Abstract: One of the challenges of using nanoparticles as catalysts is the presence of reaction-disturbing stabilizers that surround the nanoparticle surface. In this report, we demonstrate a method to synthesize stabilizer-free bismuth oxychloride (BiOCl) nanoparticles to increase photocatalytic activity. This synthesis method is remarkably simple, involving only BiCl₃ and deionized water. After heating an aqueous solution containing BiCl₃, plate-shaped BiOCl nanoparticles were formed. The stabilizer-free BiOCl nanoparticles exhibited higher photocatalytic activities compared to polyvinylpyrrolidone- and polyethyleneimine-stabilized nanoplates for the degradation of methylene blue.

Keywords: bismuth oxychloride; nanoparticles; stabilizer-free; aqueous-phase; photocatalyst

1. Introduction

Controlling size, shape, and composition can modulate the optical, electronic, magnetic, and physicochemical properties of nanoparticles. [1]. By tuning these properties, nanoparticles have been utilized in various industries, such as biomedicine, bioengineering, catalytic reactions, energy conversion, and storage [2–5]. In addition, nanoparticles can be used as catalysts for various organic chemical, electrochemical, and photochemical reactions due to their high surface-area-to-volume ratio and specific surface structures [6]. Nanoparticles synthesized using wet-chemical methods are typically coated with stabilizers composed of organic molecules or polymers to prevent agglomeration by coating the nanoparticle surface with an organic layer [7–10]. This organic layer is one of the major factors that hinder the catalytic activity of nanoparticles by blocking the interaction between reactants and active metal sites [11–13]. Furthermore, it is difficult to completely detach the stabilizer from the nanoparticles due to their strong bond to the surface of the nanoparticles. The development of a new synthetic method to make stabilizer-free nanoparticles would contribute to the goal of obtaining more active catalysts.

The field of solar photocatalysis is a promising area for the application of nanoparticles. Semiconductor-based photocatalysts have received global attention and research is underway to harness their properties, such as their photoreaction activity, physicochemical stability, high activity in the UV region, economic efficiency, and high surface area [14,15]. Recently, many studies have utilized photocatalytic nanoparticles for pollutant decomposition, CO₂ reduction, and nitrogen fixation [16–20]. Among the various semiconductor-based photocatalysts, bismuth oxychloride (BiOCl) has attracted considerable attention due to its characteristic structure, low toxicity, and low cost [15,21]. BiOCl is ternary complex semiconductor comprised of V-VI-VII main components, showing an open-layer structure in which Bi-O-Bi-Cl units alternate along the C-axis with strong Bi-O bonds and weak Van der waals forces. This unique structure of BiOCl induces an internal electrostatic field along
the [001] direction by generating a larger space for useful polarizing atoms and atomic orbitals. The internal electrostatic fields facilitate interlayer electronic transmission and enhance electron and hole separation efficiency [15,22–24]. These properties greatly increase the photocatalytic efficiency of BiOCl. The chemical and physical properties of BiOCl are better than TiO$_2$, which is mainly used as a photocatalyst. For example, the photocatalytic decomposition of dyes under UV light is higher with BiOCl compared to TiO$_2$.

In this research, we developed a method to synthesize stabilizer-free BiOCl nanoparticles to increase their photocatalytic activities. In the case of semiconductor nanoparticles, if the size is smaller than a critical threshold, the band gap increases and the wavelength range of light that can be absorbed narrows. Therefore, our objective was to synthesize BiOCl nanoparticles larger than 100 nm in diameter to avoid the band gap enlargement. The synthesis was remarkably simple and only required BiCl$_3$ and deionized water. After heating BiCl$_3$ dispersed aqueous solution, plate-shaped BiOCl nanoparticles were formed. In previous syntheses, pH adjustment using the addition of acids were needed to form BiOCl and surfactants were required to form nanosized particles. [25–29]. As predicted, the stabilizer-free BiOCl nanoparticles showed that photocatalytic activity for methylene blue degradation was improved compared to BiOCl nanoparticles stabilized by polyvinylpyrrolidone (PVP) or polyethyleneimine (PEI).

