ABSTRACT

Time-resolved observations of brown dwarfs' rotational modulations provide powerful insights into the properties of condensate clouds in ultra-cool atmospheres. Multi-wavelength light curves reveal cloud vertical structures, condensate particle sizes, and cloud morphology, which directly constrain condensate cloud and atmospheric circulation models. We report results from Hubble Space Telescope/Wide Field Camera 3 near-infrared G141 taken in six consecutive orbits observations of HN Peg B, an L/T transition brown dwarf companion to a G0V type star. The best-fit sine wave to the 1.1—1.7 μm broadband light curve has the amplitude of and period of hr. The modulation amplitude has no detectable wavelength dependence except in the 1.4 μm water absorption band, indicating that the characteristic condensate particle sizes are large (> 1 μm). We detect significantly (4.4σ) lower modulation amplitude in the 1.4 μm water absorption band, and find that HN Peg B's spectral modulation resembles those of early T type brown dwarfs. We also describe a new empirical interpolation method to remove spectral contamination from the bright host star. This method may be applied in other high-contrast time-resolved observations with WFC3.

Keywords: brown dwarfs — stars: atmospheres — methods: observational

1. INTRODUCTION

Condensate clouds fundamentally impact the spectra, the pressure-temperature structure, the luminosity evolution, longitudinal and latitudinal temperature distribution, and energy transfer in the atmospheres of most transiting exoplanets (e.g., Kreidberg et al. 2014; Sing et al. 2016; Stevenson 2016), directly imaged exoplanets (e.g., Skemer et al. 2014; Ingraham et al. 2014; Bonnefoy et al. 2016) and brown dwarfs (e.g., Marley et al. 2002; Burgasser et al. 2002; Knapp et al. 2004). Therefore, parametrized cloud models are an essential but not well tested component of atmospheric models. They play a particularly important role in many atmospheric retrieval studies (e.g. Bemmeke & Seager 2012; Line et al. 2012, 2015; Burnett & Seager 2017). However, cloud properties are highly degenerate in disk-integrated observations with other global and difficult-to-measure parameters (e.g., bulk composition, vertical mixing rate, surface gravity, non-equilibrium chemistry). Time-resolved observations of rotational modulations enable disentangling the effects of global parameters (constant for a given object) from locally varying parameters (primarily cloud coverage), thus providing a powerful method for testing cloud models. An important prediction of most cloud models is that surface gravity – through its impacts on pressure scale height and dust settling rate – will have profound effects on cloud thickness. Indeed, exceptionally thick clouds have been proposed as the origin of the very red colors and low near-infrared luminosity of several directly imaged exoplanets (e.g., Skemer et al. 2011; Marley et al. 2012).

Recent results further increased the potential of time-resolved observations and rotational mapping for brown dwarf and exoplanet atmospheric characterization. Karalidi et al. (2015) developed Aeolus that retrieves two-dimensional top-of-the-atmosphere maps from disk-integrated light curves. Apai et al. (2017) identified bands and spots in brown dwarf atmospheres, and demonstrated similarities between atmospheric circulations in L/T transition brown dwarfs and in Neptune. The discovery of rotational modulations in directly imaged exoplanets/planetary mass objects (Biller et al. 2015; Zhou et al. 2016) allows comparative studies of condensate clouds in brown dwarfs and exoplanets.

Cloud Atlas is a Hubble Space Telescope (HST) Wide field Camera 3 (WFC3) Large Treasury program (Program No.: 14241; PI: Apai). The primary goal of the Cloud Atlas project is to identify the role of surface gravity in setting the properties of condensate clouds. To achieve this goal, the project selected 21 brown dwarfs and planetary mass companions that were divided into four groups, (i) high effective temperature ($T_{\text{eff}}$) and high surface gravity ($g$), (ii) high $T_{\text{eff}}$ and low $g$, (iii) low $T_{\text{eff}}$ and high $g$, and (iv) low $T_{\text{eff}}$ and low $g$. We scheduled time-resolved spectroscopic observations for and photometric observations for. Each object was initially observed in two consecutive HST orbits to assess the presence of amplitude variability, then down-selecting a subset of objects to study with deep-look observations (DLO) with 6 to 12 follow-on orbits. We paid particular attention to the difference in rotational modulations in and out of the 1.4 $\mu$m water absorption band because it is a sensitive probe to cloud vertical structure (Yang et al. 2015). HN Peg B was among the targets we selected for six consecutive orbits DLO.

