The molecular mechanism of muscle degeneration in a lethal muscle disorder Duchenne muscular dystrophy (DMD) has not been fully elucidated. The dystrophic dog, a model of DMD, shows a high mortality rate with a marked increase in serum creatine kinase (CK) levels in the neonatal period. By measuring serum CK levels in cord and venous blood, we found initial pulmonary respiration resulted in massive diaphragm damage in the neonates and thereby lead to the high serum CK levels. Furthermore, molecular biological techniques revealed that osteopontin was prominently upregulated in the dystrophic diaphragm prior to the respiration, and that immediate-early genes (c-fos and egr-1) and inflammation/immune response genes (IL-6, IL-8, COX-2, and selectin E) were distinctly overexpressed after the damage by the respiration. Hence, we segregated dystrophic phases at the molecular level before and after mechanical damage. These molecules could be biomarkers of muscle damage and potential targets in pharmaceutical therapies.

Results

Initial pulmonary respiration caused diaphragm damage in neonatal dystrophic dogs. Physical stresses (e.g., compression in the birth canal) have been postulated to be causative factors of the increased serum CK levels in the neonatal period. Our results suggest that initial pulmonary respiration causes massive diaphragm damage in neonatal dystrophic dogs, and that osteopontin is a key molecule involved in this process. Osteopontin is a matrix protein that is involved in the regulation of cell adhesion, migration, and cytokine production. Its upregulation in the dystrophic diaphragm prior to the initial respiration suggests that it may play a role in the initial mechanical damage to the diaphragm. Additionally, the upregulation of immediate-early genes such as c-fos and egr-1, and inflammation/immune response genes such as IL-6, IL-8, COX-2, and selectin E, further support the involvement of mechanical stress in the muscle damage. These findings provide new insights into the molecular mechanisms underlying muscle degeneration in dystrophic muscle and suggest potential targets for therapeutic intervention.
normal human infants. Thus, we compared the serum CK levels in normal, carrier, and dystrophic pups after natural or Caesarean deliveries to examine the effect of reduced birth stress on CK levels. In normal and carrier neonates, serum CK levels were significantly lower after Caesarean sections relative to levels following natural delivery, while no difference was observed for dystrophic neonates (Figure 1A). These observations suggest that the stress of natural delivery is not a major causative factor in the increased CK levels of dystrophic dog neonates.

To determine whether the cause of neonatal increased CK levels could be related to initial pulmonary respiration, we obtained blood from the umbilical cords after the Caesarean sections, which reflect the condition before the initial respiration, and blood from the juxta-venular vein 1 hour after initial respiration to compare the serum CK levels among the different groups of dogs. No differences in the serum CK levels were observed between the venous blood and cord blood of normal and carrier dogs (Figure 1B). However, the CK levels were 5 times higher in the cord blood of the dystrophic dogs than in that of the normal dogs and 35 times higher in the dystrophic venous blood than in the dystrophic cord blood. Serum CK values had increased rapidly 30 min after the initial respiration and peaked between 4 and 8 hours after it (Figure 1C). The histopathology of the dystrophic diaphragm before respiration revealed a slight increase in the number of calcium-positive opaque fibers, which showed a slight infiltration of CD18-positive neutrophils, but cleaved caspase 3-positive apoptotic fibers were not observed (Figure 1D and Supplementary Figure 1). Further, we found larger interstitial spaces, massive opaque fibers indicating hyaline degeneration, and a slight increase in neutrophils after the beginning of respiration, but caspase-3 apoptotic-positive fibers, C5b-9-positive necrotic fibers and LC3-positive autophagic fibers were not overt (Supplementary Figure 1).

