Abstract

We examine the possibility that fast radio bursts (FRBs) are emitted inside the magnetosphere of a magnetar. On its way out, the radio wave must interact with a low-density $e^\pm$ plasma in the outer magnetosphere at radii $R = 10^9-10^{10}$ cm. In this region, the magnetospheric particles have a huge cross section for scattering the wave. As a result, the wave strongly interacts with the magnetosphere and compresses it, depositing the FRB energy into the compressed field and the scattered radiation. The scattered spectrum extends to the $\gamma$-ray band and triggers $e^\pm$ avalanche, further boosting the opacity. These processes choke FRBs, disfavoring scenarios with a radio source confined at $R \ll 10^{10}$ cm. Observed FRBs can be emitted by magnetospheric flare ejecta transporting energy to large radii.

1. Introduction

Fast radio bursts (FRBs) are a big puzzle. They are detected from cosmological distances with luminosities up to $10^{43}$ erg s$^{-1}$ and millisecond durations (Petroff et al. 2019). Spectacular progress in FRB observations, in particular by CHIME, has provided a wealth of data that miss theoretical explanation.

Recent FRB detection from SGR 1935+2154 (Bochenek et al. 2020; The CHIME/FRB Collaboration et al. 2020) supports the association of FRBs with magnetars. However, their emission mechanism is not established. Possible scenarios are (1) a radio source confined near the magnetar, inside its ultrastrong magnetosphere (“near-field”) and (2) emission at much larger radii from explosions launched by magnetospheric flares into the magnetar wind (“far-field”). The far-field models include a concrete radiative mechanism—synchrotron maser emission from the blast wave (Lyubarsky 2014; Beloborodov 2017, 2020; Metzger et al. 2019; Sironi et al. 2021) and possible emission from the magnetic flare ejecta itself (Lyubarsky 2020). On the other hand, it was argued that the complex temporal structure detected in FRBs (if it forms inside the source, not via propagation effects) favors the near-field scenario (Nimmo et al. 2021; The CHIME/FRB Collaboration et al. 2021).

Cosmological FRBs are $10^{10}-10^{12}$ times brighter than radio pulsations detected in several magnetars (Kaspi & Beloborodov 2017), and proposals for magnetospheric radio emission mechanisms (Thompson 2008; Beloborodov 2013a; Lyutikov et al. 2016; Lu et al. 2020) face challenges when applied to FRBs (Lyubarsky 2021). This Letter does not invoke any concrete emission mechanism; instead, we examine a generic constraint.

A simple and essential requirement for any near-field FRB scenario is the successful escape of the radio wave. The emitted wave must propagate through the plasma in the closed magnetosphere, which extends to the light cylinder

$$R_{LC} = \frac{c}{\Omega} \approx 5 \times 10^6 \left( \frac{P}{1 \text{ s}} \right) \text{ cm}, \quad (1)$$

where $P = 2\pi/\Omega$ is the rotation period of the magnetar. The plasma is immersed in the magnetospheric field $B_{bg}$ and has gyrofrequency

$$\omega_B = \frac{eB_{bg}}{mc} \approx \frac{e\mu}{mcR^3} \approx 1.8 \times 10^{13} \frac{H_{33}}{R_9} \text{ rad s}^{-1}, \quad (2)$$

where $e$ and $m_e$ are the electron charge and mass, and the magnetic dipole moment $\mu \approx B_{bg} R^3 \sim 10^{33}$ G cm$^3$ corresponds to a surface magnetic field $B_s \sim 10^{15}$ G. The radio wave frequency $\nu = \omega/2\pi \sim 1$ GHz satisfies $\nu < \omega_B$ at radii up to $R_{LC}$ if $P < 3 \mu_{1/2}^3$. s.

The magnetosphere is normally assumed to allow free escape of radio waves polarized perpendicular to the background magnetic field $B_{bg}$, especially for $\nu < \omega_B$. A standard calculation of the electron cross section for wave scattering gives $\sigma_e \approx (\omega/\omega_B)^2 \sigma_T \ll \sigma_T$ (Canuto et al. 1971) where $\sigma_T$ is the Thomson cross section. Recent discussions of FRB interaction with the magnetosphere (Kumar & Lu 2020; Lyutikov 2020) also concluded that the interaction is suppressed by $\omega_B \gg \omega$.

