ABSTRACT

Throughout the Milky Way, molecular clouds typically appear filamentary, and mounting evidence indicates that this morphology plays an important role in star formation. What is not known is to what extent the dense filaments most closely associated with star formation are connected to the surrounding diffuse clouds up to arbitrarily large scales. How are these cradles of star formation linked to the Milky Way’s spiral structure? Using archival Galactic plane survey data, we have used multiple datasets in search of large-scale, velocity-coherent filaments in the Galactic plane. In this paper, we present our methods employed to identify coherent filamentary structures first in extinction and confirmed using Galactic Ring Survey data. We present a sample of seven Giant Molecular Filaments (GMFs) that have lengths of order ~100 pc, total masses of ~10^5 - 10^6 M⊙, and exhibit velocity coherence over their full length. The GMFs we study appear to be inter-arm clouds and may be the Milky Way analogues to spurs observed in nearby spiral galaxies. We find that between 2 and 12% of the total mass (above ~10^20 cm^-2) is “dense” (above 10^20 cm^-2), where filaments near spiral arms in the Galactic midplane tend to have higher dense gas mass fractions than those further from the arms.

Key words. ISM – star formation – molecular clouds

1. Introduction

Star-forming clouds in the Milky Way – both nearby and distant – exhibit elongated structures (see Myers 2009 and references therein). The morphology appears most enhanced when viewing the densest part of the cloud, which is also the regime most intimately connected to star formation. From the early quiescent phase, filamentary morphology seems to be imprinted on all subsequent stages of star formation. However, the physical origin of filaments is still debated. A variety of models can produce dense, filamentary structures, though unambiguous observational diagnostics are still lacking to determine the dominant mechanism(s) leading to filament formation.

Filamentary structures have been observed in a variety of tracers, ranging from extinction maps at optical and infrared wavelengths (e.g. Schneider & Elmegreen 1979; Apai et al. 2005; Jackson et al. 2010; Schmalzl et al. 2010; Beuther et al. 2011; Kannan et al. 2012) to CO maps (Ungerechts & Thaddeus 1987; Goldsmith et al. 2008; Harcas et al. 2013) to far-infrared/sub-millimeter dust emission maps (e.g. Henning et al. 2010; André et al. 2010; Men'shchikov et al. 2010; Molnari et al. 2010; Schneider et al. 2010; Hill et al. 2011; Hennemann et al. 2012; Peretto et al. 2012). The recent results of Herschel have again highlighted the ubiquity of filaments in the interstellar medium (ISM) and thus rejuvenated interest in the role filamentary morphology plays in star formation.

In numerical models, filamentary structure is a natural consequence of a number of dynamic processes in the ISM such as converging flows (e.g. Elmegreen 1993; Vázquez-Semadeni et al. 2006; Heitsch & Hartmann 2008; Clark et al. 2012), the collision of shocked sheets (Padoan et al. 2001), instabilities in self-gravitating sheets (e.g. Nagai et al. 1998), or other analogous processes that compress gas to an over-dense interface. Such processes commonly occur in a global spiral potential (Dobbs et al. 2008). In non-self-gravitating cases, additional ingredients, such as magnetic fields and/or turbulence dissipation (Hennebelle 2013), are needed to preserve filaments with the properties observed in the ISM and in turbulent simulations. More massive filaments, such as those modeled by Fischera & Martin (2012) and Heitsch (2013a,b), are self-gravitating, thus the effects of continuing accretion from large scales and external pressure build-up play an important role in the observed properties.

A fundamental quantity in the understanding of the origin of Galactic filaments is the maximum length over which they can occur. This is challenging to observe for several reasons. First, until recently, few unbiased surveys of the Galactic plane that could potentially identify such structures existed. Second, the star formation occurring within filaments, especially massive ones, is very disruptive and impacts the clouds and clear signatures of the parent structure. As such, the quiescent stage of filaments, appearing as infrared-dark clouds (IRDCs), should better preserve the initial formation signatures compared to active clouds.

Jackson et al. (2010) identified a long infrared-dark filament that, according to models of Milky Way structure, coincides with a spiral arm structure. This so-called “Nessie” filament appears to be ~80 pc in projection, though more recent studies have found that it may be at least twice as long (Goodman et al. 2013). Further searches have found similarly enticing individual structures in the Galactic plane (e.g. Beuther et al. 2011; Batterson & Bally 2012; Tackenberg et al. 2013; Li et al. 2013), but to date, no comprehensive compilation of long, coherent structures in the Galaxy exists. In this paper, we present a new sample of Giant Molecular Filaments (GMFs) in the first quadrant of the Milky Way. We describe our methods for identifying filaments in projection using unbiased Galactic plane surveys and our follow-up method for confirming a filament’s coherence in velocity space. Our search has produced seven new filaments with lengths on the order of 100 pc, more than doubling the number of similar struc-
2. Filament identification

*Herschel* observations have recently highlighted the importance of filaments, as it tends to be the dominant morphology observed in star-forming clouds. These filaments are comprised of cold gas and dust, and the various signatures of which we will discuss below. Defining a true filament, however, is not a trivial task and requires several steps to be confirmed. Below we take the example of the field near the F26.7-25.4 filament discovered in this work as an illustration.

Wide-field mid-infrared (MIR) images have proven to be a powerful tool in finding candidate structures like Nessie, which was identified in the 8 µm/Spitzer/GLIMPSE image. This phenomenon is illustrated in the top panel of Figure 1 which shows the GLIMPSE 8 µm image of one of the regions near $l = 26\degree$ that we studied. The contours are drawn in decreasing steps, highlighting the type of absorption structure that would be in catalogs using this method (see Simon et al. 2006, Butler & Tan 2009, Peretto & Fuller 2009, Kagan et al. 2009). While this method has been successful in isolating the quiescent clouds in the Galactic plane, it alone may miss objects that could potentially have the same physical properties but lack the 8 µm background to be identified.