Tibialis cranialis (TC) muscle in dystrophic dogs before and after the respiration showed some opaque fibers, but no hyaline degeneration likely to diaphragm (Supplementary Figure 2). Whilst heart (left ventricle) muscle in dystrophic dogs both before and after the respiration did not present any pathological changes. Thus, we have considered that the dramatic increase in serum CK levels after the respiration is due to the specific damage of diaphragm, but not of skeletal or heart muscle. We also have examined the histopathology of 1, 2, and 3 weeks post-natal diaphragm. Serum CK levels have been drastically decreased in these dystrophic dogs and the histopathology of dystrophic diaphragm at 1 week of age was less severe compared to that at birth. Each histopathology at 2 or 3 weeks of age was not much different from at 1 week of age (Supplementary Figure 3). We, however, could not declare these findings are definitely due to a...
remarkable capacity to self-recover, since the phenotypic severity is different among the dogs. Moreover, we noticed the degeneration of affected diaphragm was not diffuse and resulted in white streaks. Number of examined affected dogs is limited at early period after birth. Therefore, we concluded that the findings of 1, 2, and 3 weeks post-natal diaphragm suggested recovery of diaphragm at certain extents, which was also indicated by the change of serum CK levels after birth.

Differentially upregulated genes in dystrophic diaphragm before and after initial respiration. Next, we carried out cDNA microarray experiments to determine the genes differentially upregulated genes before and after initial respiration in the dystrophic diaphragm, to identify genes and molecules participating in the dystrophic pathology. Many more genes were differentially upregulated (>3-fold change) in the dystrophic diaphragm compared to normal before and after initial respiration (Figure 2A and B, respectively). In the comparison, the increase in number of upregulated genes was related to membrane and inflammation/immune response before the respiration (Table 1 and Supplementary Table 1), and to the membrane and transcription/signal transduction after the respiration (Table 2 and Supplementary Table 1). After the respiration compared to before, the pattern of differentially upregulated genes were generally consistent between dystrophic and normal diaphragm (Table 3, 4, and Supplementary Table 1); however, some particular transcription/signal transduction and inflammation/immune response genes were distinctly increased in dystrophic diaphragm (Figure 2B, 2D, and Supplementary Table 1).

Upregulated genes in the dystrophic dog diaphragm before the initial respiration. We selected genes on the microarrays that were increased over 10-fold change before and after the initial respiration in the dystrophic diaphragm relative to the normal (Figure 2 and Supplementary Table 1). Prior to the initial respiration, osteopontin mRNA was most prominently upregulated in the dystrophic diaphragm (Fig 2A and Supplementary Table 1). We confirmed its upregulation with real-time polymerase chain reaction (PCR) (Figure 3A). Western blotting showed a main band of osteopontin at 69 kDa in both normal and dystrophic dogs before and after the respiration (Figure 3B and 3C). The main band sizes were roughly comparable to data in other reports. The 69 kDa osteopontin level before and after the respiration in dystrophic dogs was...
significantly increased compared to that in normal dogs, although the difference was not outstanding compared to mRNA levels (Figure 3D). Immunohistochemistry revealed that osteopontin was localized in infiltrated mononuclear cells expressing CD11b, but not CD3, and the nearby muscle surfaces (Figure 3E). Moreover, overexpression of osteopontin mRNA and protein were detected not only before but also after the respiration (Figure 2B, Figure 3, and Supplementary Figure 4B).

Besides osteopontin, matrix metalloproteinase-12 (MMP-12) mRNA level prominently upregulated in dystrophic diaphragm before the respiration (Figure 2A and Supplementary Table 1), and their upregulation were confirmed by real-time PCR (Supplementary Figure 4A). Myotuburalin related protein 10 (MTMR10) mRNA level was about 18-fold higher in dystrophic dog diaphragm compared to that of normal dog before respiration, and its level dropped rapidly to 1% of the pre-respiration level in dystrophic dog after respiration (Figure 2A and Supplementary Table 1). Real-time PCR analysis was compatible to the data of microarray (Supplementary Figure 4).

