep the notation compact, we shall omit the dependence on $z_1, z_2$ and write the critical density simply as $\Sigma_{\text{crit}}$.

From our earlier discussion in Section 2.2, we see that an alternative way to compute the stacked tangential shear is through equation (15). In the Limber approximation and assuming once again that only matter associated with the lens galaxy creates the shear signal, we have

$$\langle \gamma_{t,a}(R, z_1, z_2) \rangle = \frac{\rho_m^0}{\Sigma_{\text{crit}}} \int \frac{d^2 k}{(2\pi)^2} p^m(k_{\perp}, z_1) J_2(k_{\perp} R). \quad (47)$$

We shall use equation (46) to compute the excess surface density both analytically and from the simulation data. For the theoretical predictions, we choose to compute $w_{gm}$ in the same way as we computed $w_{gg}$ in equation (42), only this time using $b_{gm}$ from equation (40). We prefer this approach to that offered by equation (47), because it allows us to obtain $\Delta \Sigma$ in the same way for both simulations and the theory. At larger $R$ this choice is unimportant; however, at smaller radii, owing to the fact that the radial binning does not start at $R = 0$, it plays a more important role and the results from equations (45) and (47) differ systematically.

The right-hand panel of Fig. 6 presents a comparison between the theoretical predictions and measurements of $\Delta \Sigma$ as a function of the transverse spatial scale $R$, for the four magnitude bins considered. The symbols correspond to the simulations and the lines to the theory predictions. On large scales, $R > 10 h^{-1}$ Mpc, we see that similar to $w_{gg}$, the shear amplitudes in the three faintest bins are comparable, whereas the brightest galaxies have a higher amplitude. On smaller scales, $R < 0.5 h^{-1}$ Mpc, we find a systematic trend: the brighter the galaxies, the larger the amplitude of the tangential shear profile. This finding is in accord with the GGL measurements from the SDSS by Mandelbaum et al. (2006a).

On closer inspection of the faintest luminosity bin, we see that it appears to have a somewhat broad, flat-tish shear profile, with a very slight second peak at $\sim 1 h^{-1}$ Mpc, and higher amplitude than the brighter bins (excepting the brightest bin) on intermediate scales $2 < R < 10 h^{-1}$ Mpc. This might be due to the increased relative abundance of satellite galaxies compared to centrals. The satellite galaxies are mainly hosted by high-mass haloes and have an average distance from the centre of the main halo that is roughly of the order of $\sim 0.5 h^{-1}$ Mpc, and so we expect that their tangential shear profiles receive two significant contributions: the first from the dark matter associated with their own subhalo; the second comes as the shear profile radius encompasses the central cusp of the main halo. This qualitatively explains the broadening of the profile of the faintest bin. We also note that the theory underpredicts the measurements more significantly than for $w_{gg}$. This can be attributed to the small-scale inaccuracies of HaloFit contributing to $w_{gm}(< R)$ at all radii.

6 RESULTS II: COVARIANCE MATRICES FROM THE MXXL

6.1 Covariance of the projected correlation function

In Fig. 7, we present the errors on the mean projected galaxy correlation function, divided through by the signal, as a function of the transverse scale $R$, and for the magnitude bins discussed previously. The blue pentagons in the figure represent the noise-to-signal ratio estimated directly from the $N = 216$ subcubes. The unbiased estimator of the mean and covariance is

$$\langle \bar{w}_{gg}(R_i) \rangle \equiv \frac{1}{N} \sum_{k=1}^{N} \bar{w}_{gg,k}(R_i), \quad (48)$$

$$\text{Cov}(\bar{w}_{gg}(R_i, R_j)) \equiv \frac{1}{N-1} \sum_{k=1}^{N} \left[ \bar{w}_{gg,k}(R_i) - \langle \bar{w}_{gg}(R_i) \rangle \right] \times \left[ \bar{w}_{gg,k}(R_j) - \langle \bar{w}_{gg}(R_j) \rangle \right], \quad (49)$$

where $\bar{w}_{gg,k}$ is the bin-averaged estimate of the projected correlation function from the $k$th subcube. The covariance and error on the mean are then simply obtained by further dividing the right-hand side of equation (49) by the number of subcubes $N$. The red triangles denote the predictions obtained from direct evaluation of equations (26) and (32), where we scaled the variance to the entire MXXL volume.

The theoretical predictions for the brightest galaxies agree extremely well with the measured errors. This owes to the fact that on large scales, $R > 10 h^{-1}$ Mpc, the errors are determined by the Gaussian part of the variance. On smaller scales, these objects are relatively sparse, and so the shot-noise contribution to the variance quickly dominates. Both of these two limits are well characterized by our formula.

For the fainter magnitude bins, there is reasonably good agreement between our model and the data on both large ($R > 10 h^{-1}$ Mpc) and small ($R < 0.1 h^{-1}$ Mpc) scales. The former is due to the prominence of Gaussian contributions on large scales, whereas the latter is due to the shot-noise dominance on small scales. However, on intermediate scales ($0.1 < R < 1 h^{-1}$ Mpc), the agreement is not so good, and we see that the data have errors roughly a factor of $\sim 2$ larger than the predictions. This is to be expected, since for these scales the non-Gaussian corrections (e.g. the connected part of the trispectrum and also the bispectrum), which we neglected in deriving equation (32), are significant and have the effect of increasing the errors.

To compare the off-diagonal elements of the predicted and measured covariance from equations (32) and (49), we choose to examine the correlation matrix. For any covariance matrix $C[X]$, the correlation matrix $r[X]$ can be defined as

$$r[X]_{ij} = \frac{C[X]_{ij}}{\sqrt{C[X]_{ii} C[X]_{jj}}}, \quad (50)$$

where the subscript $X$ is a place-holder for the statistic. The correlation matrix obeys the constraint $|r[X]_{ij}| \leq 1, \forall i,j.$

Fig. 8 shows four rows of the correlation matrix of $r[\bar{w}_{gg}]$ at radii $(R_i, R_j)$ as a function of $R_i$ and at fixed radius $R_j$. The fixed scales correspond roughly to $R_j = 0.04, 0.1, 1, 10 h^{-1}$ Mpc, and in each panel can be quickly determined by noting that $r[\bar{w}_{gg}](R_i = R_j) = 1$. From left to right, each column represents a magnitude bin.

There are some notable trends: when the fixed scale $R_i$ is large (bottom row of the figure), the neighbouring bins of the matrix are significantly correlated, and the strength of the correlations is $r[\bar{w}_{gg}] > 0.5$. There is a decrease in the correlation coefficient as one considers brighter magnitude bins. These findings are in good agreement with our Gaussian model. When the fixed scale is small ($R_i = 0.04$ Mpc), for the brighter galaxy bins there is virtually no evidence for bin-to-bin correlations. Again this is consistent with the predictions of our model, and is attributed to the fact that for so
Figure 7. The noise-to-signal for the projected galaxy correlation function. The red triangles represent the theory prediction, and the blue pentagons the simulation measurements.

Figure 8. The correlation matrix from equation (50) for the projected galaxy correlation function. From top to bottom, the rows present four scales: $R = 0.04, 0.1, 1, 10 \, h^{-1} \text{Mpc}$. From left to right, the columns depict the four magnitude bins, as indicated in each panel. The symbols are the same as in the previous figure.
few objects the shot-noise errors simply dominate. However, when we consider the intermediate scales (second and third rows of panels in the figure), the model predictions underestimate the bin-to-bin correlations that are exhibited by the data. We interpret this as a sign that the non-Gaussian contributions to the covariance matrix, which we have neglected in our model, are significant. For a more intuitive but less quantitative depiction of the GC correlation matrix, as well as the GGL one and their cross-correlation, we refer the reader to Figs 13–16.

6.2 Covariance of the stacked tangential shear

Fig. 9 presents the errors on the mean of the stacked tangential shear as a function of the transverse scale $R$. The blue pentagons in the figure represent the noise-to-signal ratio estimated directly from the 216 MXXL subcubes estimated through

$$\langle \widehat{\gamma}_{\perp}^2(R_i) \rangle = \frac{1}{\Sigma_{\text{tot}}} \frac{1}{N} \sum_{k=1}^{N} \Delta \Sigma_k(R_i),$$

$$(51)$$

$$\text{Cov}[\widehat{\gamma}_{\perp}^2(R_i, R_j)] = \frac{1}{\Sigma_{\text{tot}}} \frac{1}{N-1} \sum_{k=1}^{N} \left[ \Delta \Sigma_k(R_i) - \langle \Delta \Sigma_k(R_i) \rangle \right] \times \left[ \Delta \Sigma_k(R_j) - \langle \Delta \Sigma_k(R_j) \rangle \right],$$

$$(52)$$

where $\Delta \Sigma_k(R_i)$ is the estimate of the excess surface density from the $k$th subcube.