2. Results

Synthesizing BiOCl nanoplates was conducted by heating a 0.05 M aqueous solution of BiCl$_3$ at 95 °C for 2 h in the absence of a stabilizer. In the reaction, the Bi cation forms [Bi$_2$O$_2$]$^{2+}$ by rapidly hydrating in the aqueous solution, which then reacts with Cl$^-$ to form BiOCl [30]. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) images of the resulting material reveal that the synthesized nanoplates had sizes of 100–800 nm and thicknesses of 35–112 nm (Figure 1a,b). The elemental distribution of the nanoplates was measured using energy-dispersive X-ray spectrometry (EDS) mapping and indicated that Bi, O, and Cl were evenly distributed throughout the nanoplates (Figure 1c). Figure 1d shows the powder X-ray diffractometry (XRD) patterns of the nanoplates, displaying diffraction peaks that corresponded well with the peaks of known BiOCl (JCPDS 06-0249). However, the intensity of the XRD peaks was slightly different from the previously reported XRD patterns of BiOCl. In previous reports on the synthesis of anisotropic nanoplates, the intensity of the XRD peaks was found to vary depending on the direction [31,32]. The strongest (001) peaks of the tetragonal BiOCl phase at 12° indicated that the nanoplate mainly grew in the (001) direction. To better understand the crystal structure of BiOCl nanoplates, the oxidation states of Bi and Cl in the nanoplates were characterized using X-ray photoelectron spectroscopy (XPS) (Figure S1). The binding energies of Bi 4f$_{7/2}$ and Bi 4f$_{5/2}$ were 163.28 and 157.98 eV, respectively, which are similar to literature values for Bi$^{3+}$ (Figure S1a) [33,34]. The Cl 2p core level spectrum composed of Cl 2p$_{3/2}$ and Cl 2p$_{1/2}$ peaks at 198.18 and 196.58 eV, respectively, correspond to Cl$^-$ (Figure S1b). These results match with the XRD measurements that indicated that the crystal structure of the nanoplates was BiOCl. The ratio of Bi to Cl in the nanoplates was determined to be 1:1.13 from the XPS measurements. It has been reported that anions, such as halide ions, will adhere to the surface of nanoparticles in the absence of typical stabilizers [35]. In the current study, it is likely that Cl$^-$ anions act as stabilizers by attaching to the surface of the BiOCl nanoparticles, supported by the observation that there were more Cl$^-$ ions than Bi atoms detected in the XPS analysis. The zeta potential analysis showed that the surface of BiOCl had a negative charge (Figure S2), which can be attributed to the adsorption of chloride ions on its surface. The negative charges on the surface give rise to repulsive forces that provide the nanoplates with electrostatic stabilization in aqueous solutions. The UV–Vis extinction spectrum, measured from an aqueous suspension of the BiOCl nanoplates, displays a broad band around 500 nm.
In the synthesis described above, the BiOCl nanoplates were synthesized in the absence of a stabilizer. BiOCl nanoplates were used to investigate the effect of stabilizers on photocatalytic reactions, so polyvinylpyrrolidone (PVP) and polyethyleneimine (PEI) were introduced to coat the surface of the nanoplates. PVP- and PEI-stabilized BiOCl nanoplates were prepared by heating BiOCl dispersed aqueous solution in the existence of PVP or PEI. The Fourier-transform infrared spectroscopy (FT-IR) spectra of PVP-stabilized BiOCl nanoplates exhibited distinct peaks at 2900 cm\(^{-1}\), assigned to a C–H bond, and 1660 cm\(^{-1}\), assigned to a C=O bond, indicating that PVP was successfully attached to the nanoplate surface (Figure 2a). For PEI-stabilized BiOCl nanoplates, peaks in the FT-IR spectra corresponding to PEI were observed (1250 cm\(^{-1}\), assigned to a C-N bond), displaying the existence of PEI on the nanoplate surface (Figure 2a). Stabilization of the nanoplates with PVP and PEI was also confirmed using a zeta potential analysis (Figure S3). The zeta potential of PVP-stabilized BiOCl nanoplates was slightly less negatively charged (−10.7 mV) than the bare BiOCl nanoplates (−20.1 mV), while PEI-stabilized nanoplates were positively charged (33.1 mV). Figure 2b,c show SEM images of the PVP- and PEI-stabilized nanoplates, confirming that there were no size or thickness changes after the stabilizer attachment. Additionally, the optical properties of the nanoparticles did not change according to the UV–Vis analysis (Figure 2d).
The photocatalytic properties of the BiOCl nanoplates were estimated for the decomposition of organic pollutants under visible light irradiation. To evaluate the photocatalytic performance of BiOCl, methylene blue (MB) was chosen as the organic pollutant. The photolysis process was investigated by checking the intensity of the major absorption peak at 668 nm associated with MB. The photocatalyst (BiOCl, PVP-stabilized BiOCl, or PEI-stabilized BiOCl) was added to a solution of MB and the intensity of the MB absorption peak according to the photocatalytic reaction rapidly decreased, and the results showed that the MB molecules were degraded effectively under visible light illumination in the existence of BiOCl nanoplates. (Figure 3a and Figure S4). Figure 3b displays the concentration of MB (C) normalized against the concentration at the start of the reaction (C₀) for the photocatalytic reaction with the nanoplates. A plot of the normalized concentration on a logarithmic scale versus the reaction time is shown in Figure 3c, demonstrating that the reaction of MB degradation has first order kinetics, as in expressed in Equations (1) and (2):