However, the small $\sigma_e$ holds only for wave amplitudes $E_0 < B_{bg}$. In fact, as the wave propagates away from the magnetar in the decreasing $B_{bg} \propto R^{-3}$, its amplitude $E_0 \propto R^{-1}$ eventually exceeds $B_{bg}$:

$$\frac{E_0}{B_{bg}} = \left( \frac{R}{R_0} \right)^2, \quad R_0 \approx 3.5 \times 10^8 \frac{H_{33}^{1/2}}{L_{42}^{1/4}} \text{ cm}, \quad (3)$$

where $L = cR^2E_0^2/2$ is the isotropic equivalent of the FRB luminosity. Hereafter, we focus on the wave propagation at radii $R > R_0$ where $E_0 > B_{bg}$. This condition is equivalent to
\( a_0 > \omega_B/\omega \), where

\[
a_0 = \frac{eE_0}{mc\omega} \approx 2.3 \times 10^4 \frac{L_{42}^{1/2}}{R_9 \nu_9} \quad (4)
\]

Waves with \( E_0 > B_{bg} \) are scattered with \( \sigma_{sc} \) exceeding \( \sigma_T \) by many orders of magnitude (Beloborodov 2021, hereafter B21). This occurs because particles \( (e^\pm) \) exposed to the wave are quickly accelerated to huge Lorentz factors, exceeding \( 10^6 \), and emit \( \gamma \)-rays at the expense of the radio wave energy. In this Letter, we examine implications of these processes for FRBs. For definiteness we consider a plane wave propagating perpendicular to \( B_{bg} \), for different propagation angles \( \theta \neq \pi/2 \) one should replace \( \omega_B \to \omega_B \sin \theta \).

2. Scattering of the Wave

2.1. Magnetospheric Plasma Density \( n_0 \)

The scattering opacity of the magnetosphere depends on its initial plasma density \( n_0 \) before it is exposed to the outgoing ultrasonic wave. One characteristic density in the problem is \( n_{co} = |\nabla \cdot E_{co}|/4\pi e \), the minimum needed to sustain the corotation electric field \( E_{co} = B_{bg} \times (\Omega \times R) \) (Goldreich & Julian 1969),

\[
n_{co} \sim \frac{\mu}{ceR^2 P} \approx 7 \times 10^4 \frac{\mu_{35}}{R_9} \left( \frac{P}{1 \text{ s}} \right)^{-1} \text{ cm}^{-3}. \quad (5)
\]

As shown above, even this low density is sufficient to choke FRBs emitted at \( R \ll R_{LC} \).

The actual density around active magnetars is higher than \( n_{co} \). The \( e^\pm \) plasma is created near the neutron star, at a radius \( R_\perp \lesssim 10 R_n \), and fills the outer magnetosphere by flowing out along the extended magnetic field lines. The particle flow \( \dot{N} \) at a radius \( R \gg R_\perp \) scales with the number of field lines connecting \( R_\perp \) and \( R \), which implies \( \dot{N}(R) \sim R^{-1} \) (Beloborodov 2020).

The value of \( \dot{N} \) may be estimated using observations of known magnetars in our galaxy. Their typical persistent luminosity in the keV band is \( L_{keV} \sim 10^{35} \text{ erg s}^{-1} \), and their spectra are nonthermal, extending with a hard slope to energies \( \gg 10 \text{ keV} \) (Kaspi & Beloborodov 2017). The spectrum is emitted by the magnetospheric \( e^\pm \) flow, which radiates its energy away via resonant cyclotron scattering (Thompson et al. 2002; Beloborodov 2013a, 2013b). The flow decelerates to a mildly relativistic speed at radius \( R_{keV} \approx 2 \times 10^7 \mu_{35}^{1/3} \text{ cm} \) (where \( h\omega_{keV} \sim 1 \text{ keV} \)), and the \( e^\pm \) supply to \( R_{keV} \) may be roughly estimated as \( \dot{N}(R_{keV}) \sim L_{keV}/m_e c^2 \). This estimate is also consistent with the theoretically expected multiplicity of \( e^\pm \) production around magnetars (Beloborodov 2013b).

Then, using the scaling \( \dot{N}(R) \sim R^{-1} \), one can estimate the \( e^\pm \) density in the outer magnetosphere as

\[
n_0(R) \sim \frac{\dot{N}(R)}{cR^2} \sim 10^{10} R_9^{-3} \left( \frac{L_{keV}}{10^{35} \text{ erg s}^{-1}} \right) \text{ cm}^{-3}. \quad (6)
\]

Note that Equations (5) and (6) both give a density \( \propto R^{-3} \). Therefore, a convenient density parameter is

\[
\dot{N} \equiv n_0 R^3. \quad (7)
\]

Equations (5) and (6) give \( \dot{N} \sim 10^{32} \) and \( 10^{37} \), respectively.

2.2. Bulk Acceleration and Compression

Before discussing the scattering opacity of the plasma, it is useful to look at the response of the magnetosphere to a force exerted by the wave. The basic response is the sudden bulk acceleration and compression.