**Discussion**

Our study demonstrated for the first time that the acute mechanical load of the initial respiration caused severe diaphragm damage in neonatal dystrophic dogs, and subsequently led to high serum CK levels and to respiratory distress. The muscle maturation in both normal and dystrophic dogs is considerably delayed compared to that in other animals and humans13. Respiratory overload in the immature respiratory muscles of dystrophic dogs may explain the respiratory distress following their birth. We found slight dystrophic changes in the absence of dynamic activity of dystrophic dog diaphragm prior to initial respiration. While, it was reported that fetal respiratory movements occurred before the delivery and are considered to be regular muscular contraction preparing initial respiratory movement of neonatal period14; therefore, the fetal respiratory movements might affect the diaphragm changes.

Before the initial respiration, the differentially upregulated genes detected by cDNA microarrays were related to inflammatory/immune response such as interleukins, cytokines or chemokines. This implies that the upregulation of these genes might affect the slight dystrophic change. Among the genes, osteopontin mRNA was mostly prominently upregulated in the dystrophic diaphragm. Osteopontin is an extracellular matrix protein with cytokine, chemokine, and cell signaling properties, can recruit neutrophils and damaged dystrophic diaphragm (Figure 4A–B). c-Fos and EGR-1 localized either in the nuclei or cytoplasm of muscle fibers, and IL6 and IL8 were expressed in the muscle cytoplasm, especially in the damaged dystrophic diaphragm (Figure 4C). We also confirmed the increased mRNA levels of COX-2 and selectin E in dystrophic diaphragm after the respiration using real-time PCR (Supplementary Figure 4).

Figure 3 | Osteopontin upregulated before the diaphragm damage in neonatal dystrophic dogs. (A) Comparison of relative osteopontin mRNA levels to 18 s in normal (Nor) and dystrophic (Dys) dogs before (n = 4, each) and after (n = 4, each) the respiration. Bar: mean ± SD; ** p < 0.01. (B) Western blotting of osteopontin and (C) CBB staining of diaphragms in normal and dystrophic dogs before and after respiration. Actin: loading control. The short and long exposure blots are included in the supplementary information. (D) Comparison of relative levels of 69 kDa osteopontin to actin in normal (Nor) and dystrophic (Dys) dogs before (n = 4, each) and after (n = 4, each) the respiration. Bar: mean ± SD; ** p < 0.01. (E) Hematoxylin-eosin (H&E) staining of diaphragms of normal and dystrophic dogs before and 1 hour after respiration. Immunohistochemistry of osteopontin, CD11b, CD3 (all green), and DAPI (blue) in normal and dystrophic dogs before and after respiration. Bar indicates 100 μm.
It has already been reported that osteopontin was produced by dystrophic muscle itself and inflammatory cells such as CD68-positive macrophages or CD3-positive T-cells. Our results showed that osteopontin was expressed in CD11b-positive monocytes/macrophages and nearby muscle surfaces. Here, we have raised a question why monocytes/macrophages were recruited in the dystrophic diaphragm even before the initial respiration. Our microarray analyses revealed that monocyte/macrophage recruiting chemokine CCL-2 (monocyte chemotactic protein-1: MCP-1) and CCL-4 (macrophage inhibitory protein-1b: MIP-1b), which are designated as muscle-produced cytokines (myokines), were significantly upregulated even before the initial respiration (Supplementary Table 1). Indeed, osteopontin has been reported to be induced by CCL-2 and CCL-4 in synovial fluid of rheumatoid arthritis. Thus, we have proposed that these myokines may recruit monocytes/macrophages and subsequently lead to induction of osteopontin.