Alternatively, extinction of starlight at near-infrared (NIR) wavelengths can be used to trace cold, intervening dust structures (e.g. Lombardi & Alves 2001, Lombardi 2009, Kainulainen et al. 2011). In short, the amount by which starlight is dimmed is proportional to the column density of material along its line of sight. This method is most reliable in the presence of many background stars, thus it also loses effectiveness with increasing Galactic latitude.

At longer wavelengths, the structures that were absorbing in the near and mid-infrared transition to optically thin emission. The *Herschel* HIGAL survey (Molinari et al. 2010) 250 µm map of the same region is shown for comparison on the bottom panel of Figure 1. While the same structure indeed does appear in emission here, so does a strong contribution from the warm dust associated with the active star formation region. In fact, because of the way dust emission depends on dust temperature, the emission from the warm dust tends to dominate the map, overwhelming the cold, compact emission that we aim to characterize. Therefore, in the following, we create our initial catalog of candidates using the NIR and MIR absorption methods.

Regardless of the candidate’s initial identification, the true extent of a filament can only be judged after it is confirmed to be coherent in velocity space as well. We selected the Galactic Ring Survey (GRS) data which immediately limits the Galactic longitude range to $17.4\degree \leq l \leq 55\degree$. We also utilised the Wienen et al. (2012) catalog of NH$_3$ observations of ATLASGAL (Schuller et al. 2009) clumps and the Shirley et al. (2013) survey of Bolocam Galactic Plane Survey (BGPS; Aquirre et al. 2011) clumps for a secondary confirmation of velocity coherence in higher-density gas tracers. As it is not possible to *a priori* say to what degree the centroid velocity would change over the length of a genuine filament, instead of setting a maximum range, we require only that any velocity gradient be continuous to be considered “coherent.”

Both the identification and verification steps outlined above are necessarily subjective, thus we can claim no statistical robustness or completeness. The criteria we imposed were designed to identify 100 pc scale quiescent structures. In the following sections, we outline our method which was carried out by all co-authors by way of “by-eye” inspection of images.

Fig. 1. Zoom in to the eastern end of the F26.7-25.4 filament. A Grayscale GLIMPSE 8 µm image (top) is plotted with contours at -7.5, -10, -12.5... MJy sr$^{-1}$ (negative to highlight absorption feature), and the HIGAL 250 µm image (bottom) is plotted with contours drawn at 5, 6, 7... Jy beam$^{-1}$.

Fig. 2. Position-velocity (PV) diagram (integrated over all latitudes) of the region shown in Figure 1 based on the Galactic Ring Survey data. The approximate positions of the spiral arm features in this longitude range from the Vallée (2008) model are labeled in white, and the filament which we identify, GMP 26.7-25.4, is labeled in red.
2.1. Creating the candidate catalog

We first selected image databases that provide unbiased and contiguous coverage in the Galactic plane. The Spitzer Galactic plane survey, GLIMPSE (Benjamin et al. 2003), is the ideal tool for identifying analogs to the known long filaments like Nessie (Jackson et al. 2010). We used the GLIMPSE/MIPSGAL image viewer. For a filament to be considered as a candidate, the absorption feature was required to extend ~1° end to end and be identified by at least three group members. We allowed for gaps in extinction, usually at sites of star formation, if the extinction structure continued further.

As an alternative and supplement to the GLIMPSE data, we use the UKIDSS Galactic Plane Survey (GPS) (Dye et al. 2006; Warren et al. 2007), which provide large NIR image mosaics with large Galactic latitude range (up to |b| ≤ 2.5°) in the northern hemisphere. The same ~1° extent and three group member confirmation was required for filament candidates to be identified in this fashion.

In total, these two methods yielded twelve candidates within the longitude range of the GRS. They are listed in Table 1. In the following section, we outline the method by which we verified that the filaments were single entities rather than multiple structures superimposed along the sightline.

2.2. Filament verification using GRS

The second step of the process is to validate the velocity coherence using the GRS survey. The publicly-available GRS data cover a velocity range from -5 to 85 km s\(^{-1}\) (or -5 to 135 km s\(^{-1}\) for l < 40°). We first created position-velocity (PV) diagrams over the full available velocity range within the longitude boundaries, integrating along the b direction, an example of which is shown in Figure 2. In some cases (e.g. GMF 41.0-41.3) we constructed the PV diagram by integrating along the longitude direction. As is clear in Figure 2, several possible features could correspond to the extinction structure, so to determine which is the best match, we created integrated intensity maps for each of the velocity ranges, which we then plotted together with the extinction image. Again, requiring verification from 3 group members, we selected the velocity features which corresponded best to the morphology of the feature seen in extinction or absorption.

Figure 2 shows that features in a PV diagram can span different ranges in velocity, i.e. widths of the horizontal band features, from a few to tens of km s\(^{-1}\); we placed no restriction on the maximum width. We list the full velocity ranges in Table 2, which can be as small as 5 km s\(^{-1}\) or as large as 13 km s\(^{-1}\). Figures A.1 through A.6 show the centroid velocity maps. As with Nessie, in which the HNC J = 1→0 centroid velocities vary by less than 7 km s\(^{-1}\) over its ~81 pc length, we find similarly small overall gradients. In Section 3, we will discuss the properties of the final filament sample in more detail.

Through this step, we eliminated candidates F29.2-27.6, F25.9-21.9, F23.8-22.8, and F20.3-19.9 because they were not found to have a common velocity over the full length, but instead were superpositions of multiple velocity components. The remaining eight candidates, two of which (F38.1-35.3 and F35.0-32.4) ended up as one coherent object, are henceforth termed “Giant Molecular Filaments” (GMFs) and are described in more detail in the next section.

2.3. Biases in our filament identification

Both extinction methods work best in the midplane of the Galaxy since the mid-infrared background and the density of background stars are both high. Dense filaments that lie out of the Galactic midplane tend to lack the contrast to be identified in 8μm extinction and may also lack a sufficient number of background sources to be appreciable in NIR extinction. Though we did not restrict the latitudes any narrower than the extent of the various surveys, the confirmed filaments have latitudes within a degree of 0°. Another consequence of using the extinction method is that we are unlikely to detect structures any further than 6 to 8 kpc (see Ragan et al. 2012).