Let us now turn to the theoretical predictions. We note that equation (29) can be rewritten for $\Delta \Sigma$ at the lens redshift $z_l$ and using the Limber approximation as done in Section 3.2 and equation (47). In the following, we shall ignore the shape-noise contribution from equation (29), since the latter is not an issue for our measurements. What is an issue however, is that we determine the matter distribution from an $N$-body simulation of finite resolution, is the particle shot noise which accompanies $P_{nm}$. We therefore write the final expression for the measured bin-averaged covariance of the excess surface density as

$$\text{Cov} \left[ \Delta \Sigma \right] (R_i, R_j) = \frac{1}{A_s} \left( \frac{\rho_{\text{crit}}}{\bar{\rho}_p} \right)^2 \int \frac{d^2k}{(2\pi)^2} J_3(k_i R_i) J_3(k_j R_j)$$

$$\times \left\{ P_{nm}(k_i) + \frac{1}{\bar{\rho}_p} P_{gg}(k_i) + \frac{1}{\bar{\rho}_g} P_{gg}(k_i) \right\},$$

$$(53)$$

where all the power spectra are taken at redshift $z_l$; the transverse area of the survey $A_s$ was introduced in Section 3.2; $\bar{\rho}_p$ and $\bar{\rho}_g$ are the mean particle and galaxy densities in the simulation. The above covariance has dimension of $L^{-1}$, as expected.

The theory predictions of equation (53) are presented as the red triangles in Fig. 9. As in the case of $w_{gg}$, we see that the agreement between theory and measurements is good on large $(R > 10 \, h^{-1} \text{ Mpc})$ and small $(R < 0.1 \, h^{-1} \text{ Mpc})$ scales. However, on intermediate scales the theory underestimates the true errors. We also notice that the predictions are increasingly poor for the fainter galaxies. For the brightest galaxies, the discrepancy at $R \sim 1 \, h^{-1} \text{ Mpc}$ is roughly a factor of $\sim 2$, whereas for the faintest galaxies it is roughly $\sim 3$. Thus, compared to $w_{gg}$, the predictions for the stacked shear seem worse, even for the shot-noise-dominated brightest galaxies. This suggests that the non-Gaussian contributions to the variance are more important for the stacked tangential shear than for the projected correlation function. However, in a real shear survey, this discrepancy may not be so crucial, since the addition of the shape-noise term will certainly be a strong source of noise on small scales. In Appendix C, we present a theoretical estimation of the impact of shape noise on the GGL variance and correlation matrix.

Fig. 10 presents four rows of the correlation matrix of $\widehat{\gamma}_{\perp}$ at $\{R_i, R_j\}$ as a function of $R_i$, and for fixed $R_i$, with the covariance estimated according to equation (52). The measurements are represented in the figure as the blue pentagons. The theoretical predictions are obtained by evaluating equation (53), and are denoted by the red triangles. The general trends are similar to those found in Fig. 8: on small scales $(R_i = 0.04 \, h^{-1} \text{ Mpc}, i.e. the top row of the figure)$, the theory and measurements show weak bin-to-bin correlations and the measurements seem somewhat noisy. Qualitatively, they are consistent with uncorrelated noise. On large scales $(R_i = 10.0 \, h^{-1} \text{ Mpc}, i.e. the bottom row of the figure)$, the measurements show significant bin-to-bin correlations. However, the correlations appear to be somewhat weaker than was found for the projected correlation function for more distant bins. In addition, the Gaussian predictions of our model do not describe these correlations as well as in the case of $w_{gg}$. On intermediate scales, $1 < R_i < 10 \, h^{-1} \text{ Mpc}$, the correlations are significantly stronger for all magnitude bins than predicted by our theoretical model. Once again, this suggests that the tangential shear signal is significantly more non-Gaussian on these scales than the projected galaxy correlation function.

6.3 Cross-covariance of the projected correlation function and stacked tangential shear

In order to perform a joint likelihood analysis of the combination of the projected galaxy correlation function and the stacked tangential shear profile, one would start by writing the joint vector of measurements:

$$X^T = \left( \hat{w}_{gg}(R_1), \ldots, \hat{w}_{gg}(R_{\mathcal{N}}), \hat{\gamma}_{\perp}(R_{\mathcal{N}}), \hat{\gamma}_{\perp}(R_{\mathcal{N}}) \right),$$

$$(54)$$

where we have normalized the measurements by their diagonal errors, so as to obtain dimensionless numbers. $\mathcal{N}$ is the number of transverse radial bins. Assuming a Gaussian likelihood, the normalized data would then be written as

$$\log \mathcal{L}(X|\phi) \propto \sum_{i,j=1}^{\mathcal{N}} [X_i - \bar{X}_i(\phi)] r[X]_{ij}^{-1} [X_j - \bar{X}_j(\phi)],$$

$$(55)$$

where $\bar{X}_i(\phi)$ is the expectation of the theoretical model and $r[X]^{-1}$ is the inverse correlation matrix. The correlation matrix is built from four blocks:

$$r[X] = \begin{pmatrix} r[w_{gg}], r[\hat{w}_{gg}, \hat{\gamma}_{\perp}] & r[\hat{\gamma}_{\perp}, \hat{w}_{gg}] \end{pmatrix},$$

$$(56)$$

where the off-diagonal blocks are simply the transpose of one another. Again, we see that $|r| \leq 1$, i.e. the absolute value of the determinant must be less than unity, through the Cauchy–Schwarz inequality.

Figs 11 and 12 present four rows and columns through the off-diagonal block $r[\hat{w}_{gg}, \hat{\gamma}_{\perp}]$ of the full correlation matrix, respectively. Note that unlike the other block matrices, the off-diagonal block is not symmetric, hence the need to examine the columns as well as the rows. Just like before, the blue pentagons denote the measurements from the 216 MXXL subcubes. The cross-covariance was estimated.
Figure 9. The noise-to-signal for the stacked tangential shear. The red triangles represent the theory predictions, while the blue pentagons correspond to the simulation measurements.

Figure 10. The correlation matrix from equation (50) for the stacked tangential shear. Just like in Fig. 8, the rows present four scales: $R_t = 0.04, 0.1, 1, 10\, h^{-1}\,\text{Mpc}$. From left to right, the columns depict results for increasingly fainter galaxies, as indicated in each panel.
Figure 11. The cross-correlation matrix of the projected galaxy correlation function and the stacked tangential shear. As in Figs 8 and 10, the rows present four scales: $R_i = 0.04, 0.1, 1, 10$ $h^{-1} \text{Mpc}$. From left to right, the columns depict the galaxy bins with decreasing brightness.

Figure 12. The cross-correlation matrix of the projected galaxy correlation function and the stacked tangential shear, this time fixing $R_j = 0.04, 0.1, 1, 10$ $h^{-1} \text{Mpc}$. From left to right, the columns depict the galaxy bins with decreasing brightness.
similarly to equations (49) and (52):
\[
\text{Cov} \left[ \tilde{w}_{gg}, \tilde{\gamma}_\perp \right] (R_1, R_j) \equiv \frac{1}{\sum_{i=1}^{N} \tilde{w}_{gg,i}(R_i)} \sum_{k=1}^{N} \left[ \tilde{w}_{gg,k}(R_k) - \langle \tilde{w}_{gg}(R) \rangle \right] \\
\times \left[ \tilde{\Delta \Sigma}_{\perp,i}(R_k) - \langle \tilde{\Delta \Sigma}_{\perp}(R) \rangle \right].
\]
Owing to the fact that we use the excess surface mass density as a proxy for tangential shear, we may rewrite equation (34) as
\[
\text{Cov} \left[ \tilde{w}_{gg}(R), \tilde{\Delta \Sigma}_{\perp}(R) \right] = \frac{2\rho_\text{crit}}{A_\text{s}} \int \frac{d^3k}{(2\pi)^3} T_0(k, R) T_\perp(k, R) \\
\times \mathcal{P}(k, \perp) \left[ \mathcal{P}_{gg}(k, \perp) + \frac{1}{n_g} \right].
\]
The theoretical predictions from this expression are presented in Figs 11 and 12 as the red triangles.