In the role of osteopontin in dystrophic muscle, it has been proposed that osteopontin mediates the early phase of muscle regeneration in injured muscle or promotes fibrosis in dystrophic muscle. Recently, it has been reported that osteopontin stimulates expression of MMP-9 resulting in causing cardiomyopathy in the mdx mice. We and other researchers have previously reported that MMP-9 can be associated with the dystrophic muscle degeneration. Indeed, MMP-9 was upregulated (4.1-fold) dystrophic diaphragms especially after the respiration (Supplementary Table 1). Taken all, osteopontin may induce muscle degeneration in dystrophic diaphragms, and have an essential role from the very early to the late stages of dystrophic pathology. Currently, osteopontin is considered to be a potential target for therapeutic intervention in DMD. We found the distinct upregulation of MMP-12 in the dystrophic diaphragms after the respiration. A recent paper showed that cleavage of osteopontin by MMP-12 modulates experimental autoimmune encephalomyelitis in C57BL/6 mice. In our result, the cleavage pattern of osteopontin was examined...
osteonpin was slightly different between normal and dystrophic diaphragms. Thus, MMP-12 might affect osteopontin processing in dystrophic diaphragm, and further studies will be needed to examine the relationship between the molecules.

Myotubularin related protein 10 (MTMR10) mRNA level was also distinctly higher in dystrophic dog diaphragm before respiration compared to that of normal dog. MTMR10 is one of MTMRs, which comprise a large family of ubiquitously expressed lipid phosphatases. Among MTMRs, MTMR2 has recently been linked to neuromuscular degenerative disorder Charcot-Marie-Tooth disease type 4B and myotubulin (MTM1) is mutated in a muscle disorder X-linked myotubular myopathy. Although the role and function of MTMR10 and its related disorder have not been identified, this molecule might have a certain role in the dystrophic pathology and we would leave it as a future study.

In damaged dystrophic diaphragms after the respiration, c-fos, egf-1, IL6, and IL8 are prominently upregulated. The upregulation of c-fos, egf-1, and IL8 in dystrophic diaphragms has not been observed prior to this study. Moreover, the overexpression of IL6 has not evoked much attention since Kurek et al. reported an increase in IL6 expression in dystrophic muscle, c-fos and egf-1 are immediate-early genes that are regulated by a local increase in Ca2+ concentration and induce a number of downstream genes, including IL6 and IL8. Both IL6 and IL8 are myokines and upregulated in exercised normal skeletal muscle. IL6 may maintain metabolic homeostasis in normal muscle, but as a pro-inflammatory cytokine, IL6 may play a role in dystrophic pathology resulting from damage by mechanical load. IL8 is a major chemokine that recruits neutrophils after injurious mechanical strain. Indeed, our results showed that a neutrophil recruitment related gene selectin E was strongly upregulated in dystrophic diaphragm after the respiration. It has been reported that neutrophil accumulation in muscle is evident within 2–6 h after muscle injury. Thus, we have examined the muscle pathology 2.5 hours after the initial respiration in dystrophic diaphragm. Infiltration of CD18 positive neutrophil was observed in the damaged dystrophic muscle (Supplementary Figure 5). A previous report indicated that neutrophils play a central role in the initial dystrophic pathology since antibody depletion of host neutrophils significantly reduces muscle necrosis. COX-2 is also distinctly upregulated in dystrophic diaphragm after the respiration compared to before. In general, COX-2 is lower expressed in every tissue except brain and kidney; however, is highly induced in inflammatory tissues. COX-2 leads to the production of prostaglandins resulted in vasodilatation 37. Recently, it has been reported that anti-inflammatory drugs inhibiting COX-2 could reduce necrosis in mdx mouse. Thus, we hypothesize that the dystrophic process after mechanical load consists initially of sarcolemmal disruption and afterward, some major genes and molecules such as c-fos, egf-1, IL6, IL8, selectin E, and COX-2 promote sterile inflammation in the dystrophic muscle, resulting in the aftermath of a necrotic event.

In this study, we have for the first time revealed the molecular mechanism of very early stage of damage in dystrophin-deficient muscle as a result of mechanical load. The mechanism presented here could also occur in the skeletal muscle of human DMD patients. However, degeneration and regeneration concurrently operate in the tissues of these patients, so that the molecular mechanism associated with each pathology cannot be identified. By studying the neonatal dystrophic dog diaphragm, we succeeded at segregating the dystrophic phases into those before and after mechanical injury. In the treatment of DMD, the promising therapeutic agent corticosteroid improves muscle function, but the underlying mechanism of its action is not fully understood. Corticosteroids strongly reduce the production of IL6, IL8, and COX-2; therefore, the genes and molecules reported here may not only be biomarkers of muscle damage but also molecular targets in pharmaceutical therapies to prevent disease progression.