HN Peg B (Luhman et al. 2007) is T2.5 type brown dwarf companion to its G0V type host star. HN Peg B has a projected angular separation of 43.2 ± 0.4" from its host star, which corresponds to a physical distance of 795 ± 15 au (Luhman et al. 2007). HN Peg B and HN Peg A have a brightness contrast of 11.07 magnitude in $J$ band. The mass of HN Peg B is estimated to be 12 – 30 $M_{\text{Jup}}$, based on evolutionary tracks (Luhman et al. 2007; Leggett et al. 2008). Upon its discovery, Luhman et al. (2007) classified HN Peg B to be low or intermediate surface gravity based on the youth of the host star (e.g., Gaidos 1998, 200-800 Myr; Barnes 2007, 237 ± 33 Myr). However, Leggett et al. (2008) found that the near infrared spectra of HN Peg B agree better with higher gravity template ($\log g = 4.81$), which casts doubt on the original low surface gravity classification.

Using Spitzer Space Telescope time-resolved photometry Metchev et al. (2015) discovered rotational modulations in both the [3.6] and the [4.5] channels, broad-band light curves of HN Peg B. Metchev et al. (2015) classified the variability period type as long and used a Fourier series fit to determine the rotation period to be hr, close to the total observation length. The discovery of its rotational modulations made HN Peg B an ideal brown dwarf companion for time-resolved spectroscopy.

2. OBSERVATIONS AND DATA REDUCTION

We observed HN Peg B using Hubble Space Telescope/Wide Field Camera 3 near infrared (HST/WFC3/IR) channel on May 16, 2017 as part of the HST Treasury program Cloud Atlas. We monitored the target using the G141 low-resolution ($R \sim 130$ at 1.4$\mu$m) grism in six consecutive orbits (8.6 hours time baseline).

In order to minimize the contamination to HN Peg B’s observed spectrum by its host star we constrained the roll angle of the telescope to separate the primary and companion spectra on the detector. However, instrumentally-scattered grism-dispersed light from the bright host star is also distributed in a complex band-like pattern across the field-of-view that contaminates the traditional sky background at the location of the companion spectrum (see Figure 1). At the location of the maximum, HN Peg A’s contamination pattern contributes about 25% of the pixel counts and, without mitigation, degrades the precision of the spectral and variability measure-
ments. In § 2.1, we describe in detail how we removed the contamination band pattern.

Most data reduction procedures were done using aXe (Kümmel et al. 2009) based pipeline following previous HST/WFC3 brown dwarf time-resolved spectral observation studies (e.g., Apai et al. 2013; Lew et al. 2016). However, after the sky background subtraction we included an additional step (described below) to remove the band pattern. After this step we followed the regular reduction approach, i.e., we fed the band-subtracted frames to aXe and extracted the spectral sequence.

The extracted light curve for HN Peg B showed easily recognizable signatures of ramp effect systematics. These systematics were widely reported in time-resolved HST/WFC3 observations (e.g., Berta et al. 2012; Apai et al. 2013; Deming et al. 2014). We successfully removed these systematics in the band subtracted light curves using the solid state physics-motivated RECTE charge trap correction method (Zhou et al. 2017).

2.1. Primary Star Contamination Removal: Procedures

Thanks to the well-defined and repeatable spatial variations of the contamination pattern, we successfully removed them using an empirical interpolation method.

Our band subtraction algorithm includes three steps: (1) band recognition, (2) mapping the bands to a coordinate system that established based on band structure gradient and (3) interpolation. Image processing tasks that we used are available in python package scikit-image (van der Walt et al. 2014). First, the algorithm recognizes and isolates the bands from the rest of the image structure. To avoid the confusion of bands with the spectrum of HN Peg B we pre-processed every frame by conservatively masking the spectral trace’s of HN Peg B and background stars (Figure 1 panel B). We then use “inpainting” algorithms (Bertalmio et al. 2001) to interpolate masked image regions. “inpainting” algorithms reconstruct masked pixels based on non-masked region, and improve the precision in recognizing the bands. We then segmented the bands and the background using locally optimized thresholding method. The algorithm computed a threshold mask based on local pixel neighborhood, which effectively marked the foreground pixels (band pattern) as “1” and background pixels as “0” (Figure 1 panel C). Contours on the binary images were then used to identify individual bands. To filter out low SNR detection, we selected contours that were entirely included in the image and had enclosed sizes that are larger than 30 percentile of those of all detected contours. This procedure resulted in eight bands identified per frame (Figure 1 panel D).