Our candidate identification method also biases us in favour of identifying quiescent structures. Star formation events, if luminous enough, can disrupt a cloud sufficiently such that it will no longer appear as a continuous extinction structure. For example, the G32.02+0.06 filament described in Batterby & Bally (2012), while in the longitude range of our search, was not identified as a candidate because it shows strong star formation activity, which disrupts the extinction signature that we sought in our hunt for quiescent structures.

The GRS confirmation step also has its limitations. Many sight lines in the Galactic plane exhibit multiple velocity components in 13CO, and with the inherent distance ambiguity problem (e.g. Roman-Duval et al. 2009), distance determination is far from straightforward. As mentioned above, we have adopted the near distance for the velocity component most closely matching the morphology of the absorbing structure. As a secondary verification, we also consult additional catalogs of dense-gas tracer observations, namely the Wienen et al. (2012, hereafter W12) NH\(_3\) survey of dense ATLASGAL clumps, Red MSX survey (RMS Lumsdon et al. 2013), or the Shirley et al. (2013, hereafter S13) N\(_2\)H\(^+\) and HCO\(^+\) follow-up survey of clumps in the Bolocam Galactic Plane Survey. Though these are catalogs of pointed observations rather than unbiased maps, these tracers more closely probe the densest structures, thus enabling us to validate the association of these emission peaks with the large scale coherent velocity structure seen in the GRS data.

| Table 1. Extinction filament candidates within GRS longitude range |
|------------------------|----------------|----------------|----------------|----------------|
| Initial name | Lower l | Upper l | Lower b | Upper b |
| F18.0-17.5 | 17.4 | 18.3 | +0.0 | +0.7 |
| F20.3-19.9 | 19.5 | 20.4 | -1.3 | +0.2 |
| F20.0-17.9 | 17.6 | 20.2 | -0.7 | +0.3 |
| F23.8-22.8 | 22.1 | 23.8 | +0.8 | +2.0 |
| F25.9-21.9 | 21.7 | 26.2 | -1.0 | +0.5 |
| F26.7-25.4 | 25.2 | 27.0 | +0.5 | +2.2 |
| F29.2-27.6 | 27.2 | 29.4 | -0.5 | +0.5 |
| F35.0-32.4 | 32.3 | 36.0 | -0.3 | +0.8 |
| F35.3-34.3 | 33.7 | 35.6 | -2.0 | +0.4 |
| F38.1-35.3 | 34.6 | 38.9 | -0.9 | +0.6 |
| F41.0-41.3 | 40.8 | 41.4 | -0.8 | +0.5 |
| F54.0-52.0 | 48.0 | 54.4 | -0.5 | +0.7 |

3. Results

3.1. A sample of 7 velocity coherent filaments

We find seven velocity coherent filaments in the longitude range of the GRS, the basic properties of which are listed in Table 2. In Figures A.1 through A.6 we show the GLIMPSE 8 μm image in greyscale. We label sources associated with star formation, such as Westerhout objects (Westerhout 1958), bright (S_{12} μm > 100 Jy) IRAS sources, and Hii regions detected in the CORNISH survey (Parcell et al. 2013). We show contours of ^13 CO integrated intensity (white) and ATLAGAL 870 μm emission (blue) to give an impression of the envelope and dense gas areas, respectively.

In the colour panels, the first moment (centroid velocity) map of ^13 CO is displayed. We plot the positions of all clumps from the Bolocam Galactic Plane Survey (BGPS, Rosolowsky et al. 2010; Aguirre et al. 2011). Using the Shirley et al. (2013) follow-up measurements of both the HCO^+ and N2H^+ tracers, the BGPS clumps are marked with circles if their adopted vlsr lies within the velocity range of the GMF, and they are marked with an x if the velocity is outside of that range. We mark with diamonds the positions of W12 NH3 clumps with velocities in the range. This secondary check against the catalogs of dense gas tracers helps us to validate that the dense gas is at the same distance as the ^13 CO cloud from the GRS.

To place the filaments in a Galactic context, we display latitude of the physical Galactic midplane when possible. Because the Sun lies ~25 pc above the Galactic midplane, the Galactic coordinate (l,b) = (0.0) does not actually coincide with the location of the Galactic center (Blaauw et al. 1960). Consequently, at the typical distances of the structures in this sample, the physical midplane is closer to b ~ 0.5°. In most cases, the filaments we identify lie within the real midplane. We note the average projected height off of the plane in parsecs in Table 3.

Finally, we note the association in longitude and velocity space to the predicted positions of the spiral arms of the Milky Way as compiled by Vallée (2008). In most cases, we find little or no association between the filaments and spiral arm structures, in contrast with the recent findings of Goodman et al. (2013) regarding the Nessie filament. In the following, we describe each GMF individually, noting their association (or lack thereof) with other well-known regions of star formation and the predicted positions of spiral arms.

### Table 2. GMFs with coherent velocities

| Initial name | Lower l [°] | Upper l [°] | Lower b [°] | Upper b [°] | Angular length [°] | Velo. range [km s^{-1}] | Distance length [kpc] | < vlsr [km s^{-1} kpc^{-1}] |
|--------------|-------------|-------------|-------------|-------------|---------------------|-------------------------|-------------------|-------------------|
| GMF18.0-16.8 | 16.4        | 18.3        | 0.0         | +1.2        | 2.5                 | 21 - 25                 | 2.1 - 2.4         | 98                |
| GMF20.0-17.9 | 17.6        | 18.2        | -0.7        | +0.3        | 1.8                 | 37 - 50                 | 3.3 - 3.7         | 110               |
| GMF26.7-25.4 | 25.2        | 26.7        | +0.5        | +2.2        | 2.0                 | 41 - 51                 | 2.9 - 3.3         | 108               |
| GMF38.1-32.4a| 33.4        | 37.1        | -0.4        | +0.6        | 3.8                 | 50 - 60                 | 3.3 - 3.7         | 232               |
| GMF38.1-32.4b| 34.6        | 35.6        | -1.0        | +0.2        | 1.5                 | 43 - 46                 | 2.8 - 3.0         | 76                |
| GMF41.0-41.3 | 40.8        | 41.4        | -0.5        | +0.4        | 1.3                 | 39 - 42                 | 2.7 - 2.8         | 62                |
| GMF54.0-52.0 | 52.3        | 54.1        | -0.3        | +0.3        | 2.2                 | 20 - 26                 | 1.9 - 2.2         | 79                |
| Nessie₂      | 337.7       | 339.1       | -0.6        | -0.4        | 1.5                 | 35 - 41                 | (3.1)            | 81                |
| G32.02+0.06³  | 31.3        | 32.2        | -0.1        | 0.3         | 1.0                 | 92 - 100                | 5.5 - 5.6         | 80                |