Methods

Experimental dogs. For comparisons of serum CK values and mortality rates, we used normal (n = 71), carrier (n = 37), and dystrophic (n = 41) pups obtained by 39 natural deliveries, and normal (n = 39), carriers (n = 26), and dystrophic (n = 34) pups derived from 28 Caesarean sections between December 2001 and April 2008. The dogs were born in the dystrophic dog (CXMD), breeding colony at the General Animal Research Facility, National Institute of Neuroscience, National Center of Neurology and Psychiatry (NCNP, Tokyo, Japan). Electrical sections were performed at the expected delivery date based on the results of an LH surge kit (Witness LH, Synbiotics, Kansas City, MO, USA) or when the body temperature of the pregnant carrier dog decreased acutely. Pregnant dogs were induced and maintained by inhalation of isoflurane (2.0–3.0%) for general anesthesia, and pups were surgically-delivered by Caesarean sections. After the sections, placental membranes should be removed from the neonate’s body and head, and the umbilical cord should be clamped and ligated approximately 2 cm from the body. The oropharynx should be cleared of respiratory secretions and swelling the neonate to remove secretions is widely practiced. The chest wall should be vigorously rubbed not only to remove placentas fluids but also to stimulate spontaneous respiration. Vocalization is a good sign that the lungs are well expanded. Suplementary oxygen should be provided by face mask or by placing the puppies in an oxygen induction chamber once spontaneous respiration. Puppies should be immediately dried with a warm, dry towel and placed under a radiant heat source. We routinely used doxapram in neonates delivered by Caesarean sections to stimulate spontaneous respiration because it is extensively used in veterinary neonatal respiration. For the histopathological and molecular analyses, we have obtained all samples after the euthanasia but not naturally died after birth.

To determine the time course of serum CK values, we used normal (n = 5), carrier (n = 5), and dystrophic (n = 5) dogs derived from three additional Caesarean sections. We performed the histopathological and molecular biological experiments on dogs (n = 4) in each group delivered in the Caesarean sections mentioned above. The experiments were conducted under the guidelines provided by the Ethics Committee for the Treatment of Laboratory Animals of the National Institute of Neuroscience (approval Nos. 13-03, 14-03, 15-03, 16-03, 17-03, 18-03, 19-04, and 20-04). We performed experiments with consideration for preventing excessive pain.

Determination of serum creatine kinase (CK) level. The blood samples from the umbilical cord at Caesarean sections and the jugular vein of each dog were taken using a syringe, and the serum was separated by centrifugation at 1,800 x g for 10 min at room temperature. Among the dogs, we measured serum CK levels in cord blood of normal (n = 5), carrier (n = 3), and dystrophic (n = 6) dogs at 30 min, 1, 2, 4, 8, 24, and 48 h. Serum CK levels were assayed using an automated colorimetric analyzer (FD3500, Fujifilm Medical, Tokyo, Japan).