Second, we regularized the selected bands and mapped them with a unified coordinate system. For each band we started the regularization by identifying the “semi-major axis”, defined as the semi-major axis of an ellipse with the same normalized second central moment as the band region. The “semi-major axis” measurement is a good estimate of the length and orientation of the bands (Chaumette 2004). We assumed that the top and bottom endpoints of each “semi-major axis” lay on two lines. Therefore we performed linear regressions to the top and bottom axis endpoints. The endpoints were then adjusted along the axes such that the respective points joined contiguously and co-linearly without any discontinuity. We then established an orthogonal coordinate system for each band. We converted the \((x, y)\) image coordinates of each pixel to coordinates \((\rho, r)\) in which \(\rho\) is the distance from the upper end of the band in the “semi-major axis” direction and \(r\) is the distance from the point to the semi-major-axis. In addition, we normalized \(\rho\) to the length of the semi-major-axis to account for the individual length of each band. The new coordinate systems were established for individual bands, and the axes of the coordinate systems were aligned with gradients of the surface brightness of each band.

Third, we used empirically-determined interpolation functions to calculate the pixel values where bands and astrophysical spectra overlapped; i.e. in the regions masked as shown in Figure 1 panel B. We fit a bi-cubic spline surface to each band. Numbers of knots for the cubic splines were 5 and 4 for \(r\) and \(\rho\) direction, respectively. Finally, the best-fitting spline surface was the model for band intensity distribution (Figure 1 panel E) and was used for its subtraction (Figure 1 panel F).

2.2. Contamination Removal: Error Analysis

We evaluated the band subtraction quality by injecting synthetic spectra to the original data and then measuring the difference of the injected and extracted signals with and without band subtraction. Using the software aXeSIM (Kümmel et al. 2009) we injected simulated rotational modulation signals by multiplying the synthetic spectra with a sinusoidal time series and adding the products to the original frames. We then processed the synthetic datasets in two ways, once with band removal and the once without. We performed ten iterations in a Monte Carlo fashion. For each iteration, the injected sinusoidal signal had random amplitude, period, and phase. The results are presented in Figure 2.

3. KECK/NIRSPEC OBSERVATIONS OF HN PEG B

We also present here a moderate-resolution \((R \approx 2300)\) J-band spectrum of HN Peg B that was obtained with Keck/NIRSPEC on 8 July 2008. We used the N3 (1.143–1.375 \(\mu m\)) filter with a two-pixel (0′′38) wide slit, and exposed for a single ABBA sequence totalling 40 min of integration time. Standard stars and arc lamps were observed after the target. We performed the preliminary data reduction
Figure 1. An example for original \( I \) frame, intermediate product, and the result after band subtraction. The order of the images corresponds to the sequence of reduction steps. The Images are: A) image before band subtraction; B) high S/N bands with astrophysical signal masked out; C) thresholding results, foreground pixels are plotted in white; D) coordinate regularization and re-mapping; E) empirically interpolated surface; F) image after band subtraction.
with the REDSPEC pipeline (Prato et al. 2002, REDSPEC Data Reduction Manual¹). Individual exposures were flat-fielded, rectified, and wavelength calibrated. Optimal extraction of the spectra was done with the IRAF APALL package. After correcting for telluric absorption the individual spectra were median combined. The final NIRSPEC N3 spectrum of HN Peg B is shown in Figure 3, where it is compared to the spectra of 100-150 Myr-old late-L dwarfs and of field (>500 Myr-old) L7 and T2 dwarfs.