The magnetic field \( B_{bg} \) plays a key role in the wave–plasma interaction (even when \( B_{bg} \ll E_0 \)). Without \( B_{bg} \), an initially static \( e^\pm \) plasma exposed to the ultrastrong radio burst would immediately develop outward bulk motion with a huge Lorentz factor \( \gamma_p \approx a_0 \) (B21). Most of the radio wave would not even interact with the plasma, as the plasma would surf the leading front of the wave, unable to penetrate it. \( B_{bg} \neq 0 \) plays a key role by arresting the ultrarelativistic bulk motion and so enforcing wave–plasma interaction. Larmor rotation of particles in \( B_{bg} \) effectively couples the plasma to the background magnetic field lines. On scales larger than the Larmor scale, the plasma behaves as an MHD fluid. This fluid still experiences some acceleration as it interacts with the wave, but now the bulk acceleration is controlled by the effective inertial mass of the magnetic field, \( B_{bg}^2/4\pi c^2 \), which exceeds the plasma rest mass density \( n_0 m_e \) by many orders of magnitude.

The cross section for wave scattering will be defined in the fluid rest frame, which can accelerate relative to our initial lab frame (the magnetosphere rest frame before the wave). We now evaluate the speed of this frame (plasma bulk speed \( \beta_p = v_p/c \)) assuming \( B_{bg} \) perpendicular to the wave propagation direction (\( \theta = \pi/2 \)). Extension to oblique \( B_{bg} \) is straightforward: one should make an additional Lorentz boost along \( B_{bg} \) such that the wave propagation becomes perpendicular to \( B_{bg} \) in the boosted frame.

The MHD coupling implies that the momentum received by the plasma from the wave is shared with the background field, so there appears an outward Poynting flux \( S_{bg} = (c/4\pi)\mathbf{E}_{bg} \times \mathbf{B}_{bg} \) and the magnetic field lines begin to drift with speed \( \beta_{bg} = \mathbf{E}_{bg} / \mathbf{B}_{bg} \). Here, \( \mathbf{E}_{bg} \) and \( \mathbf{B}_{bg} \) are the new values of the background field, changed from the pre-wave values \( \mathbf{B}_{bg} \) and \( \mathbf{E}_{bg} \approx 0 \). In the ideal MHD approximation, the plasma and the background field drift with equal speed,

\[
\beta_p = \beta_{bg} = \frac{\mathbf{E}_{bg}}{\mathbf{B}_{bg}}. \quad (8)
\]

Acceleration to \( \beta_p \) is accompanied by compression,

\[
\frac{\dot{B}_{bg}}{B_{bg}} = \frac{n}{n_0} = \frac{1}{1 - \beta_p}. \quad (9)
\]

The wave compresses the magnetosphere of radius \( R \) into a shell of thickness \( (1 - \beta_p)R \).

Let \( E' \) be the isotropic equivalent of the FRB energy and \( \tau_{sc} < 1 \) be the scattering optical depth encountered by the radio wave as it propagates out to a radius \( R \). Momentum lost by the wave \( \tau_{sc} E/c \) is mostly taken by the magnetospheric field, which dominates over plasma,

\[
(1 - \beta_p)R \frac{S_{bg}}{c^2} \approx \tau_{sc} \frac{E}{4\pi R^2 c}. \quad (10)
\]
where \( S_{bg} / c^2 = \beta_p B_{bg}^2 / 4\pi c \) is the momentum density of the background field. This gives the equation for \( \beta_p \),
\[
\frac{\beta_p}{1 - \beta_p} \approx \tau_{sc} \frac{E}{R^2 B_{bg}^2} \approx \tau_{sc} R_g^3 \frac{E_\gamma}{\mu_3^3}.
\]

One can see that any significant scattering at \( R > 10^9 \) cm is accompanied by sweeping the outer magnetosphere to a high Lorentz factor \( \gamma_p = (1 - \beta_p^2)^{-1/2} \). This bulk acceleration must be self-consistently taken into account when calculating the wave scattering.

The wave has a small duration \( T \sim 1 \) ms \( \ll R/c \). The compressed magnetospheric shell crosses the wave and exits behind it on the timescale \( t_{cross} = T / (1 - \beta_p) \). As long as \( t_{cross} < R/c \), the plasma is not stuck in a leading portion of the wave, and the entire wave interacts with the plasma. The condition \( t_{cross} < R/c \) is satisfied at
\[
R < R_{surf} \approx 6 \times 10^9 \tau_{sc}^{-1/2} \frac{E_{bg}^{-1/2}}{T_{bg}^{-1/2} \mu_{33}} \text{ cm}.
\]

For typical parameters, \( R_{surf} \) is comparable to \( R_{LC} \), and \( t_{cross} < R/c \) is satisfied in the entire magnetosphere.