Histopathology and immunohistochemistry. After euthanasia, diaphragm, tibialis cranialis (TC) and heart (left ventricle) muscles were snap-frozen in cooled isopentane. Cryostat sections (7 μm) were cut and stained with hematoxylin and eosin (H&E) or alizarin red, pH 4.1, for 20 min at room temperature to visualize the cytosolic calcium. Some sections were dried for 15 min and pre-incubated with phosphate-buffered saline (PBS) containing 5% bovine serum albumin or heat-inactivated normal goat serum at pH 7.4. The sections were incubated with primary antibodies for 16 hrs at room temperature with fluorescent isothiocyanate (FITC)-labeled secondary antibodies (10 μg/ml) at room temperature for 1 h before washing in 5% BSA. The sections were mounted using Fluorescent Mounting Medium with DAPI (Vector Laboratories, Burlingame, CA, USA) and assessed under fluorescence microscopes BZ-9000 (Keyence, Osaka, Japan) and Eclipse E800 (Nikon, Tokyo, Japan). Primary antibodies used were: CD3 (C7930, Sigma-Aldrich, St Louis, MO, USA), CD11b (MCA1777S, AbD Serotec, Oxford, UK), CD18 (MCA1780, AbD Serotec), C5aR-9 (ab66768, Abcam, Cambridge, UK), cleaved caspase 3 (#9661, Cell Signaling Technology, Beverly, MA, USA), LC3 (#4187, Cell Signaling Technology), osteopontin (RB-9097, Thermo Fisher Scientific, Waltham, MA, USA), c-Fos (#2250, Cell Signaling Technology), EGR-1 (#4353, Cell Signaling Technology), IL6 (sc-8010, Santa Cruz Biotechnology, Santa Cruz, CA, USA), and IL8 (sc-109-401-311, Rockland Immunohistochemical, Gilbertsville, PA, USA).

Western blotting. Diaphragm muscles were homogenized in sample buffer (62.5 mM Tris- HCL, pH 6.8, 2% sodium dodecyl sulfate, 10% glycerol), or T-PER Tissue Extraction Reagent for osteopontin (Thermo Fisher Scientific, Waltham, MA, USA). After centrifugation (15,000 g for 10 min), the supernatant was removed and the protein concentration was assayed using a DC Assay Kit (Bio-Rad, Hercules, CA, USA). Protein homogenates were denatured at 95°C for 5 min or 70°C for 10 min or 15 min. Ten or forty micrograms of each muscle extract was separated on 5-15% polyacrylamide gels, blotting membranes were incubated with 5-15% PVDF (FDC3500, FujiFilm Medical, Tokyo, Japan). Protein homogenates were denatured at 95°C for 5 min or 70°C for 10 min or 15 min, then with fluorescein isothiocyanate (FITC)-labeled secondary antibodies (10 μg/ml) at room temperature for 1 h before washing in 5% BSA. The sections were mounted using Fluorescent Mounting Medium with DAPI (Vector Laboratories, Burlingame, CA, USA) and assessed under fluorescence microscopes BZ-9000 (Keyence, Osaka, Japan) and Eclipse E800 (Nikon, Tokyo, Japan). Primary antibodies used were: CD3 (C7930, Sigma-Aldrich, St Louis, MO, USA), CD11b (MCA1777S, AbD Serotec, Oxford, UK), CD18 (MCA1780, AbD Serotec), C5aR-9 (ab66768, Abcam, Cambridge, UK), cleaved caspase 3 (#9661, Cell Signaling Technology, Beverly, MA, USA), LC3 (#4187, Cell Signaling Technology), osteopontin (RB-9097, Thermo Fisher Scientific, Waltham, MA, USA), c-Fos (#2250, Cell Signaling Technology), EGR-1 (#4353, Cell Signaling Technology), IL6 (sc-8010, Santa Cruz Biotechnology, Santa Cruz, CA, USA), and IL8 (sc-109-401-311, Rockland Immunohistochemical, Gilbertsville, PA, USA).
cDNA microarray. Diaphragm muscles from normal and dystrophic dogs were used and after initial respiration (n = 4, each) were snap-frozen in liquid nitrogen and stored at −80 °C. Total RNA was purified using an RNaseasy Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer’s protocols. The RNA concentration was also determined using a NanoDrop ND-1000 UV-Vis spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). RNA quality was checked using an Agilent Bioanalyzer 2100 (Agilent Technologies, Santa Clara, CA, USA). Total RNA was also extracted from normal and dystrophic dog myocardium and was actually applied to a whole genome oligo microarray 44 K (Agilent Technologies). Hybridization was performed by Bio Matrix Research Co., Ltd. (Nagareyama, Chiba, Japan). Briefly, 500 ng of RNA was converted to double-stranded cDNA with an RNA Spinkel kit (one color) (Agilent Technologies) using a T7 promoter primer, followed by transcription to generate Cy3-labelled cRNA probes with Quick Amp Labeling Kit (Agilent Technologies). Fragmented cRNA (1.65 μg) was placed in 110 μl hybridization solvent, and then placed on each chip, which was incubated at 65 °C for 17 hrs rotating at 60 rpm. Following hybridization, the arrays were processed by post-hybridization washes. Fluorescent images were captured using an Agilent Technologies microarray scanner (Agilent Technologies). Global normalization was performed to compare genes from chip to chip using GeneSpring 10.0 (Tomy Digital Biology, Denver, CO, USA). Differentially expressed genes were identified by comparison between normal and dystrophic dogs before and after respiration. The differentially expressed genes were selected by ANOVA tests. P < 0.01 with correction for multiple testing by the Benjamini and Hochberg method for the false discovery rate, and a 5% cutoff was used. The array data were deposited in the Gene Expression Omnibus (GEO) database (Accession number: GSE32460).