As shown in Figure 3, the two K I absorption doublets at \( \lambda \simeq 1.1692-1.1778 \mu m \) and \( \lambda \simeq 1.2437-1.2529 \mu m \) are well-established surface gravity-sensitive diagnostics for distinguishing young (\( \lesssim 150 \) Myr-old) from field-aged (\( \gtrsim 500 \) Myr) ultra-cool dwarfs (Allers & Liu 2013; Liu et al. 2016). The comparison among the J-band spectra (Figure 3) shows these lines in HN Peg B to be comparable in strength to the field-aged objects, and much stronger (more pressure-broadened) than in the young objects. We therefore conclude that the age of HN Peg B is likely \( \gtrsim 500 \) Myr. This is consistent with the findings of Luhman et al. (2007), who assign a 100-500 Myr age for the primary HN Peg A from chromospheric activity and space kinematics arguments. The age also agrees well with the conclusions of (Leggett et al. 2008), wherein they find best-fit to 1 - 4 micron spectral models (e.g., their Fig 4) with moderately high surface gravities (log \( g =4.8 \)) in the older end of the age range 100-500 Myr. Evolution model calculations of Leggett et al. (2008) predict a mass of \( 28 M_{\text{Jup}} \) for an age of 500 Myr.

4. RESULTS

We obtained high-quality G141 spectral time series for HN Peg B. Our spectra cover the wavelength range from 1.1 to 1.7\( \mu m \) including the J photometric band and most of the H band, as well as the water and methane absorption bands. The spectra of HN Peg B were dominated by water absorption near 1.1 and 1.4\( \mu m \), which is consistent with an L/T transitional spectral type. The SNRs of the spectral are \( \sim 170 \) at the bright J and H band peaks and \( \sim 40 \) at the faint 1.4\( \mu m \) water absorption bands.

Figure 3. The Keck/NIRSPEC $J$-band spectrum of HN Peg B compared to the spectra of young and field-aged L/T transition dwarfs: the 10±3 Myr-old late-L TWA member 2MASS J1207−3932B (Chauvin et al. 2004), the Myr-old L7.5 dwarf HD 203030B (Metchev & Hillenbrand 2006; Miles-Páez et al. 2017), and the field-age (>500 Myr old) L7 and T2 dwarfs DENIS J02051159AB and SDSS J12540122 (spectra from McLean et al. 2003). $J$ band spectra for L/T transition brown dwarfs. HN Peg B resembles high surface gravity field brown dwarfs.

We constructed near-infrared light curves of HN Peg B for 1.1-1.7 $\mu$m white light as well as $J$, $H$ and the water absorption band (Figure 4). $J$ and $H$ photometric points were integrations of the product of the spectrum and MKO $J/H$ filter transmittances. The water band photometry was integrated from 1.37 $\mu$m to 1.41 $\mu$m. We achieved an SNR of $\sim 850$ for the 1.1-1.7 $\mu$m broadband light curve. HN Peg B’s light curves showed a rising trend in amplitude over the 8.6 hours time span with the lowest point at the second orbit.

4.1. Sinusoidal fit

The main purpose of our investigation is not the detailed analysis of the light curve morphology but the study of the wavelength-dependence of the variations. Nevertheless, in order to explore a likely range of periodicity in the observed variations, we fit a simple sinusoidal function to the light curves of HN Peg B. This is motivated by Spitzer photometric studies (Metchev et al. 2015; Apai et al. 2017). We found the best-fit sinusoid’s amplitude to be $1.206\%\pm0.025\%$ and its period to be $15.4\pm0.5$ hours. This near-infrared amplitude is greater than the Spitzer 3.6 $\mu$m band amplitude ($0.77\%\pm0.15\%$ Metchev et al. 2015) and very similar to the 4.5 $\mu$m band’s amplitude (Metchev et al. 2015, 1.1\%±0.5\%). However, we note that light curves are expected to significantly evolve between the two observations, and WFC3/G141 and Spitzer probe different atmosphere altitudes (Yang et al. 2016). Our best-fit period agrees within the uncertainties with the period of $18\pm4$ hours estimated from the 21h-long Spitzer light curve presented in Metchev et al. (2015).

In order to explore possible wavelength-dependent phase shifts (e.g., Buenzli et al. 2012; Apai et al. 2013; Yang et al. 2016) we performed similar sinusoidal fits to each of the three spectral bands shown in Figure 4. In these fits we kept the periods fixed to the best-fit value from the broadband results (15.4 hr) and investigated the possible phase and amplitude differences between the bands. For the $J$ and $H$ bands, we derived amplitudes of $1.28\%\pm0.03\%$ and $1.25\%\pm0.03\%$.