On small scales ($R < 0.1 \ h^{-1} \ Mpc$, i.e. the top row of the figures), we see that for all of the magnitude bins considered, the cross-correlation coefficient is small ($r < 0.2$), and reasonably consistent with the theoretical predictions from equation (58). On large scales ($R \sim 10 \ h^{-1} \ Mpc$, i.e. the bottom row in the figures), the cross-correlation coefficient is larger, with $r \sim 0.8$ for some of the bins. Also, the theoretical predictions are qualitatively in agreement, although the measurements do show a stronger degree of correlation. On intermediate scales (the middle two rows), the measurements show stronger bin-to-bin correlations than predicted by the theory. These correlations on intermediate to large scales are important to include in any joint likelihood analysis of GC and GGL. Otherwise, the likelihood search may lead to biased and overoptimistic parameter constraints.

6.4 Testing the jackknife method to estimate covariances

We now want to see how the correlation matrices estimated from the entire MXXL data compare to those evaluated through the jackknife method.

We pick one of the subcubes of the simulation, and generate 64 jackknife samples by removing a region of the subcube and estimating the projected correlation functions from the remaining data. The regions that are removed are in the shape of a rectangular parallelepiped, with the long side aligned with the $\hat{x}$ direction of the subcube, i.e. the projection direction, and the shorter sides describing a square in the $\hat{x} - \hat{y}$ plane. The latter is obtained by dividing the subcube side into eight equal segments along both $\hat{x}$ and $\hat{y}$ directions, resulting in 64 adjacent squares. Thus, the dimensions of each parallelepiped are $62.5 \times 62.5 \times 500 [h^{-1} \ Mpc]^3$.

The rest of the calculations follow the same path as detailed in Section 5.1. Each jackknife sample requires its own random catalogue. Just as before, the galaxies and dark matter particles are subsampled 32 times, in order to reduce the shot noise and the parameter describing the relative density of the simulation and random data. The resulting correlation functions are the average of the 32 subsample measurements. Once the projected correlation functions and excess surface density are computed for each jackknife sample, we combine them to estimate the covariance matrices for $\Delta \Sigma$ and $w_{gg}$:
\[
\text{Cov} \left[ \tilde{X}, \tilde{Y} \right] (R_1, R_j) = \frac{N_{\text{samp}}}{N_{\text{samp}}} \sum_{k=1}^{N_{\text{samp}}} \left[ \tilde{X}_k(R_k) - \langle \tilde{X}(R) \rangle \right] \\
\times \left[ \tilde{Y}_k(R_k) - \langle \tilde{Y}(R) \rangle \right] ,
\]
where $N_{\text{samp}} = 64$; $X$ and $Y$ stand for $w_{gg}$ and $\Delta \Sigma$, and the mean is the average of the jackknife samples:
\[
\langle \tilde{X}(R) \rangle = \frac{N_{\text{samp}}}{N_{\text{samp}}} \sum_{k=1}^{N_{\text{samp}}} \tilde{X}_k(R).
\]
In Fig. 13, we present a comparison between our original measurement of the correlation matrix of $w_{gg}$ and the one obtained through jackknife resamplings, for the four magnitude bins that we have considered. In each panel, the upper-right half depicts the original correlation matrix, while the lower left shows the jackknife result. The agreement is remarkable, with the jackknife result being slightly noisier than the full one. Similarly, Fig. 14 shows the same comparison for the excess surface density. Figs 15 and 16 present the original and jackknife cross-correlation matrices, respectively.

In all figures the jackknife result appears a little more correlated than the original measurement, but in general the agreement is surprising. Although not shown, we have also compared the variance for $w_{gg}$ and $\Delta \Sigma$: the findings were very similar, with the jackknife variance being a little noisier, but essentially matching the original measurement rather well.

7 CONCLUSIONS

In this paper, we have explored the required ingredients for performing a joint likelihood analysis of GC and GGL. The combination of these probes has the potential to enable simultaneous constraints of the cosmological and galaxy formation model parameters.

In Section 2, we developed an analytic framework to predict the projected correlation function and the stacked tangential shears of a population of galaxies. We provided both exact and Limber-approximated expressions for the observables in the flat-sky limit. In Appendix A, we presented the full derivations of the auto- and cross-covariance matrices. In Section 3, we summarized the results for the case where the underlying density fluctuations are Gaussian and modulated by a shot-noise contribution. The two necessary ingredients for the results of Sections 2 and 3 are the galaxy–galaxy and galaxy–matter power spectra or alternatively a model for the bias defined by equations (39) and (40).

The theoretical predictions of the models were then tested against measurements from numerical simulations of structure formation. In Section 4, we provided a brief overview of the MXXL simulation. The galaxy catalogues were generated using the Garching SAM of galaxy formation, which enabled us to compute the $u, g, r, i, z$ SDSS absolute magnitudes. As a diagnostic of the SAM galaxies we presented the evolution of the GLF for the five bands. We also explored certain properties of the galaxies as a function of absolute $r$-band magnitude ($M_r$), allowing us to understand the impact of the finite mass resolution of the MXXL simulation on the derived galaxy properties. Through detailed comparison with the Millennium simulation, we determined that resolution effects were qualitatively important only for magnitudes fainter than $M_r > -19$.

In Section 5, we described our methods for estimating the projected correlations from the MXXL. This required the implementation of fast and efficient algorithms, since the dark matter distribution was represented by over 300 billion dark matter particles and the galaxy catalogue contained more than a billion objects. We thus developed a parallel k-D tree algorithm for computing the correlation functions of the subsampled matter and galaxy distributions.

We split the galaxy catalogues into four subsamples based on their $M_r$, with the constraint that $M_r < -19$. We also sliced the
Figure 13. The correlation matrix of $w_{gg}$ for the four magnitude bins considered. The upper-right triangle of the matrix represents the correlation matrix measured from the whole simulation, i.e. the same as in Fig. 8. The lower-left triangle is the correlation matrix obtained from jackknife samplings of one of the subcubes of the simulation.

dark matter and galaxy catalogues into a series of 216 subcubes of volume $500h^{-3}\text{Mpc}^3$. As a step towards modelling the GC and GGL signals, we examined the projected galaxy–galaxy and galaxy–galaxy mass correlation functions using the estimator proposed by Landy & Szalay (1993). We also computed the bias coefficients as a function of scale from these statistics. We found that on large scales, $R > 10h^{-1}\text{Mpc}$, the bias was consistent with being linear and deterministic. On smaller scales, the bias possessed a complex scale dependence, which varied with the magnitude bin through the larger number of satellites and their spatial distribution, as well as the decreasing host mass for the centrals in the fainter bins. We also found that the cross-correlation coefficient was significantly greater than unity on small scales. This could be explained as a consequence of an exclusion effect – no two galaxies may be closer than the sum of their respective virial radii.

We next computed the excess surface mass density $\Delta \Sigma$, which is directly proportional to the tangential shear, and the projected galaxy correlation function for each of the magnitude bins and for each of the 216 subcubes. These were compared to the theoretical predictions in the Limber approximation. The evaluation of the theory required a model for the non-linear matter power spectrum and the scale dependence of the bias. For the former, we used the HALOFIT code (Smith et al. 2003), and for the latter we took directly the measured bias. We found that on small scales the theory underpredicted the measurements by $\lesssim 20$ per cent for $w_{gg}$ and by $\lesssim 30$ per cent for $\Delta \Sigma$. This was attributed to the diminished accuracy of HALOFIT on small scales. Both functions displayed complicated features for galaxies in the faintest magnitude bin $M_r > -20$. This was again attributed to the increased abundance of satellite galaxies.

In Section 6, we used the measured estimates of $w_{gg}$ and $\Delta \Sigma$ from the subcubes to construct the auto- and cross-covariance matrices. We found that on large and small scales the errors were reasonably well described by the Gaussian plus shot-noise model. However, on intermediate scales, $0.1 < R < 10h^{-1}\text{Mpc}$, the measured errors were significantly larger by a factor of $\sim 2-3$. This suggests that in order to accurately model the covariance matrix one needs to take account of the non-Gaussian contributions from the bi- and trispectrum. Note that in the case of GGL, the presence of shape noise does alleviate some of the non-Gaussianities on intermediate scales, as shown in Appendix C.

