Structure and properties of indium-doped ZnO films prepared by RF magnetron sputtering under different pressures

Li-Ping Peng* , A-Ling He, Liang Fang, Xiao-Fei Yang

Abstract High conductive and transparent In-doped ZnO thin films were deposited on glass substrates by radio-frequency (RF) magnetron sputtering at 250 °C. Argon gas was used as the sputtering gas, and its pressure varies from 0.1 to 4.0 Pa. The influences of deposition pressure on the structural, electrical and optical properties of the films were investigated by means of X-ray diffraction (XRD), scanning electron microscope (SEM) and Hall and transmittance measurements. The optical constant of the films was estimated from transmittance data using a nonlinear programming method. It is found that the deposition pressure affects the properties of the films significantly. The film deposited at 2.0 Pa shows the optimal crystal quality with a high transmittance of 85% in the visible range and a low resistivity of $2.4 \times 10^{-3}$ Ω-cm and can thus be used as a transparent electrode.

Keywords ZnO thin films; Transparent conductive oxide; Optical constant; Magnetron sputtering

1 Introduction

Indium tin oxide (ITO) is used as transparent conductive oxide (TCO) in many kinds of applications such as transparent electrodes, window materials in solar cell and flat panel display. However, high cost of ITO motivated efforts to develop substitutes. ZnO is a promising candidate of ITO in TCO applications due to its high optical transmission in the visible range, low resistivity, low cost, abundant and no toxic [1]. ZnO with a hexagonal structure has a wide optical band gap of 3.3 eV and shows n-type conductivity because of non-stoichiometry. The resistivity of undoped ZnO is not low enough for the use as TCO, so Group III elements such as Al, Ga and In are usually used as dopants to improve the electrical properties and stability of ZnO-based films [1–8]. Owing to its suitable ionic radius (0.062 nm) and electronegativity (1.7) [1], it was reported to be the most promising element as dopant to enhance the photoelectric properties of ZnO thin films.

To use ZnO-based materials in optical and electrical devices with high performance and reliability, it is important to deposit high-quality ZnO films with n-type characteristics. It was reported that n-type ZnO films were prepared by pulsed laser deposition (PLD), radio-frequency (RF) magnetron sputtering, chemical vapor deposition (CVD), etc. As for RF magnetron sputtering, deposition pressure affects the structural, electrical and optical properties significantly. But few reports were found about the influence of deposition pressure on RF magnetron sputtering In-doped ZnO (ZnO:In) films. In this work, ZnO:In thin films were deposited on glass substrates by RF magnetron sputtering, and the deposition pressure dependence of structural, electrical and optical properties of the ZnO:In thin films was studied. Also, a nonlinear programming...
method was used to estimate the optical constants of the films from only transmittance spectra.

2 Experimental

Powder target (In/(In + Zn) = 5 at%) prepared from high-purity ZnO (99.99 %) and In$_2$O$_3$ (99.99 %) powder was used as sputtering source material. Glass (15 mm $\times$ 15 mm $\times$ 1 mm) was used as substrate, which was ultrasonically cleaned in acetone, rinsed in alcohol and then dried in hot air. ZnO:In transparent conductive thin films were deposited by 13.56 MHz RF magnetron sputtering. The distance between the target and substrate was 70 mm. In order to avoid contaminating the film, the chamber was evacuated to a base pressure of $6.6 \times 10^{-4}$ Pa. Argon gas was introduced into the chamber through a mass flow controller. The target was pre-sputtered for 15 min to remove contaminants. The mass flow of argon gas was fixed at 24 ml min$^{-1}$, and the total pressure changed from 0.1 to 4.0 Pa. The substrate temperature was maintained at 250 $^\circ$C, and the deposition lasted 60 min for all the films.

The structure of the films was analyzed by X-ray diffractometer (XRD, MRD-SingleScan) with Cu K$_\lambda$ radiation ($\lambda = 0.154$ nm). The surface morphology of the films was investigated by scanning electron microscopy (SEM, Oxford, Nova400). The film thickness was measured by a Dektak II step-measurer. The electrical properties of the films were measured by a Bio-Rad Microscience HL5500 Hall system at room temperature. The transmission spectrum of the film was measured by a double-beam ultraviolet visible (UV–Vis) spectrophotometer in the wavelength range of 300–800 nm at room temperature, and the optical constant of the films was estimated from transmittance spectra by a nonlinear programming method.

3 Results and discussion

The film thickness was measured by a Dektak II step-measurer, and the thicknesses are 662, 393, 286 and 259 nm for the films prepared under the pressures of 0.1, 1.0, 2.0 and 4.0 Pa, respectively. Figure 1 shows the growth rate of ZnO:In thin films as a function of the deposition pressure. The deposition rate decreases from 11.0 to 4.3 nm min$^{-1}$ with deposition pressure increasing from 0.1 to 4.0 Pa. A similar result was reported by Assuncao et al. [9] for ZnO:Ga thin films prepared by RF magnetron sputtering. They suggested that with deposition pressure increasing, the mean free path decreases and the sputtered species undergo many collisions, leading to a thermalization of the film-forming particles. The surface mobility of these species decreases, and thus, the growth rate decreases.