Column 1: GMF name; Column 2-5: upper and lower Galactic longitude and latitude; Column 6: Angular length of the filament from end to end in degrees; Column 7: Centroid velocity range spanned by filament in km s^{-1}; Column 8: Kinematic “near” distance computed using the Reid et al. (2009) model assuming standard Galactic parameters; Column 9: Projected length of filament; Column 10: Average velocity gradient along filament. Comments: (1) This filament may extend to higher latitudes not probed by the current data. (2) From Jackson et al. (2010). (3) From Battersby & Bally (2012).

3.1.1. GMF 18.0-16.8

This filament is at the edge of the longitude coverage of the GRS, but the supplemental velocity information provided by the W12 catalog confirms that it extends to l ~ 16.8°. Figure A.1 shows this filament in a narrow velocity range (21-25 km s^{-1}). To the north of this filament lies M16, also known as the Eagle Nebula, estimated to be roughly 2 kpc from the Sun (Hill et al. 2012), which is in agreement with the distance derived to the rest of the structure we find. We find 16 BGPS clumps from the S13 catalog and 6 clumps from the W12 catalog that have consistent velocities.

This structure lies well above the location of the Galactic midplane. According to the Vallée (2008) model, the velocity of this filament appears to agree with the predicted value of the Perseus spiral arm, however at this longitude the Perseus arm begins from the “far” side of the Galaxy at 12 kpc distance. Due to its close association with M16 and strong extinction features, we maintain our adoption of the “near” kinematic distance, which means it is unrelated to the Perseus arm.

3.1.2. GMF 20.0-17.9

GMF 20.0-17.9, shown in Figure A.2 was already identified in part by Tackenberg et al. (2013) and exhibits an arc-like projection between two “bubble” structures. There are 39 BGPS clumps within the velocity range, and 16 ATLASGAL clumps exhibiting consistent velocities in NH3 (W12). This field also contains 100 BGPS clumps with large velocity offsets from the given range. In fact, each MIR-bright region has associated Hii regions with velocities around 65 km s^{-1} (Urquhart et al. 2011), and thus appear to be unrelated to the filament we find at 37 to 50 km s^{-1}, W39, on the other hand, does have a consistent velocity (Parcell et al 2013).

The Galactic midplane appears to intersect with this filament, and its velocity agrees fairly well with that of the Scutum-Centaurus (SC) spiral arm (Vallée 2008). It is possible, like in L1 et al. (2013), that a massive star formation event, in this case probably associated with W39, may have carved the arc-like structure seen in this filament.
3.1.3. GMF 26.7-25.4

While GMF 26.7-25.4, shown in Figure A.3, appears parallel to the Galactic plane, it lies ~1.3°, or ~66 pc, above the physical midplane. Also as a consequence of its high latitude, it is poorly covered by the BGPS spectroscopic survey, and the W12 catalog only finds one source with a consistent velocity. This also appears to be one of the most quiescent filaments in that there are no prominent IR sources, except IRAS 18348-0526, and the only two HII regions cataloged in the CORNISH survey appear to be at different velocities according to the corresponding W12 measurements.

3.1.4. GMF 38.1-32.4: two overlapping structures

Perhaps unsurprisingly, at longitudes near the meeting place of the bar and spiral arm of the Galaxy, this region has multiple objects of interest. Between longitudes 32° and 38°, three candidates were identified in extinction (see Table 1). Upon examination in the GRS data, we found that F38.1-35.3 and F35.0-32.4 were connected in velocity space (between 50 and 60 km s$^{-1}$), and F35.3-34.3, which overlaps with the previous two, had distinct velocities offset to lower values (43 to 46 km s$^{-1}$). While the latter structure (GMF 38.1-32.4b) is not especially elongated along the Galactic plane, it still has length ~80 pc. The former (GMF 38.1-32.4a), which is very much extended along the midplane, is the longest and most massive object in our sample. We show both velocity components in Figure A.4.

The different velocity ranges indicate that these filaments lie at different distances. The larger filament (GMF 38.1-32.4a) is also further away and has 85 BGPS (S13) clumps and 12 W12 clumps within its velocity range. W44 is a massive dense clump at 3.7 kpc (Solomon et al. 1987), consistent with the distance of GMF 38.1-32.4a. The smaller filament (GMF 38.1-32.4b) coincides with 9 BGPS clumps in its velocity range. Since it is nearer than the first, the projection of the Galactic midplane (dashed line) is at slightly lower latitude with which it intersects. There are another 149 BGPS clumps whose velocities coincide with neither of the filaments identified here, and there are 18 HII regions detected by CORNISH, but given the confusion in this region, it is difficult to determine which are associated with the filaments.

3.1.5. GMF 41.0-41.3

This filament extends mainly perpendicular to the Galactic plane, unlike most of the rest of the sample. There are three BGPS sources with consistent velocities, one W12 NH$_3$ clump, but no CORNISH HII regions. As shown in Figure A.5, the projected Galactic midplane just barely intersects with the southernmost tip of the filament.

The central IR-bright region corresponds to the position of supernova remnant 3C397 and the BGPS clumps in that region are at velocity of ~60 km s$^{-1}$, well outside of the selected velocity range for the filament. This filament corresponds to molecular gas that is thought to be in the foreground of the remnant, which also serves to confine the remnant (Jiang et al. 2010). Otherwise, this filament appears rather quiescent.