Finally, we compared the auto- and cross-covariances obtained from the jackknife samplings of one of the subcubes of MXXL with the full simulation covariances. We concluded that the jackknife method is remarkably effective, for both auto- and cross-covariances.

Importantly, we found that the cross-covariance between $w_{gg}$ and $\Delta \Sigma$ was not zero. The elements of the cross-covariance matrix showed significant bin-to-bin correlations with $r \sim 0.8$ for some elements on large scales. This result is important, since in a number of previous analyses we neglected the cross-correlation of GC and GGL. Our results suggest that if these correlations are ignored, then a standard likelihood analysis would lead to biased and overoptimistic constraints on the parameters of the models.

In the future, more work will be required to establish an accurate model of the GC and GGL signals on scales $R < 5h^{-1}\text{Mpc}$. We note that, whilst the SAM model of galaxy formation is not to be taken as an exact replica of reality, it nevertheless captures many of the effects that we expect to have to model when constraining model parameters with real data. It will also be important to determine how well the combination of GC and GGL can actually break the degeneracies between the galaxy formation and cosmological parameters. We shall aim to explore this in a future paper. In the meantime, we note that Eifler et al. (2014) have explored clustering and lensing probe combinations and have included additional non-Gaussian terms in the modelling of the covariances. However, they have assumed a rather simplistic modelling of the galaxy bias, which we showed here is not the case. This leads us to suspect that their results will be somewhat overoptimistic.

Another possibility is the exploration of the $\gamma$ statistic (Baldauf et al. 2010; Mandelbaum et al. 2013), which was developed to remove the complicated scale dependences of the bias. However, what is not clear is whether the $\gamma$ statistic in combination with GC can provide constraints on both the cosmological and galaxy formation model that are competitive with the standard statistics. We leave this for future work.

ACKNOWLEDGEMENTS

The authors would like thank Simon White, Eiichiro Komatsu, Peter Schneider and Gary Bernstein for useful discussions, Bruno Henriques for providing the Millennium simulation galaxy catalogue used in Fig. B1. They are also grateful to Volker Springel, Adrian Jenkins, Carlos Frenk and Carlton Baugh for their contribution to the MXXL simulation used in this study. The MXXL was carried out on Juropa at the Jülich Supercomputer Centre in Germany. LM thanks MPA for its kind hospitality while this work was being performed. LM was supported by the DFG through the grant MA 4967/1-2. RES acknowledges support from ERC Advanced Grant 246797 GALFORMOD.

APPENDIX A: DERIVATION OF THE AUTO- AND CROSS-COVARIANCE MATRICES

A1 Derivation of the covariance matrix of stacked tangential shear

To simplify the notation, from now on we shall consider that all 2D integrals are implicitly done on the survey area $\Omega$, without explicitly stating so in every case.

Using equation (11) we write

$$\langle \tilde{\gamma}_i(t_1)\tilde{\gamma}_j(t_2) \rangle = \frac{1}{N_t^2} \int d^2x \int d^2y \sum_{i,j=1}^{N_t} \left[ \frac{\delta_D(x-x_i)\delta_D(y-y_j)}{\Omega} \right] \langle \gamma_i(t_1;x)\gamma_j(t_2;y) \rangle$$

$$= \frac{1}{N_t^2} \left[ \int d^2x \int d^2y \langle n_x(x)\gamma_i(t_1;x)\gamma_j(t_2;y) \rangle + \int d^2x \int d^2y \langle n_y(y)\gamma_i(t_1;x)\gamma_j(t_2;y) \rangle \right] . \tag{A1}$$

In the above double sum, the special case where $i=j$ gives rise to the three-point function $\langle n_x(x)\gamma_i(t_1;x)\gamma_j(t_2;x) \rangle = \bar{n}_i \langle \gamma_i(x+\theta;x)\gamma_i(x+\theta;x) \rangle$. Similarly, the case where $i \neq j$ yields a four-point function which can be expressed as $\langle n_x(x) n_y(y) \gamma_i(x+\theta;x) \gamma_j(y+\theta;y) \rangle = \bar{n}_i \bar{n}_j \langle \gamma_i(x+\theta;x)\gamma_j(y+\theta;y) \rangle$. Since this work assumes the Gaussianity of all cosmological fields, we ignore their odd-point functions, as well as the connected functions. After decomposing the four-point function in the above relation into products of two-point functions, in accordance with Wick’s theorem, we write equation (A1) as

$$\langle \tilde{\gamma}_i^2(t_1)\tilde{\gamma}_j(t_2) \rangle = \frac{1}{\Omega^2} \left[ \bar{n}_i \int d^2x \int d^2y \langle \gamma_i(x+\theta;x)\gamma_i(x+\theta;y) \rangle + \bar{n}_j \int d^2x \int d^2y \langle \gamma_j(x+\theta;x)\gamma_j(x+\theta;y) \rangle \right]$$

$$+ \langle \delta_i(x)\delta_i(y) \rangle \left[ \langle \gamma_i(x+\theta;x)\gamma_j(y+\theta;y) \rangle + \langle \delta_i(x)\gamma_i(y+\theta;y) \rangle \right]$$

$$+ \langle \delta_j(x)\gamma_j(y+y+\theta;y) \rangle \left[ \langle \delta_j(x)\gamma_j(x+\theta;x) \rangle \right] . \tag{A2}$$

We now proceed to the computation of each of the five terms in equation (A2), omitting for now the inverse square of the survey area that multiplies the whole covariance. Our final goal is to fact the azimuthal average of the covariance in equation (27). We first introduce the shape-noise contribution to the covariance of the tangential shear at $\theta_1, \theta_2$ with respect to the origins $\theta_{01}, \theta_{02}$:

$$\langle \gamma_i(\theta_1;\theta_{02})\gamma_j(\theta_2;\theta_{01}) \rangle = \frac{\sigma_s^2}{2\bar{n}_s} \cos[2(\phi_{\theta_1-\theta_{01}} - \phi_{\theta_2-\theta_{02}})] \delta_D(\theta_1 - \theta_2), \tag{A3}$$
where we defined \( \sigma_\gamma^2/2 = \sigma_\gamma^2 = \sigma_\gamma^2 \) as the variance per shear component in the measurement of one source galaxy. We assume the source galaxies to have a mean angular density of \( \bar{n}_s \). In the above, we also assumed that the shape noise does not correlate different positions in the source plane, i.e. we ignore for example the effect of intrinsic alignments which might introduce precisely such correlations.

Starting with the first term, we employ equation (6) to write

\[
T_1(\theta_1, \theta_2) = \frac{1}{n_s} \int d^2x \langle \gamma_1(x + \theta_1; x) \gamma_1(x + \theta_2; x) \rangle = \frac{\Omega_s}{n_s} \left\{ \int \frac{d^2l}{(2\pi)^2} C_{\delta D}(l) C_{\gamma \gamma}(l) + \frac{\sigma_\gamma^2}{2\pi} \delta_\theta(\theta_1 - \theta_2) \right\}.
\]

Writing that \( \delta_\theta(\theta_1 - \theta_2) = \delta_\theta(\theta_1 - \theta_2) \delta_\theta(\phi_{\theta_1} - \phi_{\theta_2})/\bar{n}_s \), we compute the azimuthal average of the above equation using equations (7) and (9). Thus, the first term of the covariance of the stacked shear estimator is

\[
T_{1,\omega}(\theta_1, \theta_2) = \int_0^{2\pi} d\phi_{\theta_1} d\phi_{\theta_2} T_1(\theta_1, \theta_2) = \frac{\Omega_s}{n_s} \int \frac{d^2l}{(2\pi)^2} \left[ C_{\gamma \gamma}(l) + \frac{\sigma_\gamma^2}{2\pi} \right] J_2(l_1) J_2(l_2).
\]

where we have put the shape-noise term in a similar form to the rest of the first term by using the Bessel identity:

\[
\delta_\theta(\theta_1 - \theta_2) = \int \frac{d^2l}{(2\pi)^2} J_2(l_1) J_2(l_2).
\]

The second term of the covariance matrix is a constant, equal in fact to 0. This can be seen through a simple change of variables: \( x' = x + \theta_1 \) and \( y' = y + \theta_2 \) which leaves the Jacobian unchanged, \( d^2x' = d^2x, d^2y' = d^2y \). Relabelling \( x' = x \) and \( y' = y \), we write

\[
T_2(\theta_1, \theta_2) = \int d^2x d^2y \langle \gamma_1(x + \theta_1; x) \gamma_1(y + \theta_2; y) \rangle = \int d^2x \int d^2y \langle \gamma_1(x; x - \theta_1) \gamma_1(y; y - \theta_2) \rangle = 0.
\]

In the above, we have used the ergodic theorem and implicitly assumed that the survey area is sufficiently large so that the tangential shear integrated over it behaves like the ensemble average of the tangential shear, and is therefore equal to 0.