Figure 2 shows the XRD patterns of ZnO:In thin films deposited on glass at different deposition pressures. All the films show a peak at $2\theta \approx 34^\circ$, which is attributed to (002) ZnO, indicating good orientation along c-axis almost independence of the deposition pressure. No In$_2$O$_3$ phase is found in the XRD patterns, suggesting that In substitutes Zn in the hexagonal lattice or In segregates to non-crystalline region in the grain boundary and forms In–O bond [10]. The (002) peak becomes more intense with deposition pressure increasing, reaches a maximum at 2.0 Pa and then decreases as the deposition pressure further increases. It can be induced that the ZnO:In film deposited at 2.0 Pa has better crystal quality than others. Figure 3 shows SEM image of ZnO:In thin films deposited at 2.0 Pa, and a smooth surface with dense grain of about 80 nm in size is obtained.
The electrical resistivity of the films depends strongly on the deposition pressure. Figure 4 shows the variation in electrical resistivity ($\rho$) and carrier concentration ($n$) as a function of deposition pressure. The electrical resistivity increases slowly from $1.2 \times 10^{-3}$ to $2.4 \times 10^{-3}$ $\Omega$ cm with the deposition pressure from 0.1 to 2.0 Pa, and then, it increases sharply with the deposition pressure further increasing. The carrier concentration decreases from $9.2 \times 10^{20}$ to $2.1 \times 10^{20}$ cm$^{-3}$ with the deposition pressure increasing from 0.1 to 4.0 Pa. The lower resistivity of the films deposited at lower pressure is due to higher carrier concentration supplied from the substitution of In by replacement of the host Zn atoms. The substituted In atoms ionize into In$^{3+}$ so that a free electron can be contributed. At lower pressure, the sputtered species have higher surface mobility on the substrate, which will result in more In substitution, leading to a higher carrier concentration. With deposition pressure increasing, the species kinetic energy decreases, which degrades In substitution, and thus, the carrier concentration decreases and the resistivity increases. A similar phenomenon is also found in the ZnO:Ga films [11], and the mechanism demands further experiment and investigation.

Transmittance of the ZnO:In thin films as a function of wavelength in the range of 300–800 nm is shown in Fig. 5. All the films exhibit a sharp fundamental absorption edge at about 380 nm. The transmittance of the films is affected by the deposition pressure significantly. The film deposited at 0.1 Pa shows lower transmittance because of high thickness. Film deposited at 1.0 Pa or higher pressure shows a high transmittance of about 85% in the visible range.

To estimate the optical constants of the films using transmittance data only is a very challenging problem with many local non-global solutions. A new method based on nonlinear programming techniques proposed in Refs. [12–14] can successfully estimate the optical constant of thin film only by its transmittance spectra. Figures 6 and 7 show the obtained refractive index and extinction coefficient, respectively. As shown in Fig. 6, the refractive index increases with wavelength decreasing and is in the range of 1.9–2.6 eV, which is in comparison with the ZnO:In thin films prepared by sol–gel method reported by Caglar et al. [15]. From Fig. 7, it can be seen that all the films show a very weak extinction coefficient in the region of 400–800 nm, but below 400 nm, the extinction coefficient increases significantly. From extinction coefficient, the absorption coefficient can be obtained. Using the derived absorption coefficient, the optical band gap of the samples was estimated by extrapolation of the linear portion of square of the absorption coefficient against photon energy. The optical band gap values estimated locate at 3.26–3.48 eV.

From above, it is known that the electrical resistivity deteriorates, but the transmittance gets better with deposition pressure increasing. An optimal pressure should be chosen to deposit ZnO:In thin films as TCO. This work...
shows that the resistivity increases slowly, but the transmittance increases significantly with deposition pressure of lower than 2.0 Pa. The film deposited at 2.0 Pa with a lower resistivity of $2.4 \times 10^{-3} \Omega \cdot \text{cm}$ and a higher transmittance of 85% in the visible region can be used as a transparent electrode.

4 Conclusion

In-doped ZnO thin films were deposited on glass substrates by RF magnetron sputtering under different pressures from a powder target. The structural, electrical and optical properties of the films were investigated. All the ZnO:In thin films are hexagonal wurtzite with $c$-axis perpendicular to the substrates. The resistivity of the films increases with deposition pressure increasing, accompanied with a reduction in carrier concentration. The transmittance of the films is affected by the deposition pressure significantly, and the films deposited at a pressure of 1.0 Pa or higher have high transmittance of about 85% in the visible range. A nonlinear programming method was used to estimate the optical constant of the films. Calculation results show that the refractive index of the films is in the range of 1.9–2.6 eV, a low weak extinction coefficient is in the visible range and the optical band gap is located at 3.26–3.48 eV. The optimal deposition pressure for ZnO:In thin films as TCO is 2.0 Pa, which has a low resistivity of $2.4 \times 10^{-3} \Omega \cdot \text{cm}$ and a high transmittance of 85% in the visible region.