3.1.6. GMF 54.0-52.0

Part of this filament has been identified recently by Kim et al. (2013), who find it is in an early phase of cluster formation relative to standard local molecular clouds. GMF54.0-52.0 shares a common projected area with the 500 pc gas wisp identified in Li et al. (2013), which coincides with the Perseus spiral arm on the far side of the Galaxy (Dame et al. 2001). Here, we study gas in a different velocity range (20 to 26 km s$^{-1}$) displayed in Figure A.6.

Within this structure, there are 18 BGPS clumps which have velocities between 20 to 26 km s$^{-1}$. Three HII regions were detected in this range in the CORNISH survey, but none appear to have consistent velocities. W52 is projected in the vicinity, but there is not independent measurement of its velocity in the literature. The IR-bright region to the west resides at a different velocity (2.6 km s$^{-1}$) and thus appears to be a unassociated region of (high-mass) star formation (Urquhart et al. 2011). Therefore, although the IR image would lead one to conclude that this filament is vigorously forming stars, it appears largely devoid of the signposts explored here.

3.2. Physical properties

Next we derive the basic physical properties of each GMF. By first deriving the kinematic distance, we can then calculate the size, mass and density of each GMF. We provide the values for the analogous structures Nessie (Jackson et al. 2010) and G32.02+0.06 (Battersby & Bally 2012) for comparison.

3.2.1. Kinematic distance, length, and mean velocity gradient

Our sample of filaments exhibits large-scale velocity coherence in that they have relatively smooth velocity gradients in a continuous elongated structure. We use the velocities to derive a kinematic distance range according to the BeSSeL results (Reid et al. 2009) assuming the standard Galactic parameters. The velocity ranges and the corresponding kinematic distance ranges are listed in Table 2.

We measure the angular length from end to end of the significant $^{13}$CO emission (above 1 K km s$^{-1}$) in the selected velocity range and convert these to physical length using the mean kinematic “near” distance. We have not attempted to correct for projection effects, thus the lengths reported in Table 2 are lower-limits. The maximum projected length is 232 pc for GMF 38.1-32.4a, which interestingly is one of the filaments that agrees most closely to the location of the Galactic midplane. Determining the width of the GMFs, which is substantially different between the dense gas structure and the large scales traced by $^{13}$CO, is not a trivial task and beyond the scope of this paper. A comprehensive study of the widths, their relationship with each other and to their galactic environment, will be addressed in a future paper.

We compute the average velocity gradient over the entire length of the filament. We find values between 40 and 80 km s$^{-1}$ kpc$^{-1}$, and longer filaments tend to exhibit larger mean velocity gradients. No correlation exists between velocity gradient and longitude or distance. We list the values in Table 2.

3.2.2. Mass

We calculate the filament mass in two ways: first using dust emission, which is a useful probe the densest gas, and second using the $^{13}$CO emission to probe the total mass in the cloud. To restrict our measurements to equivalent areas, we first create masks using the significant $^{13}$CO emission (>{1 K km s$^{-1}$}) in the indicated velocity ranges (see Table 2), which is the area shown in boldface letters in Figure A.6.

Article number, page 5 of 15
In order to determine the total amount of dense gas, we use dust emission from the ATLASGAL 870 μm dust emission survey (Schuller et al. 2009). Due to filtering out of large-scale emission, the ATLASGAL data are sensitive primarily to the densest gas. After the 13CO masking, we uniformly impose an additional emission threshold of 250 mJy (5 σ) and compute the column density assuming a temperature of 20 K, gas-to-dust ratio of 100, and a dust opacity at 870 μm of 1.42 g cm²⁻¹, interpolated from Ossenkopf & Henning (1994). With these assumptions, our column density sensitivity is of the order 10⁻³⁷ cm⁻². Assuming the mean distance to each filament, we calculate the total dense gas mass. We find dense gas mass values that range between 8 and 500 × 10⁴ M☉. They are listed in Table 3.

To calculate the mass of the cloud, we use the 13CO emission above 1 K km s⁻¹ within the selected velocity range. 13CO(1-0) is considerably more widespread than the dust emission because it is excited in low density (< 1 K km s⁻¹); Column 3: Dense gas mass fraction; Column 4: Galactocentric radius; Column 5: Angle measured from the Galactic centre-Sun line to the filament's position in the disk; Column 6: Mean height above the Galactic midplane. Values in parentheses are for filaments which intersect with the projected plane. Column 7: Association with star formation region or spiral arm.

Comments: (1) The dense gas mass from the two filaments within GMF 38.1-32.4 partly overlap. While the envelope mass estimated from spec-troscopic CO data accounts for the di

terent velocity components, in the overlap regions, the ATLASGAL continuum data sums contributions from both components.

3.2.3. Dense gas mass fraction (DGMF)

A number of recent studies of star formation in Milky Way molecular clouds have arrived at the consensus that one key quantity governing the efficiency with which a cloud forms stars is the fraction of the “dense” gas in a molecular cloud (Goldsmith et al. 2008; Heiderman et al. 2010; Lada et al. 2010, 2012), often referred to as the dense gas mass fraction (DGMF). We calculate the DGMF by taking the ratio of dense gas to total cloud mass over the same areas. We find DGMF values between 1.6 and 12.0%, with a mean of 5.4%. These values are generally consistent with the DGMF found in local star-forming clouds (Kainulainen et al. 2009; Lada et al. 2010, high-mass star-forming clumps; Johnson et al. 2009; Battisti & Heyer 2014), and other large molecular filaments (Kainulainen et al. 2011; Battisper & Bally 2012).