Figure 4. HN Peg b’s light curves in WFC3 G141 band pass. Observed 1.1-1.7 $\mu$m broad, $J$, water, and $H$ bands light curves are plotted in dots with errorbars. For each bands, we also plot 30 sinusoids that are randomly selected from the posterior distributions of the sinusoidal fits (§4.1).
and phases of $0.663 \pm 0.005$ and $0.639 \pm 0.005$, respectively. Therefore, the sinusoidal amplitudes of $J$ and $H$ bands are statistically identical within $1\sigma$ and are slightly larger than the broad-band value. $J$ and $H$ bands have a phase difference of $2.4\%$. However, we consider this possible phase difference tentative given the very basic light curve modeling applied here, which also affects our uncertainty estimates. In contrast to the $J/H$ bands the $1.4\mu m$ water band light curve does not have enough precision to produce a reliable phase measurement (see Figure 4).

4.2. Spectral modulations

The high SNR spectral time series allowed us to investigate the wavelength dependence of the rotational modulations. Following a method introduced by Apai et al. (2013) we selected the eight spectra closest to the brightest segment and the eight spectra closest to the faintest segment of the lightcurve and median-combined each sets. In Figure 5 we plot the two median spectra and their relative difference. Following Buenzli et al. (2015), we defined spectral modulation as

$$\frac{\Delta F_\lambda}{F_\lambda} = \frac{F_{\lambda, \text{max}} - F_{\lambda, \text{min}}}{F_{\lambda, \text{mean}}}$$

and plot it in the bottom panel of Figure 5. Two key results are immediately apparent from Figure 5. First, the spectral modulations are very gray, essentially identical in the $J$- and $H$-bands. Second, the amplitude is significantly reduced in the $1.4\mu m$ water absorption band: The relative water band maximum-to-minimum difference (wavelengths ranging from $1.37$ to $1.41\mu m$) is only $0.80 \pm 0.41\%$ while this difference outside the water absorption band is $2.56 \pm 0.06\%$. The difference in the water band ($1.37\mu m < \lambda < 1.41\mu m$) is $4.36\sigma$ below that outside of water band and only $1.9\sigma$ level above zero. Similar reductions of modulation amplitude in water absorption band have been previously found in all three L/T transition brown dwarfs with HST/G141 time-resolved spectroscopy (Apai et al. 2013; Yang et al. 2015; Buenzli et al. 2015).

5. DISCUSSION

5.1. Spectral slopes and Amplitudes

Our WFC3/G141 time-resolved spectroscopy of HN Peg B enlarges the small sample (size of 3) of L/T transition brown dwarfs that have precise spectro-photometric rotational modulation measurements. In addition, HN Peg B is different from the existing sample of field L/T transition brown dwarfs because it is a companion to a star, with a star-to-companion mass ratio estimated to be $>30$. Here we compare HN Peg B with L/T transition brown dwarfs 2M2139, SIMP0136 (Apai et al. 2013; Yang et al. 2015), and Luhman 16B (Buenzli et al. 2015) to explore the wavelength dependence of their rotational modulations. We compiled the four objects’ spectral modulation curves in Figure 6. The spectral modulation curves of 2M2139, SIMP0136, and Luhman 16B are reproduced from literature. The four objects’ broadband modulations amplitudes range from 2.56% to 24.9%, however, their modulations all follow a similar pattern. Each of the four rotational amplitude curves show a significant decrease in the $1.4\mu m$ water absorption band. We identify three quantities to characterize spectral modulations: the $1.1$ – $1.7\mu m$ broadband modulation amplitude, the difference in the $1.4\mu m$ water absorption with respect to the adjacent continuum bands $\frac{\Delta F_{\lambda, \text{out}}}{F_{\lambda, \text{out}}} = \frac{\Delta F_{\lambda, \text{in}}}{F_{\lambda, \text{in}}}$, and the $\frac{\Delta F_{\lambda}}{F_{\lambda}}$-modulations’ spectral slope measured outside of the water absorption band. We follow Yang et al. (2015) to define $\frac{\Delta F_{\lambda}}{F_{\lambda}}$ as the weighted average $\frac{\Delta F_{\lambda}}{F_{\lambda}}$ with HST/WFC3 filter F139M’s throughput and with that of filter F127M and F153M (Dressel 2017). The results are listed in Table 1.