\[ \frac{dC}{dt} = -kC \]  

and

\[ \ln \left( \frac{C}{C_0} \right) = -kt \]  

where \( k \) is the rate constant. The rate constant of stabilizer-free BiOCl nanoplates was estimated to be \( 1.14 \times 10^{-3} \text{ min}^{-1} \), which was faster than PVP-stabilized BiOCl nanoplates and PEI-stabilized BiOCl nanoplates (Figure 3d, \( 8.283 \times 10^{-4} \text{ min}^{-1} \) and \( 1.0 \times 10^{-3} \text{ min}^{-1} \), respectively.) These differences in rate indicate the importance of the surface condition of the nanoplates in the catalytic reaction.

(b) Normalized concentration of MB on a linear scale. (c) Normalized concentration of MB on a logarithmic scale. (d) Bar diagram showing the degradation percentage of MB molecules after irradiation under visible light.

3. Materials and Methods

3.1. Materials

All reagents were commercially available and were used without further purification. Bismuth (III) chloride (BiCl$_3$, trace metal basis), polyvinylpyrrolidone (PVP, ACS reagent, MW ~ 55,000), and polyethyleneimine (PEI, ACS reagent, MW ~ 750,000) were purchased from Sigma-Aldrich.

3.2. Synthesis of BiOCl Nanoplates

In total, 10 mL of an aqueous solution of BiCl$_3$ 0.5 mmol was heated at 95 °C for 2 h. After the reaction, the products were collected using centrifugation, washed twice with a mixed solution of water and acetone and then dried in oven at 80 °C for 1 h.

3.3. Attachment of Stabilizer to the Surface of BiOCl Nanoplates

In total, 0.1 g of BiOCl nanoplates was well dissolved in 5 mL of water (solution A) and 0.02 g of each stabilizer was dissolved in 5 mL of water (solution B). Solution B was added to solution A and the mixed solution was stirred at 50 °C for 1 h. After the reaction, the products were collected using centrifugation and washed using a mixed solution of water and acetone.

3.4. Characterization

The crystal structures of the photocatalysts were characterized by using a D8 Advance X-ray diffractometer (XRD). The sizes and morphologies of the nanoparticles were measured using scanning electron microscopy (SEM, Merlin, Carl Zeiss). The elemental
distribution of the nanoparticles was obtained using transmission electron microscopy (TEM, JEM-2100F, JEOL) and energy-dispersive X-ray spectrometry (EDS, JEM-2100F). The optical properties were estimated using a Cary 60 UV-Vis spectrophotometer (Agilent Technologies). X-ray photoelectron spectroscopy (XPS) analysis was conducted using a K-Alpha spectrometer (Thermo Electron) to determine the oxidation state of the elements in the nanoparticles. The Brunauer–Emmett–Teller (BET) surface area of the nanoparticle was estimated using a nitrogen adsorption method with a BELSORP-max (MP). Zeta potential tests were conducted on a zeta potential analyzer (Zetasizer Nano ZS, Malvern, pH = 6.19). Fourier-transform infrared spectroscopy (FT-IR) was measured by using a Spectrum One system (PerkinElmer).

3.5. Evaluation of Photocatalytic Activity

In total, 5.0 mg of catalyst was added to a 50 mL aqueous solution of methylene blue (MB) (10 mg/L). To establish the adsorption–deposition equilibrium of MB molecules on the catalyst, the solution was stirred for 30 min in the absence of light. A 200 W mercury lamp (Raynics, Korea) was used to evaluate photocatalytic reaction under visible light irradiation. During the reaction, 3 mL aliquots were removed from the solution and centrifuged to remove the catalysts (1350 rpm, 5 min). The supernatant was transferred to a cuvette and UV–Vis absorption spectra were analyzed in the range of 300–800 nm.

4. Conclusions

In summary, we have synthesized stabilizer-free BiOCl nanoplates that demonstrate enhanced photocatalytic activity. The synthesis is simple, involving only the heating of an aqueous solution containing BiCl₃. The stabilizer-free BiOCl nanoplates exhibited a higher photocatalytic activity compared to PVP- and PEI-stabilized nanoplates. We anticipate that this method to easily synthesize BiOCl nanoparticles can be expanded to the preparation of other oxyhalide nanoparticles, which can then be used as catalysts for many reactions.