We now turn our attention to the calculation of the third term of equation (A2), henceforth denoted as \( T_3 \):

\[
T_3(\theta_1, \theta_2) = \int d^2x d^2y \langle \delta_\theta(x) \delta_\theta(y) \rangle \langle \gamma_1(x + \theta_1; x) \gamma_1(y + \theta_2; y) \rangle.
\]

Using the invariance under translation due to the homogeneity of the Universe, we have that \( \langle \delta_\theta(x) \delta_\theta(y) \rangle = \langle \delta_\theta(x - y) \delta_\theta(0) \rangle \), and \( \langle \gamma_1(x + \theta_1; x) \gamma_1(y + \theta_2; y) \rangle = \langle \gamma_1(x - y + \theta_1; x - y) \gamma_1(y + \theta_2; 0) \rangle \). Changing variables \( x' = x - y \) and relabelling \( x' = x \), we write

\[
T_3(\theta_1, \theta_2) = \Omega_s \int d^2x \langle \delta_\theta(x) \delta_\theta(0) \rangle \langle \gamma_1(x + \theta_1; x) \gamma_1(x + \theta_1; 0) \rangle.
\]

Note that \( T_3 \) also has a contribution from shape noise, which we address below. We shall evaluate equation (A7) in Fourier space. The Fourier transforms of the shear and galaxy density fluctuations are written as four integrals over the wavevectors which can be reduced to two integrals, by using the definitions of the convergence and galaxy power spectra in equation (13):

\[
T_3(\theta_1, \theta_2) = \Omega_s \int \frac{d^2l_1}{(2\pi)^2} \frac{d^2l_2}{(2\pi)^2} C_{\delta D}(l_1) C_{\gamma \gamma}(l_2) e^{i l_1 \cdot (\theta_1 - \theta_2)} \cos[2(\phi_{\theta_1} - \phi_{\theta_2})] \cos[2(\phi_{\theta_1} - \phi_{\theta_2})] \int d^2x e^{i l_1 \cdot (\theta_1 - \theta_2)}
\]

\[
+ \frac{\sigma_\gamma^2}{2\pi} \int d^2x \langle \delta_\theta(x) \delta_\theta(0) \rangle \cos[2(\phi_{\theta_1} - \phi_{\theta_2})] \delta_\theta(x + \theta_1 - \theta_2)
\]

\[
= \Omega_s \int \frac{d^2l}{(2\pi)^2} C_{\delta D}(l) C_{\gamma \gamma}(l) e^{i l \cdot (\theta_1 - \theta_2)} \cos[2(\phi_{\theta_1} - \phi_{\theta_2})] \cos[2(\phi_{\theta_1} - \phi_{\theta_2})]
\]

\[
+ \frac{\sigma_\gamma^2}{2\pi} \int \frac{d^2l}{(2\pi)^2} C_{\delta D}(l) e^{i l \cdot (\theta_1 - \theta_2)} \cos[2(\phi_{\theta_1} - \phi_{\theta_2})].
\]
We now calculate the azimuthal average of this term, using just as before equation (9). For the shape-noise term, we also change variables to \( \phi_{\theta_1} = \phi_{\theta_2} - \phi_1 \):

\[
T_{3,a}(\theta_1, \theta_2) = \int_0^{2\pi} \int_0^{2\pi} d\phi_{\theta_1}d\phi_{\theta_2} T_{3}(\theta_1, \theta_2) = \Omega_1 \left\{ \int \frac{d^2l}{(2\pi)^2} C_{gg}(l) C_{\kappa\kappa}(l) J_2(l\theta_1) J_2(l\theta_2) \right. \\
\left. + \frac{\sigma_g^2}{2\pi} \int \frac{d^2l}{(2\pi)^2} C_{gg}(l) \int \int d\phi_{\theta_1}d\phi_{\theta_2} e^{i(l\theta_1 \cos(\phi_{\theta_1}) - l\theta_2 \cos(\phi_{\theta_2}))} \cos[2(\phi_{\theta_1} - \phi_{\theta_2})] \right\} \\
= \Omega_1 \left\{ \int \frac{d^2l}{(2\pi)^2} C_{gg}(l) \left[ C_{\kappa\kappa}(l) + \frac{\sigma_g^2}{2\pi} \right] J_2(l\theta_1) J_2(l\theta_2) \right\}. \quad (A9)
\]

Moving on to the fourth term of equation (A2), we take advantage of the homogeneity of the Universe and of equation (14) to write:

\[
T_4(\theta_1, \theta_2) = \int d^3x d^3y \left\langle \delta_g(x) \gamma_l(x + \theta_1; x) \right\rangle \left\langle \delta_g(y) \gamma_l(y + \theta_2; y) \right\rangle = \Omega_1^2 \left\langle \delta_g(0) \gamma_l(\theta_1; 0) \right\rangle \left\langle \delta_g(0) \gamma_l(\theta_2; 0) \right\rangle = \Omega_1^2 \left\langle \tilde{\gamma}_l^{\gamma}(\theta_1) \right\rangle \left\langle \tilde{\gamma}_l^{\gamma}(\theta_2) \right\rangle. \quad (A10)
\]

Note how this fourth term exactly cancels the second one of the covariance in equation (27), once we remember the factor of \(1/\Omega_1^2\) that we deliberately left out.

Proceeding to the fifth term, we once again use the invariance under translation due to the inhomogeneity of the Universe to write:

\[
\left\langle \delta_g(x) \gamma_l(x + \theta_2; y) \right\rangle = \left\langle \delta_g(x - y) \gamma_l(\theta_2; 0) \right\rangle, \quad \text{and} \quad \left\langle \delta_g(y) \gamma_l(x + \theta_1; x) \right\rangle = \left\langle \delta_g(y - x) \gamma_l(\theta_1; 0) \right\rangle.
\]

Making the change of variables \( x' = x - y \) to eliminate one of the surface-area integrals on the right-hand side, and relabelling \( x' = x \), we obtain:

\[
T_5(\theta_1, \theta_2) = \int d^3x d^3y \left\langle \delta_g(x) \gamma_l(x + \theta_2; y) \right\rangle \left\langle \delta_g(x') \gamma_l(\theta_1; 0) \right\rangle = \Omega_1 \int d^3x \left\langle \delta_g(x) \gamma_l(\theta_2; 0) \right\rangle \left\langle \delta_g(-x) \gamma_l(\theta_1; 0) \right\rangle. \quad (A11)
\]

Using equations (6) and (13), we can further write:

\[
T_5(\theta_1, \theta_2) = \Omega_1 \int d^3l \left( C_{gg}(l) \cos[2(\phi_{\theta_1} - \phi_1)] \cos[2(\phi_{\theta_2} - \phi_2)] \right) e^{i(l\theta_1 + \theta_2)}. \quad (A12)
\]

The azimuthal average of this expression can be obtained with the help of equation (9):

\[
T_{3,\omega}(\theta_1, \theta_2) = \int_0^{2\pi} \int_0^{2\pi} d\phi_{\theta_1}d\phi_{\theta_2} T_{5}(\theta_1, \theta_2) = \Omega_1 \int d^3l \left( C_{gg}(l) \right) J_2(l\theta_1) J_2(l\theta_2). \quad (A13)
\]

Finally, putting together all the terms in equations (A4), (A5), (A9), (A10) and (A13), as well as the factor \(1/\Omega_1^2\) that we left out earlier, we reexpress equation (A2) as:

\[
\text{Cov}[\tilde{\gamma}_l^{\gamma}](\theta_1, \theta_2) = \frac{1}{\Omega_1} \int_0^{\infty} d^3l \left( C_{gg}(l) \right) J_2(l\theta_1) J_2(l\theta_2) \left\{ \left[ C_{\kappa\kappa}(l) + \frac{\sigma_g^2}{2\pi} \right] + C_{\kappa\kappa}(l) \right\}. \quad (A14)
\]

This equation concludes the theoretical predictions for the stacked tangential shear estimator and its covariance.