Relative gene expression based on real-time RT-PCR. We picked up the genes from the microarray analyses by using of the cutoff of value as 10-fold. We used the same RNA that was isolated for the DNA microarrays and prepared cDNA using SuperScript III Reverse Transcriptase (Invitrogen, Carlsbad, CA, USA). Gene-specific primer sets were designed for the previously published dog 18 s rRNA and newly designed osteopontin, c-fos, egr-1, IL6, ILB, COX-2, Selectin E, MMP-12, and MT MTRN1 mRNA are listed in Supplemental Table 2 The primer specificity was tested by running a standard PCR using 100 ng of total RNA from normal and dystrophic dogs, and the primer was finally applied to a whole genome oligo microarray 44 K (Agilent Technologies). The mRNA levels were analyzed by real-time quantitative RT-PCR using a Bio-Rad iCycler system (Bio-Rad) and a SYBR premix Ex Taq II kit (Takara, Tokyo, Japan), and running for 40 cycles of 95 °C for 20 s and 60 °C for 1 min. Each cDNA sample was duplicated, and the corresponding no-RT mRNA sample was included as a negative control. The mRNA level of each sample for each gene was normalized to that of the 18 s RNA. The relative mRNA level was presented as 2^[(Ct/gene of interest) – (Ct/18 s rRNA = C.gene of interest)]. Expression values were normalized to 18 s rRNA and compared between normal and dystrophic dogs before and after the initial respiration in (n = 4, each).

Statistics. Direct comparisons between 2 groups of data were performed using the Student’s unpaired t-test. Multiple statistical differences between groups were compared by one-way analysis of variance (ANOVA) followed by Holm’s post-hoc test. All data are indicated as mean values ± standard error of the mean (SEM). AP < 0.05 was judged to be a significant difference.

**Acknowledgements**

We thank Hideki Kita, Shin'ichi Ichikawa, Yumiko Yahata, Takayuki Nakayama, Kazue Kinoshita, Ryoko Nakagawa, Yuko Kasahara, Takashi Saito, and Michihiro Imamura (Department of Molecular Therapy) for their technical assistance. This work was supported by a Grant-in-Aid for Research on Nervous and Mental Disorders (19A-7), a Health Sciences Research Grant for Research on Psychiatric and Neurological Diseases and Mental Health (H18-kokoro-019), a Health and Labor Sciences Research Grants for Translational Research (H19-Translational Research-003 and H21-Clinical Research-015) from the Ministry of Health, Labor and Welfare of Japan, and a Grants-in-Aid for Scientific Research (B) from The Ministry of Education, Culture, Sports, Science and Technology of Japan (21300157 to AN).

**Author contributions**

A.N. conducted the experiments and wrote the manuscript; M.K., M.K. and N.Y. performed the experiments and Caesarean sections on our colony dogs; K.Y., T.O. and S.T. participated in data interpretation and supervised the study, execution, and manuscript preparation. All authors reviewed the manuscript.