While the DGMF tends to go down with increasing Galactocentric radius, we also find that GMFs centred (in latitude) closer to the Galactic midplane tend to have higher DGMF values than those significantly out of the plane. These trends are visualised in Figure 3, in which we show the height above the plane as a function of Galactocentric radius. The size of the circle corresponds to the DGMF compared to the mean (shown in the upper right). The most extreme example of a filament out of the plane, the perpendicular filament GMF 41.0-41.3, has the smallest DGMF (1.6%) while GMF 20.0-17.9, the filament closest to the Galactic midplane, exhibits a DGMF of 50% (Goodman et al. 2013), though because HCN emission was used to compute the total cloud mass (instead of 13CO emission as in this paper) this value may be inflated. Still, it appears that the DGMF is connected to the location and environment of the filament. We acknowledge that these trends are weak and statistically robust with the present data, thus we refrain from any further quantitative analysis.

Table 3. Physical properties of GMFs

| Name      | Cloud mass [M☉] | Dense gas mass [M☉] | DGMF [%] | Rgal [kpc] | β [degrees] | <z> [pc] | Assoc. |
|-----------|-----------------|---------------------|----------|------------|-------------|---------|-------|
| GMF18.0-16.8 | 1.5e+5           | 3.9e+3              | 2.7      | 6.5        | 4.6         | 55      | M16, W37 |
| GMF20.0-17.9 | 4.0e+5           | 4.8e+4              | 12.0     | 5.0        | 7.7         | (12)    | W39, SC-arm |
| GMF26.7-25.4 | 2.0e+5           | 1.3e+4              | 6.5      | 5.7        | 9.4         | 68      |        |
| GMF38.1-32.4a | 7.0e+5           | 3.7e+4              | 5.3      | 5.9        | 12.8        | (24)    | W44    |
| GMF38.1-32.4b | 7.7e+4           | 5.0e+3              | 6.5      | 6.2        | 11.5        | (5)     |        |
| GMF41.0-41.3 | 4.9e+4           | 7.7e+2              | 1.6      | 6.5        | 12.5        | 19      |        |
| GMF54.0-52.0 | 6.8e+4           | 2.4e+3              | 3.5      | 7.3        | 11.2        | 25      | W52    |
| Nessie     | 3.9e+5           | 3.0e+4              | 15.0     | 4.7        | 19.7        | 48      |        |
| G32.02+0.06 | 2.0e+5           | 3.0e+4              | 15.0     | 4.7        | 19.7        | 48      |        |

Column 1: GMF name; Column 2: Total cloud derived from the integrated 13CO emission from the GRS down to 1 K km s⁻¹; Column 3: Dense gas mass derived from dust continuum with ATLASGAL 870 μm data; Column 4: Dense gas mass fraction; Column 5: Galactocentric radius; Column 6: Angle measured from the Galactic centre-Sun line to the filament’s position in the disk; Column 7: Mean height above the Galactic midplane. Values in parentheses are for filaments which intersect with the projected plane. Column 8: Association with star formation region or spiral arm.

Note that in the case of F38.1-32.4, since there are two overlapping filaments at different velocity ranges, the computed dense gas mass for each structure includes a contribution from the unrelated cloud.

The observed gradient with Galactocentric radius was fit wight he following linear relation 12C/13C = 5.41 Rgal + 19.03.

Article number, page 6 of 15
We find that the GMFs do not correlate well with the spiral arm loci (see also Figure 2). One exception, GMF 20.0-17.9, appears to intersect with the locus of the SC arm at low-l end. If one does the same exercise for Nessie in the fourth quadrant of the Galaxy, the filament corresponds precisely to the SC arm prediction, as has been confirmed by Goodman et al. (2013).

The schematic shown in Figure 4 shows where the arm has its peak density, but the actual arm width and its projection into $v_{lsr}$ are not well-defined. It is thus worth exploring the margin by which the GMFs seem to deviate from the arms. Estimates of spiral arm width in the literature range from 0.1 to 0.4 kpc (Vallee 2008, Reid et al. 2009). Typical uncertainties in the kinematic distance method are of order 0.5 kpc, so up to a 1 kpc range uncertainty must be allowed for in this discussion. GMF 18.0-16.8, GMF 20.0-17.9 and GMF 26.7-25.4 are in the longitude range intersecting with the SC arm, and at those longitudes, the SC arm should roughly lie 3.5, 3.7 and 4.3 kpc from the Sun. The median distances to those GMFs are 2.3, 3.5 and 3.1 kpc, so only GMF 20.0-17.9 falls within the uncertainty range. Similarly the nearer Sagittarius arm lies at 1 kpc at l=18°, gradually increasing to 2 kpc at l=41°, yet the GMFs are all more distant than this arm by more than 1 kpc (except GMF 41.0-41.3 which is ~700 pc from the Sagittarius arm locus). Even with these considerations, the GMFs appear to be largely inter-arm in nature: more distant the nearby Sagittarius spiral arm and foreground to the prominent SC arm.

We find that most filaments are centred near or above the physical Galactic midplane. The approximate position of the physical midplane is shown in Figures A.3, A.4 and A.5, in the other cases, the midplane is too far south to be shown in the panel. In Table 3 we compute the average height above the midplane in parsecs. There are three cases – GMF 20.0-17.9 and GMF 38.1-32.4 (a and b) – where the filament intersects with the estimated position of the midplane of the Milky Way. GMF 20.0-17.9 and GMF38.1-32.4a are also the two most massive and two longest filaments in the sample. Otherwise, the filaments do not agree well with the Galactic midplane and, as in the case of GMF 41.0-41.3, can be oriented more perpendicular to the plane. If one performs the same exercise with Nessie, it exactly coincides with the latitude range of the Galactic midplane (Goodman et al. 2013).

That we have identified most of the GMFs are above the physical midplane is perhaps not surprising given the parameters of most Galactic plane surveys. It is unlikely that GMFs preferentially reside above the plane. Due to the fact that most Galactic Plane Surveys to date have a narrow latitude coverage centred on $b = 0^\circ$, while the true midplane is in fact at negative latitudes due to the Sun’s height above the plane, analogous structures below the midplane would reside at latitudes $b < 0.5^\circ$.