### A2 Derivation of the covariance matrix of the 3D galaxy correlation function

We define a general estimator for the galaxy overdensity field with respect to a random galaxy catalogue as:

\[
\hat{F}_g(x) = \frac{w(x)}{A} [n_g(x) - \alpha n_R(x)],
\]

where \( n_g(x) \) is the galaxy number density field; \( w(x) \) is a weight function; \( n_R(x) \) is the number density of a mock galaxy catalogue, used to compute any excess correlation in our data set; \( \alpha \) quantifies how dense the random catalogue is compared to the galaxy data, i.e. the smaller \( \alpha \), the better the estimator:

\[
\alpha = \frac{\langle n_g(x) \rangle}{\langle n_R(x) \rangle} \approx \frac{\int d^3x \hat{n}_g(x)}{\int d^3x \hat{n}_R(x)}.
\]

In the above, the mean density of galaxies can vary across the survey, if the survey is a small volume-limited one or simply flux limited. Note that the above definition of \( \alpha \) ensures that the density fluctuation estimator is unbiased, i.e. \( \langle F_g(x) \rangle = 0 \). Finally, the normalization constant is:

\[
A = \int d^3x \hat{n}_R(x)w^2(x). \quad (A16)
\]

This estimator for the galaxy overdensity field has been reviewed in the recent work of Smith & Marian (2014), who showed that the galaxy correlation function is related to the covariance of the galaxy overdensity field estimator:

\[
\langle \hat{F}_g(x_1)\hat{F}_g(x_2) \rangle = \frac{w(x_1)w(x_2)\hat{n}_g(x_1)\hat{n}_g(x_2)}{A} \left[ \xi_{gg}(x_1, x_2) + \frac{(1 + \alpha)}{\hat{n}_g(x_2)} \delta_D(x_1 - x_2) \right]. \quad (A17)
\]

MNRAS 451, 1418–1444 (2015)
In the following, we shall assume that (i) our survey is volume limited and large enough so that the galaxy number density field has constant mean density; (ii) the random catalogue also has constant mean density; (iii) the weights are constant and equal to 1. Whilst this means that our estimator is sub-optimal in terms of maximizing the signal-to-noise for the galaxy correlation function, it is perfectly adequate for the purpose of this work. Under these assumptions, we define the estimator for the galaxy correlation function as

$$\hat{\xi}_{gg}(x) = \int d^3 y \hat{F}_g(y) \hat{F}_g(x+y) \quad \text{with} \quad x \neq 0,$$  \hspace{1cm} (A18)

where we ignore the 0-lag correlation, affected by a shot-noise term as seen in equation (A17). The reason for this is that our measurements from numerical simulations will not contain the 0-lag contribution. The normalization constant also has the simple expression $A = \bar{n}^2 V$, where $V$ is the survey volume. The estimator is unitless, and in the limit that the survey volume is large, it is also unbiased. Its covariance is given by

$$\text{Cov}[\xi_{gg}(r_1, r_2)] = \int d^3 x d^3 y \left\langle \hat{F}_g(x) \hat{F}_g(x+r_1) \hat{F}_g(y) \hat{F}_g(y+r_2) \right\rangle - \left\langle \hat{F}_g(x) \hat{F}_g(x+r_1) \right\rangle \left\langle \hat{F}_g(y) \hat{F}_g(y+r_2) \right\rangle.$$  \hspace{1cm} (A19)

To shorten the notation, we shall denote any function $g(x_i) \equiv g_i, g(x_i, x_j) \equiv g_{ij}, g(x_i, x_j, x_k) \equiv g_{ijk}$ and so on. We shall also temporarily drop the subscript $g$ from ‘galaxy’ in the correlation functions. The above covariance requires us to compute the four-point function $(\hat{F}_1 \hat{F}_2 \hat{F}_3 \hat{F}_4)$. Since the details for this calculation are fully explained in Smith & Marian (2014), here we just write directly the result, retaining the weights and varying mean densities for the moment in order to preserve the generality of the calculation. For the same reason, we also retain some terms originating in the 0-lag correlations, and drop them later:

$$\left\langle \hat{F}_1 \hat{F}_2 \hat{F}_3 \hat{F}_4 \right\rangle = \frac{\prod_{i=1}^4 (w_i \bar{n}_i)}{A^2} \left\{ \xi_{1234} + \frac{\xi_{123}}{\bar{n}_4} \left( \delta_D^{14} + \delta_D^{24} + \delta_D^{34} \right) + \frac{\xi_{124}}{\bar{n}_3} \left( \delta_D^{13} + \delta_D^{23} + \delta_D^{24} \delta_D^{34} \right) + \frac{\xi_{134}}{\bar{n}_2} \delta_D^{13} + \frac{\xi_{12} \bar{n}_4}{\bar{n}_3} \left( \delta_D^{14} + \delta_D^{24} + \delta_D^{34} \right) + \frac{\xi_{14} \bar{n}_3}{\bar{n}_2} \delta_D^{14} + \left(1 + \alpha \right) \delta_D^{12} \right\}.$$  \hspace{1cm} (A20)

We also need the ingredient $\left\langle \hat{F}_1 \hat{F}_2 \hat{F}_3 \hat{F}_4 \right\rangle$ which is shown in Smith & Marian (2014) to be

$$\left\langle \hat{F}_1 \hat{F}_2 \hat{F}_3 \hat{F}_4 \right\rangle = \frac{\prod_{i=1}^4 (w_i \bar{n}_i)}{A^2} \left\{ \xi_{1234} + \frac{1 + \alpha}{\bar{n}_2} \xi_{14} \delta_D^{14} + \frac{1 + \alpha}{\bar{n}_4} \xi_{12} \delta_D^{12} + \frac{1 + \alpha^2}{\bar{n}_2 \bar{n}_4} \delta_D^{12} \right\}.$$  \hspace{1cm} (A21)

Putting together equations (A20) and (A21) and rearranging the terms, we write

$$\left\langle \hat{F}_1 \hat{F}_2 \hat{F}_3 \hat{F}_4 \right\rangle - \left\langle \hat{F}_1 \hat{F}_2 \hat{F}_3 \hat{F}_4 \right\rangle = \frac{\prod_{i=1}^4 (w_i \bar{n}_i)}{A^2} \left\{ \left( \delta_D^{14} + \delta_D^{24} + \delta_D^{34} \right) + \frac{1 + \alpha}{\bar{n}_2} \xi_{14} \delta_D^{14} + \frac{1 + \alpha}{\bar{n}_4} \xi_{12} \delta_D^{12} + \frac{1 + \alpha^2}{\bar{n}_2 \bar{n}_4} \delta_D^{12} \right\}.$$  \hspace{1cm} (A22)

Just as in the case of the stacked tangential shear of galaxies from the previous section, here too we work under the assumption of Gaussianity of the galaxy density field. In the above equation, the first term in round brackets on the right-hand side vanishes under this assumption, i.e. we ignore the connected four-point correlation function, as well as the three-point functions of the galaxy density field. We shall also ignore all terms with contributions from the 0-lag correlations, e.g. terms containing $\delta_D^{12}$ and $\delta_D^{34}$, and also contributions from the bin containing the value $r = 0$, e.g. the terms with the products $\delta_D^{14} \delta_D^{23}$ and $\delta_D^{13} \delta_D^{24}$. The reason for the latter is that the binning of the simulation data starts from values larger than 0.