Among the four brown dwarfs HN Peg B has the lowest modulation amplitude as well as the flattest spectral modulation slope. HN Peg B’s measured spectral modulation slope – outside of $1.4\mu m$ molecular absorption bands – agrees with wavelength-independent modulations. The broadband am-

---

**Figure 5.** Wavelength dependence of HN Peg B’s rotational modulation amplitudes. We median combined the 8 brightest (blue) and 8 faintest (orange) spectra, and calculated their difference based on Equation 1. Three sub-panels highlight $J$, water, and $H$ bands. Spectra and their difference are all smoothed using a Gaussian kernel with $\sigma = 1.5$ pixels.
plamdes and spectral modulation-wavelength slopes of L/T transition brown dwarfs follow a correlation that was initially recognized by Lew et al. (2016) using a sample of six brown dwarfs that have WFC3/G141 rotational modulation measurements. The low amplitude and flat spectral modulation spectral slope of HN Peg B further reinforces this empirical trend.

5.2. Cloud top heights

The lower modulation amplitude in the 1.4 μm water absorption band can be explained by a model proposed by Yang et al. (2015) (sample including L and L/T transition brown dwarfs), who used an analytical approximation as well as a radiative transfer model to demonstrate the mechanism. In this model the relative modulation amplitude in- and out of the water absorption band is approximately given by \( \epsilon = \exp(\tau_{\text{cont.}} - \tau_{\text{water}}) \), where \( \tau_{\text{cont.}} \) and \( \tau_{\text{water}} \) are the optical depths measured from the top of atmosphere to the cloud layer that introduces the modulations. We explored the implications of this model in the context of the spectral slopes observed in Table 1. Along with their spectra in Figure 6, we also plot the pressure levels the different wavelengths probe the atmospheres — 80% of the flux emerge from the gray shaded region and above in lower panel of Figure 6. We adopt the same pressure level results for SIMP0136 from Yang et al. (2016), because of the similarities of spectral type between HN Peg B and SIMP0136. For example, in the J-band continuum window observations will typically probe down to about 7-9 bar pressures, while in the 1.4 μm water band observations probe only down to about 2-4 bar pressure levels. Therefore, the effective top of atmosphere near 1.4 μm is \( \sim 3 \) bar lower in pressure than it is in the continuum band. This in turn implies that \( \tau_{\text{cont.}} - \tau_{\text{water}} \) is negative and modulation in water absorption band is smaller than it is in the continuum band. The relative modulations in- and out of the 1.4 μm water absorption band for HN Peg B agree well (within 1σ uncertainty) with those reported for the other three L/T transition brown dwarfs. This similarity suggests that the vertical cloud structure for HN Peg B is not different from the three L/T transition brown dwarfs studied previously.

5.3. Constraints on Cloud Particle Sizes

We also investigate the characteristic particle size in the condensate clouds assuming that Mie scattering extinction is the primary source of modulations, following Hiranaka et al. (2016). While the best constraints on atmospheric aerosol particle sizes come from broad wavelength coverage, the flat slope over our WFC3 spectral range does allow us to place a constraint on the minimum particle size of the clouds. We used the same model as Schlawin et al. (2017) in which clouds that introduce the modulations are made of spherical forsterite grains and optically thin, and the dust particle size is described by a log-normal distribution characterized by the median grain radius \( r \) and the scale parameter \( \sigma_r \). In this model the spectral modulation amplitudes linearly scale with the Mie extinction coefficients. We find that in order to reproduce a flat modulation spectral slope, the model requires relatively large characteristic particle sizes (\( r > 1.0 \mu m \)). The particle size we find for HN Peg B is significantly greater than those for dusty late L-type brown dwarfs (\( \sim 0.2 - 0.4 \mu m \), Schlawin et al. 2017; Lew et al. 2016), but similar to some less-varying L dwarfs (2M1507, Yang et al. 2015, LP261-B, Manjavacas et al. 2017).