Though our statistics are limited, the masses and DGMFs for GMFs within the physical midplane tend to be higher than for those out of the plane (GMF 26.7-25.4 seems to be the exception here, with a high DGMF and large offset from the plane). What seems to play an even stronger role (though our statistics are limited) is the association with spiral arms. For instance, GMF 20.0-17.9 is the single filament we find that is near a spiral arm, both in longitude-velocity space and latitude. It also has the highest DGMF of the sample. Nessie, another bona-fide spiral arm filament (Goodman et al. 2013) has a DGMF of roughly 50%. The tendency of spiral arm clouds to have higher DGMFs would be consistent with what is found in M51 by Hughes et al. (2013). They found that molecular clouds within the spiral arms have a higher fraction of gas at high densities than inter-arm clouds. If this trend for GMFs to have higher DGMF within spiral arms is
validated with a larger sample, it would indicate that the position of a (filamentary) cloud structure with respect to the spiral arms plays a central role in determining its DGMF and hence its star formation.

4.2. GMFs: Milky Way inter-arm clouds or spurs?

One of the fundamental questions in studies of spiral galaxies is what role (if any) do the spiral arms play in the production of stars in galaxies? While molecular gas is observed to be more concentrated in the spiral arms, whether the arm itself plays a direct role in inducing star formation is not clear. The inter-arm nature of the GMFs we have identified make them important population with which to investigate the role of spiral arms in the Milky Way, as they are probably more appropriate clouds to compare with those studied in external galaxies than nearby molecular clouds. For example, the PAWS survey of M51 (Schinnerer et al. 2013) represents the current state-of-the-art in extragalactic studies, reaching 40 pc resolution and a mass sensitivity of 1.2×10^6 M⊙ (Colombo et al. 2014). If the GMFs resided in M51, most would be resolved and detectable.

Inter-arm cloud populations have been scrutinised observationally in external galaxies (Elmegreen 1980; Aalto et al. 1999; Scoville et al. 2001; Shetty et al. 2007; Foyle et al. 2010; Hughes et al. 2013; Colombo et al. 2014), in the Milky Way (Robotham et al. 2010; Moore et al. 2012; Eden et al. 2013) and in numerical simulations (e.g. Kim & Ostriker 2002; Chakrabarti et al. 2003; Dobbs et al. 2006; Shetty & Ostriker 2006). The history of inter-arm clouds is related to so called “spurs” or “feathers” emanating from the spiral arms, which have been credited to either the growth of gravitational or magneto-Jeans instabilities preferentially perpendicular to the arm (Balbus 1988) or, alternatively, to the rotational shearing of over-densities in the spiral arm itself (Dobbs et al. 2006; Shetty & Ostriker 2006). While the exact properties and lifetimes of spurs and inter-arm features are subject to ongoing theoretical work, only recently have observations been able to systematically study inter-arm clouds in external galaxies at high enough angular resolution to probe individual molecular cloud scales (e.g. the PAWS survey Schinnerer et al. 2013).

Both observations and simulations of spiral galaxies indicate that spurs and strong inter-arm features are most prominent on the trailing side of spiral arms in the outer regions of disk galaxies. The situation for inter-arm clouds appears to get significantly more complex in the inner regions of galaxies, where spiral arms are more tightly wound. For an illustrative example, one need not look further than the arm of the Whirlpool galaxy at 13CO (GMFs) based on initial identification in mid-infrared extinction seen in the Spitzer/GLIMPSE images and confirmation of velocity coherence using 13CO data from the Galactic Ring Survey. We require an angular length of at least 1 degree, and after confirmation we found that these structures ranged from 60 to 230 pc in length. We calculate their total masses in using both the 13CO and complementary dust emission data at 870 μm from the ATLASGAL survey to trace the total cloud and the dense gas mass, respectively. We find the ratio between the two (the DGMF) to range between 2 and 12%, consistent with measurements in local star-forming clouds and a recent estimate of the galactic mean Battisti & Heyer 2014).

Most filaments have some association with – at most – a low level of star formation. As our technique requires the GMFs to appear in extinction, we are especially sensitive to quiescent clouds. Using their positions and velocities, we place the GMFs
in the Galactic context using a model of the Milky Way’s kinematic structure. We find that most GMFs appear to be spiral arm spurs or inter-arm clouds to which extinction studies may be especially sensitive in the first quadrant due to our orientation with respect to the Scutum-Centaurus spiral arm. The DGMF in the GMFs is tentatively correlated with their environment: the closer a GMF is to the physical Galactic midplane and to a spiral arm structure, the higher its DGMF tends to be, though better statistics are needed to confirm this in the entire Milky Way plane. If this trend is genuine, it would mirror what is observed in M51 by Hughes et al. (2013) where the molecular clouds within spiral arms have a higher fraction of dense gas than inter-arm clouds. As such, the GMFs could play an important role in connecting the Milky Way to other galaxies and provide a tool for studying the small scale effects of feedback and dynamics in the inter-arm regions. This sample of seven GMFs is a starting point in thoroughly mining the Galactic plane in all quadrants, which will allow for a statistically robust study of the link between GMFs and Galactic structure.