To write down the covariance for the estimator defined by equation (A18), we set $\bar{n}_i = \bar{n}_g, w_i = 1, \quad (i = 1, 2, 3, 4)$, and we combine equations (A19) and (A22) discarding all the above-mentioned terms:

$$\text{Cov}[\xi_{gg}(r_1, r_2)] = \int d^3 x d^3 y \left\{ \xi_{gg}(x, y) \left[ \frac{1 + \alpha}{\bar{n}_g} \delta_D(x-y) \right] + \frac{\xi_{gg}(x, y + r_2) + 1 + \alpha}{\bar{n}_g} \delta_D(x-r_1 - y + r_2) \right\}.$$  \hspace{1cm} (A23)
where we have used the homogeneity of the Universe to write $\xi_{gg}(\mathbf{r}_1, \mathbf{r}_2) = \xi_{gg}(r_1 - r_2)$. A little further manipulation of the above equation gives us the expression for the covariance of the galaxy correlation function estimator in equation (A18):

$$\text{Cov}[\hat{\xi}_{gg}] (\mathbf{r}_1, \mathbf{r}_2) = \frac{1}{N_g} \left\{ \int d^3x \left[ \hat{\xi}_{gg}(\mathbf{x}, \mathbf{x} + \mathbf{r}_1 - \mathbf{r}_2) + \hat{\xi}_{gg}(\mathbf{x}, \mathbf{x} + \mathbf{r}_1) \hat{\xi}_{gg}(\mathbf{x}, \mathbf{r}_2 - \mathbf{r}_1) \right] + \frac{2(1 + \alpha)}{R_g} \left[ \hat{\xi}_{gg}(\mathbf{r}_1 + \mathbf{r}_2) + \hat{\xi}_{gg}(\mathbf{r}_1 - \mathbf{r}_2) \right] \right\}.
$$

(A24)

Note that this expression is in accord with the work of Smith (2009), with the lag-0 and bin-0 contributions excluded.

Just like in the previous section on stacked tangential shear, we are actually interested in the azimuthally averaged covariance. To obtain the azimuthal average, we shall work in cylindrical coordinates, suitable to the projected correlation functions discussed in Section 2.3. Writing $\delta_D(\mathbf{r}_1 - \mathbf{r}_2) = \frac{2i\nu}{R_g} \delta_D(\chi_1 - \chi_2)\delta_D(\phi_1 - \phi_2)$ and $\delta_D(\mathbf{r}_1 + \mathbf{r}_2) = \frac{2i\nu}{R_g} \delta_D(\chi_1 - \chi_2)\delta_D(\phi_1 - \phi_2 + \pi)$, we compute

$$\text{Cov}[\hat{\xi}_{gg}] (\mathbf{r}_1, \mathbf{r}_2) = \frac{1}{N_g} \left\{ 2\pi \int_0^{2\pi} d\phi_R \int_0^{2\pi} d\phi_R' \text{Cov}[\hat{\xi}_{gg}] (\mathbf{r}_1, \mathbf{r}_2) \right\}$$

(A25)

where we have used $k = \sqrt{k_1^2 + k_2^2}$, $r_i = \sqrt{R_i^2 + \chi_i^2}$, $i = 1, 2$ for more compact notation, and equation (21) to express $\xi_{gg}$ in terms of $P_{gg}$.

Equation (A25) represents the azimuthally averaged covariance matrix of the galaxy correlation function estimator introduced in equation (A18).

### A3 Cross-covariance matrix of stacked tangential shear and the projected galaxy correlation function

We shall compute the cross-covariance of the estimators for the angular correlation function of galaxies and the stacked tangential shear. We take this approach because the angular correlation function in a thin redshift shell – which is our assumption for the lens population – is in fact equal to the projected correlation function.

Equation (33) defines the cross-covariance, which can be further written as

$$\text{Cov} \left[ \hat{\xi}_{gg} (\theta_1), \hat{\gamma}_s (\theta_2) \right] = \frac{1}{N_g} \int_\Omega d^2x d^2y \left\{ \left\langle \hat{F}_g (\mathbf{x}) \hat{F}_g (\mathbf{y}) \gamma_s (\mathbf{y}) \eta_s (\mathbf{y}) \right\rangle - \left\langle \hat{F}_g (\mathbf{x}) \hat{F}_g (\mathbf{y}) \right\rangle \left\langle \gamma_s (\mathbf{y}) \eta_s (\mathbf{y}) \right\rangle \right\},
$$

(A26)

where $\theta_1$ and $\theta_2$ are two angular position vectors, and the estimator for the galaxy overdensity field is defined by equation (A15), only in this case for 2D vectors. The normalization constant is defined just as before $A_{2D} = \int d^2x \tilde{\eta}_g (\mathbf{x}) w^2 (\mathbf{x})$. Here we shall assume unitary weights for which $A_{2D} = \Omega n_g = N_g / \Omega$.

The first factor in the curly brackets on the right-hand side of the above equation can be written as

$$\left\langle \hat{F}_g \hat{F}_g \eta_s \gamma_s \right\rangle = \left\langle \hat{F}_g (\mathbf{z}_1) \hat{F}_g (\mathbf{z}_2) \eta_s (\mathbf{z}_1 + \mathbf{z}_2) \gamma_s (\mathbf{z}_1 + \mathbf{z}_2) \right\rangle
$$

$$= \frac{1}{A_{2D}} \left\{ \left\langle n_{g1} n_{g2} \eta_s \gamma_s \right\rangle - \alpha \left[ \left\langle n_{g1} n_{g2} \gamma_s \gamma_s \right\rangle + \left\langle n_{g1} n_{g2} \gamma_s \gamma_s \right\rangle \right] + \alpha^2 \left\langle n_{g1} n_{g2} \gamma_s \gamma_s \right\rangle \right\}.
$$

(A27)

We compute these terms using the expansion of the galaxy number density as a sum of Dirac delta functions at the positions of the galaxies, e.g. equation (11). Starting with the first term,

$$\left\langle n_{g1} n_{g2} \gamma_s \gamma_s \right\rangle = \sum_{i,j,k} \left\langle \delta_D (\mathbf{z}_1 - \mathbf{x}) \delta_D (\mathbf{z}_2 - \mathbf{x}) \gamma_s (\mathbf{z}_1 + \mathbf{z}_2) \gamma_s (\mathbf{z}_1 + \mathbf{z}_2) \right\rangle
$$

$$= T_{i\neq j \neq k} + T_{i=j \neq k} + T_{i \neq j = k} + T_{i = j = k}.
$$

(A28)

Considering now the term with $i \neq j \neq k$, we use the fluctuation in the number density of galaxies $n_g (\mathbf{z}) = \tilde{n}_g [1 + \delta_g (\mathbf{z})]$ just like in Section 2.1. Dropping the subscript ‘g’ for simplicity, we write

$$T_{i \neq j \neq k} = \tilde{n}_g^3 \left\langle (1 + \delta_1)(1 + \delta_2)(1 + \delta_3) \gamma_s \gamma_s \right\rangle
$$

$$= \tilde{n}_g^3 \left\{ \left\langle \delta_1 \delta_2 \delta_3 \gamma_s \right\rangle + \left\langle \delta_1 \delta_2 \gamma_s \gamma_s \right\rangle + \left\langle \delta_1 \delta_3 \gamma_s \gamma_s \right\rangle + \left\langle \delta_2 \delta_3 \gamma_s \gamma_s \right\rangle + \left\langle \delta_1 \gamma_s \gamma_s \right\rangle + \left\langle \delta_2 \gamma_s \gamma_s \right\rangle + \left\langle \delta_3 \gamma_s \gamma_s \right\rangle + \left\langle \gamma_s \gamma_s \right\rangle \right\}.
$$

(A29)

where we applied Wick’s theorem to the four-point function in order to arrive at the last line. The subscript ‘c’ in the remaining four-point function indicates that it is connected. We also used $\left\langle \gamma_s \right\rangle = 0$ to remove the last term on the second line, and will repeat this step henceforth.
We now address the second term of equation (A27) and use the fact that \( \bar{\delta}_i \).