5.4. Toward High-Contrast Time-resolved Spectroscopy

In addition to the astrophysical results our study illustrates the complicating factors (contamination and complex spectrally dispersed point spread function) introduced by nearby

\(^a\)HN Peg b’s modulation amplitude should be considered a minimum since our observations covered only \( \sim 50-60\% \) of the rotational phase space.

HST Rotational Modulations of HN Peg B

Figure 6. Comparison of HN Peg B with L/T transition brown dwarfs that have WFC3/G141 time-resolved observations. Upper: Spectral modulations defined in equation 1 are plotted. Lines are best-fit linear trends for spectral modulations out of 1.4 μm water absorption band. Lower: Vertical spans of the atmosphere that are probed by different wavelength light curves are indicated in gray. (Pressure levels are calculated specifically for SIMP0136. Wavelength ranges that were not listed in Yang et al. (2016) are interpolated with adjacent bands. Red solid and dashed line show cloud base and top, respectively.)

6. SUMMARY

The key results of our study are as follows:

(i) Our study demonstrates an empirical image processing method that can remove the contamination from the spectrally dispersed side lobes of the point spread functions of bright, close companions to the target in G141 observations.

(ii) We present time-resolved spectroscopy of the rotational modulations in the L/T transition brown dwarf mass companion HN Peg B. We confirm the presence of rotational modulations in the light curve of HN Peg B. The 1.1μm-1.7μm broadband modulation amplitude and period are 1:206±0.025% and 15.4±0.5 hours, respectively, which are consistent with those reported in the Spitzer Space Telescope photometric study by Metchev et al. (2015), considering the different wavelengths of observation. The temporal baseline of our observations corresponds to about 60% of the estimated rotational period of HN Peg B. Our light curve appears to probe the minimum of the light curve, but not its peak.

(iii) We found that the rotational amplitude outside the water absorption band is nearly independent of wavelength: our measurements are consistent with an amplitude of 1:25% in the 1:1-1:65μm wavelength range, with the exception of the 1:4μm water band. We found a significantly reduced variability amplitude in the water band. The modulation amplitude in the water absorption band is lower than that of the continuum by more than 4σ level.

(iv) HN Peg B is a non-tidally locked brown dwarf companion for which rotational spectral mapping is possible. We found that its rotational modulations resemble closely those observed in higher-gravity and (presumably) older T2 brown dwarfs (2M2139: Apai et al. 2013; Luhman 16: Buenzli et al. 2015) and that of the likely planetary-mass but unbound brown dwarf SIMP0136 (Apai et al. 2013).

(v) Assuming Mie scattering, the fact that HN Peg B’s rotational modulation amplitude is very close to wavelength-independent argues for the characteristic dust particle size of the cloud to exceed 1μm.

Our study increased the small sample of L/T transition brown dwarfs with time-resolved spectroscopy. We show that the nature of the rotational modulations in the first L/T companion to a star resembles those observed in field brown images). Second, we show that the median brightness of the stripes decay as 1/N², where N is the stripe number. Therefore, an optical contamination correction model will likely improve WFC3/G141 time-resolved observations for which the targets are close binaries (e.g., Buenzli et al. 2015; Beatty et al. 2017) or have nearby bright sources. Future versions of WFC3/G141 PSF simulators (e.g., aXeSIM, Kümmel et al. 2009; Wayne, Varley et al. 2017) may also take this effect into account.
dwarfs, suggesting that cloud vertical structures are similar for companions to stars and for individual brown dwarfs.

We acknowledge the anonymous referee for a constructive report that improves the manuscript. We acknowledge Dr. Sandy Leggett for valuable discussion on HN Peg B’s spectral fitting and Dr. Peter McCullough for helpful discussion on the cause of the image contamination. Y.Z. acknowledges support in part by the NASA Earth and Space Science Fellowship Program - Grant NNX16AP54H. D.A. acknowledges support by NASA under agreement No. NNX15AD94G for the program Earths in Other Solar Systems. Support for Program number 14241 was provided by NASA through a grant from the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Incorporated, under NASA contract NAS5-26555. Based on observations made with the NASA/ESA Hubble Space Telescope, obtained in GO program 14241 at the Space Telescope Science Institute.