Appendix A: Image gallery
Fig. A.1. Top: Grayscale of the 8 µm GLIMPSE image of F18.0-16.8. The white contour shows the 13CO integrated intensity of 2 and 7 K km s\(^{-1}\). The blue contour is ATLASGAL 870µm emission of 250 mJy beam\(^{-1}\). IRAS sources and W37 are marked with red stars, and H\(\text{ii}\) regions found in the CORNISH survey are shown in red circles. M16 is a prominent emission source in this region, north of the filament but at a consistent characteristic velocity. Bottom: Colourscale of the centroid velocity field from the GRS 13CO data where the integrated intensity is above 1 K km s\(^{-1}\) in the indicated velocity range, shown in the colour bar in km s\(^{-1}\). In circles, we show all \(v_{\text{lsr}}\) measurements of BGPS clumps that have velocities within the 13CO velocity range and with \(\times\) those \(v_{\text{lsr}}\) values outside of the 13CO velocity range. The diamonds are positions in the Wienen et al. (2012) catalog with a matching velocity. The black contours are the 13CO integrated intensity at 2 and 7 K km s\(^{-1}\).
Fig. A.2. Top: Grayscale of the 8 µm GLIMPSE image of F20.0-17.9. The white contour shows the $^{13}$CO integrated intensity of 3.5 K km s$^{-1}$. The blue contour is ATLASGAL 870µm emission of 250 mJy beam$^{-1}$. IRAS 18248-1229 and W39 are both labeled with red stars, and Hii regions from the CORNISH survey are marked with red circles. The black line is the location of the Galactic plane at the distance of this filament. Bottom: Colour scale of the centroid velocity field from the GRS $^{13}$CO data where the integrated intensity is above 1 K km s$^{-1}$ in the indicated velocity range, shown in the colour bar in km s$^{-1}$. In symbols, we show all $v_{\text{lsr}}$ measurements of BGPS clumps, indicating in circles those clumps that have velocities within the $^{13}$CO velocity range and with $\times$ those $v_{\text{lsr}}$ values outside of the $^{13}$CO velocity range. The diamonds are positions in the [Wien et al. (2012)] catalog with a matching velocity. The black contour is the $^{13}$CO integrated intensity at 3.5 K km s$^{-1}$. 
Fig. A.3. Top: Grayscale of the 8 µm GLIMPSE image of F26.7-25.4. The white contour shows the $^{13}$CO integrated intensity of 2 K km s$^{-1}$. The blue contour is ATLASGAL 870 µm emission of 250 mJy beam$^{-1}$. The red star is the position of IRAS 18348-0526, and the red circles are CORNISH detected H$n$ regions. Bottom: Colourscale of the centroid velocity field from the GRS $^{13}$CO data where the integrated intensity is above 1 K km s$^{-1}$ in the indicated velocity range, shown in the colour bar in km s$^{-1}$. The circle indicates a pointing from the Wielen et al. (2012) NH$\textsc{iii}$ catalog that has a consistent velocity, though the other two pointings (×, in the bottom right corner) have velocities outside of the $^{13}$CO range. The diamonds are positions in the Wielen et al. (2012) catalog with a matching velocity. The black contour is the $^{13}$CO integrated intensity at 2 K km s$^{-1}$. 

Article number, page 12 of 15
Fig. A.4. Centre: Grayscale of the 8\,µm GLIMPSE image of F38.1-32.4. The white contour shows the \(^{13}\)CO integrated intensity of 0.5 K km s\(^{-1}\) between 50 and 60 km s\(^{-1}\) (bottom), and the yellow contour shows the \(^{13}\)CO integrated intensity of 0.5 K km s\(^{-1}\) between 43 and 46 km s\(^{-1}\) (top). The blue contour is ATLASGAL 870\,µm emission of 250 mJy beam\(^{-1}\). Red stars indicate the positions of IRAS sources and W44, and red circles are the positions of H\textsc{ii} regions from the CORNISH survey. The solid black line is the location of the Galactic plane at the distance of the 50-60 km s\(^{-1}\) filament, and the dashed black line corresponds to the plane at the distance of the 43-46 km s\(^{-1}\). Top and bottom: Colourscale of the centroid velocity field from the GRS \(^{13}\)CO data for the 43 to 46 km s\(^{-1}\) (top) and 50 to 60 km s\(^{-1}\) (bottom) filaments where the integrated intensity is above 1 K km s\(^{-1}\) in the indicated velocity range, shown in the colour bar in km s\(^{-1}\). In symbols, we show all \(v_{\text{lsr}}\) measurements of BGPS clumps, indicating in circles those clumps that have velocities within the respective \(^{13}\)CO velocity ranges and with \(\times\) those \(v_{\text{lsr}}\) values outside of the \(^{13}\)CO velocity ranges. The diamonds are positions in the [Wienen et al., 2012] catalog with a matching velocity. The black contours are the \(^{13}\)CO integrated intensity of 2 and 7 K km s\(^{-1}\).
Fig. A.5. Left: Grayscale of the 8 µm GLIMPSE image of F41.0–41.3. The white contour shows the 13CO integrated intensity of 1 K km s\(^{-1}\). The blue contour is ATLASGAL 870µm emission of 250 mJy beam\(^{-1}\). The solid black line shows the location of the Galactic midplane at the distance of this filament. The solid black line is the location of the Galactic plane at the distance of this filament. The supernova remnant 3C397 is the (unrelated) bright IR emission region. Right: Colourscale of the centroid velocity field from the GRS \(^{13}\)CO data where the integrated intensity is above 1 K km s\(^{-1}\) in the indicated velocity range, shown in the colour bar in km s\(^{-1}\). In symbols, we show all \(v_{lsr}\) measurements of BGPS clumps, indicating in circles those clumps that have velocities within the \(^{13}\)CO velocity range and with \(\times\) those \(v_{lsr}\) values outside of the \(^{13}\)CO velocity range. The diamonds are positions in the Wienen et al. (2012) catalog with a matching velocity. The black contours are the \(^{13}\)CO integrated intensity of 2 and 7 K km s\(^{-1}\).
Fig. A.6. Top: Grayscale of the 8\,µm GLIMPSE image of F54.0-52.0. The white contour shows the 13CO integrated intensity of 2\,K\,km\,s^{-1}. The blue contour is ATLASGAL 870\,µm emission of 250\,mJy\,beam^{-1}. The red star shows the location of W52, and the red circles show CORNISH detections of H\textsc{ii} regions. Bottom: Colourscale of the centroid velocity field from the GRS 13CO data where the integrated intensity is above 1\,K\,km\,s^{-1} in the indicated velocity range, shown in the colour bar in km\,s^{-1}. In symbols, we show all $v_{lsr}$ measurements of BGPS clumps, indicating in circles those clumps that have velocities within the $^{13}$CO velocity range and with $\times$ those $v_{lsr}$ values outside of the $^{13}$CO velocity range. The diamonds are positions in the [Wienen et al.] (2012) catalog with a matching velocity. The black contours are the $^{13}$CO integrated intensity at 2 and 7\,K\,km\,s^{-1}.