Combining equations (A31) and (A32), we obtain a final expression for the first part of the cross-covariance, i.e. equation (A27):

\[
\sum_{i,j} \langle \bar{\delta}_D (z_i - x) \delta_D (z_j - x) \rangle = \tilde{\bar{\eta}}_\delta \left\{ \langle \delta_1 \delta_1 \rangle + \langle \delta_1 \delta_2 \rangle \left( 1 + \frac{\delta_D^2}{\bar{\eta}} \right) \right\}.
\]

(A31)

Putting together all these terms, we rewrite equation (A28) as

\[
\langle n_g n_g n_g \rangle = \tilde{\bar{\eta}}_\delta \left\{ \langle \delta_1 \delta_1 \rangle \left( 1 + \frac{\delta_D^2}{\bar{\eta}} \right) \right\}.
\]

(A32)

We now address the second term of equation (A27) and use the fact that \( \bar{\eta}_\delta = \alpha \bar{\eta}_g \):

\[
\langle n_g n_R n_g \rangle = \tilde{\bar{\eta}}_\delta \left\{ \langle \delta_1 \delta_1 \rangle \left( 1 + \frac{\delta_D^2}{\bar{\eta}} \right) \right\}.
\]

Combining equations (A31) and (A32), we obtain a final expression for the first part of the cross-covariance matrix given by equation (33). In completely similar way to the calculation above, we write

\[
\langle \hat{F}_1 \hat{F}_2 \rangle \langle n_g \rangle = \frac{\tilde{\bar{\eta}}_\delta}{A_{2D}} \left\{ \langle \delta_1 \delta_2 \rangle + \frac{\delta_D^2}{\bar{\eta}} \right\}.
\]

(A34)

Finally, putting together equations (A33) and (A34), we obtain the desired result:

\[
\langle \hat{F}_1 \hat{F}_2 \rangle \langle n_g \rangle = \frac{\tilde{\bar{\eta}}_\delta}{A_{2D}} \left\{ \langle \delta_1 \delta_1 \rangle \langle \delta_2 \delta_2 \rangle \left( 1 + \frac{\delta_D^2}{\bar{\eta}} \right) \right\}.
\]

(A35)

The above equation is general in the sense that it contains both Gaussian and non-Gaussian terms, as well as contributions from the 0-lag correlations, i.e. all terms containing \( \delta_D^2 \). Discarding the latter contributions, as well as the non-Gaussian ones, we write a final and simplified expression:

\[
\langle \hat{F}_1 \hat{F}_2 \rangle \langle n_g \rangle = \frac{\tilde{\bar{\eta}}_\delta}{A_{2D}} \left\{ \langle \delta_1 \delta_1 \rangle \langle \delta_2 \delta_2 \rangle \right\}.
\]

(A36)
Repeating the latter equation into equation (A26), we write
\[ \text{Cov} \left[ \hat{w}_{gg}(\theta_1), \hat{y}_g(\theta_2) \right] = \frac{\Omega_1^3}{N_g A_{2D}^2} \int_{\Omega_1} d^2 x d^2 y \{ \langle \delta_g(x) \delta_g(y) \rangle \langle \delta_g(x + \theta_1 y + \psi_1) \rangle \langle \delta_g(x + \theta_1 y + \psi_1) \rangle \langle \delta_g(x + \theta_1 y + \psi_1) \rangle \langle \delta_g(x + \theta_1 y + \psi_1) \rangle \langle \delta_g(x + \theta_1 y + \psi_1) \rangle \langle \delta_g(x + \theta_1 y + \psi_1) \rangle \} . \] (A37)

We shall detail only the computation of first term of the above equation, since the steps are fairly similar to those taken in Sections A1 and A2. We label this first term \( C_1 \) to shorten the notation. Using the definition of the correlation function as the Fourier transform of the power spectrum, and noting that \( \bar{n}_g/N_g/A_{2D} = 1/\Omega_1 \), we write
\[ C_1 = -\frac{1}{\Omega_1^2} \int_{\Omega_1} d^2 x d^2 y \int \frac{d^2 k}{(2\pi)^2} e^{i(k \cdot x - y)} C_{gg}(l) \int \frac{d^2 l'}{(2\pi)^2} e^{i(l' \cdot \theta_1 - y)} \cos[2(\phi_{\theta_1} - \phi_l)] C_{\phi}(l') \]
\[ = -\frac{1}{\Omega_1^2} \int d^2 l \frac{d^2 l'}{(2\pi)^2} C_{gg}(l) C_{\phi}(l') \cos[2(\phi_{\theta_1} - \phi_l)] \int d^2 x e^{i\phi_{\theta_1} - y} \int d^2 y e^{-i\phi_l} \]
\[ = -\frac{1}{\Omega_1} \int d^2 l \frac{d^2 l'}{(2\pi)^2} C_{gg}(l) C_{\phi}(l') \cos[2(\phi_{\theta_1} - \phi_l)] e^{i(l - l')} . \] (A38)

The remaining three terms of equation (A37) are computed in the same way, leading to the following result for the cross-covariance:
\[ \text{Cov} \left[ \hat{w}_{gg}(\theta_1), \hat{y}_g(\theta_2) \right] = -\frac{1}{\Omega_1^2} \int d^2 l \frac{d^2 l'}{(2\pi)^2} \cos[2(\phi_{\theta_1} - \phi_l)] \left[ e^{i(l - l')} + e^{i(l + l')} \right] C_{\phi}(l') \left[ C_{gg}(l) + \frac{1}{\bar{n}_g} \right] . \] (A39)

**APPENDIX B: GALAXY CATALOGUE COMPARISON**

Fig. B1 presents various properties of galaxies from the Millennium simulation as a function of r-band magnitude, e.g. the fraction of each galaxy type, the host halo mass, the distance to the central galaxy and the subhalo mass. The galaxy catalogue is very similar to that described in Guo et al. (2011). The redshift is 0.24.
APPENDIX C: THE IMPACT OF SHAPE NOISE

We present a theoretical calculation of the impact of shape noise on the GGL results. Whilst we do not have shape noise in our simulations, we have particle shot noise, which qualitatively acts in a similar way to shape noise, but quantitatively is different.

As an example, we use the shape-noise values of Mandelbaum et al. (2013). We take $\sigma^2_{\gamma} / 2 = 0.365^2$, $\bar{n}_s = 1.2$ galaxies/arcmin$^2$. Our approach is to translate the contribution that this shape-noise level would have to our GGL covariance into an effective shot-noise contribution that we can just replace into equation (53). Matching the constants multiplying the shape-noise and shot-noise terms in equations (29) and (53), we write

$$\frac{\sigma_{\gamma}^2}{2\bar{n}_s \bar{n}_g^{2D}} = \left( \frac{\rho_m^0}{\Sigma_{\text{crit}}} \right)^2 \frac{1}{D^2(z_l)} \frac{1}{\bar{n}_p} \frac{1}{\bar{n}_g^{2D}},$$

where we have differentiated between angular and volume densities; $D(z_l)$ denotes the angular diameter distance to the lens redshift. Assuming all lenses to be at the same redshift $z_l$, the relationship between the angular and volume density of lens galaxies is given by $\bar{n}_g^{3D} = D^2(z_l)(2\chi_{\text{max}})\bar{n}_g^{2D}$, where $\chi_{\text{max}}$ is the projection length used throughout this work. Using this, the equation above can be expressed as

$$\frac{\sigma_{\gamma}^2}{2\bar{n}_s} = \left( \frac{\rho_m^0}{\Sigma_{\text{crit}}} \right)^2 \frac{1}{D^2(z_l)} \frac{1}{\bar{n}_p} \frac{\chi_{\text{max}}}{\bar{n}_g^{2D}}.$$  \hspace{1cm} (C2)

Evaluating equation (C2) for a general source redshift of $z_s = 1$, we obtain the effective particle shot noise for the SDSS measurements of Mandelbaum et al. (2013): $\bar{n}_{p,\text{SDSS}} = 2.88 \times 10^{-5}$ $[h^{-1} \text{ Mpc}]^{-3}$. This is to be compared to our shot-noise value $\bar{n}_{p,\text{MXXL}} = 1.58 \times 10^{-2}$ $[h^{-1} \text{ Mpc}]^{-3}$. Equivalently, the MXXL shot noise would correspond to an effective source galaxy density of $\sim 660$ galaxies/arcmin$^2$. For a survey with $\sigma_{\gamma}^2/2 = 0.3^2$, the MXXL shot noise would be equivalent to $\bar{n}_s = 440$ galaxies/arcmin$^2$. Note however that the SDSS survey volume is significantly larger than that of our subcubes.

The top panels of Fig. C1 illustrate the effect of shape noise on the GGL correlation matrix, for the brightest and faintest galaxy bins considered in this work. There are two consequences of increased shape noise or, equivalently, particle shot noise. First, the off-diagonal elements are present mostly on larger scales, e.g. $\sim 5 - 10$ $h^{-1}$ Mpc, compared to the lower MXXL noise, where they stretch to $\sim 1$ $h^{-1}$ Mpc. Secondly, the correlations are weaker. Since our predictions are obtained using the measured bias, there is also a dependence on magnitude, with the brighter galaxies being less correlated than the fainter ones. The bottom panels of the figure show the noise-to-signal, with the area of SDSS accounted for. As expected, the SDSS predictions are higher.