### 2.3. Scattering Optical Depth

For a successfully escaping wave, the net energy lost to scattering \( \tau_{sc} \) must be small compared with the wave energy \( \mathcal{E} = 4\pi R^2 FT \), where \( F = eE_\gamma^2 / 8\pi \) is its energy flux. The lost energy fraction may be written as
\[
\tau_{sc} = \frac{\mathcal{E}_{sc}}{\mathcal{E}} \sim n_0 \sigma_{sc} \mathcal{E}, \quad \mathcal{E} = LT,
\]

where \( n_0 \) is the initial (pre-wave) plasma density, and \( \sigma_{sc} \) is the scattering cross section of \( e^\pm \) measured in frame \( K' \) that moves with speed \( \beta_p \) (the rest frame of the accelerated and compressed magnetospheric shell).

Hereafter, all quantities with primes refer to frame \( K' \). In this frame, the background field is purely magnetic: \( B_{bg} = 0 \), \( E_{bg} = 0 \). Transformations of the wave frequency \( \omega \) and field \( B_{bg} \) to frame \( K' \) give
\[
\omega' = \frac{\omega}{\gamma_p (1 + \beta_p)} \quad \text{and} \quad \omega_{bg}' = \frac{\omega_{bg}}{\gamma_p} = \gamma_p (1 + \beta_p) \omega_{bg}.
\]

Wave strength parameter \( a_0' = a_0 \) is Lorentz invariant.

In frame \( K' \), a minimum Lorentz factor developed by particles oscillating in the wave is \( \gamma' \sim a_0^3 \). Each particle emits curvature radiation with power \( \mathcal{E}_{r,c} = \mathcal{E}_{r,c} \), which determines the effective scattering cross section \( \sigma_{sc} = \mathcal{E}_{sc}/F' \). To get an idea of the importance of scattering, one can start with a simple guess that particles in waves with \( E_0 > B_{bg} \) emit similarly to the known result at \( B_{bg} = 0 \): \( \mathcal{E}_{sc} \sim e^2 \omega_{bg}^2 \gamma'^4 \sim e^2 \omega^2 a_0^4 \), which gives \( \sigma_{sc} \sim a_0^2 \sigma_T \) (Landau & Lifshitz 1975). Then, one finds
\[
\tau_{sc} \sim \frac{\sigma_{sc}^2}{R^2} \sim \frac{3 \times 10^5}{R_9^4} \frac{L_{sc}}{a_0^2 \sigma_T} \gamma_3^2 \mathcal{N}_{37}.
\]

The actual effect of \( B_{bg} \) on \( \sigma_{sc} \) is not small and can give \( \sigma_{sc} \gg a_0^2 \sigma_T \) (Section 2.4). Furthermore, we will show below that even a much smaller \( n_0 \sim n_{co} \) \( (N \sim 10^3) \) provides sufficient seeds for \( e^\pm \) avalanche, which again leads to \( \tau_{sc} \gg 1 \).

### 2.4. Scattering Cross Section

Cross section \( \sigma_{sc} = \mathcal{E}/F' \) expresses irreversible energy losses of the radio wave caused by the radiative power \( \mathcal{E}_r \) of each particle oscillating in it. The produced radiation has a huge characteristic frequency \( \omega' \equiv a_0 \gamma^2 \omega' \) (B21) and a small radiation formation length \( l_F \sim \gamma^2 / \omega' \sim c / (\omega' \sigma_0) \). The inter-particle distance \( l' \sim n'^{-1/3} \approx 10^{-3} R_0 (N_{36})^{-1/3} \) is smaller than \( c / \omega' \), but far greater than \( c / \omega_c' \). The radiative process is not coherent—each particle radiates \( \gamma \)-rays independently (besides, the oscillation of the particles becomes incoherent when their orbits develop chaos, as described in B21). Therefore, \( \sigma_{sc} \) can be found by examining the behavior of a single particle in the wave.

One can also verify that the plasma is unable to screen the radio wave, as the maximum electric current \( 4 \pi n' \) is far below the wave displacement current \( 4 \pi E_0 / 4\pi \). Their ratio equals \((\omega' / \omega)^2 (\gamma' / a_0)^2 \), where
\[
\omega' = \left( \frac{4\pi e^2 n_0^2}{m_e c^2} \right)^{1/2}
\]

is the plasma frequency and \( n' = (1 + \beta_p) n_0 \) is the particle density in frame \( K' \). Any collective processes on the plasma timescale \( \omega_p^{-1} \) are slow and negligible compared with wave scattering by individual particles. This is an interesting special feature of strong waves.

B21 calculated the particle motion in frame \( K' \) and found \( \sigma_{sc} \) in two regimes (which approximately correspond to the olive and pink regions in Figure 1):

(I) If \( \omega_p < \omega' \), the particle motion is dominated by the \( \omega' \) oscillations in the wave. Then,
\[
\frac{\sigma_{sc}}{a_0^2 \sigma_T} \approx \begin{cases} 1 & a_0 < a_1' \\ (a_0 / a_1')^{0.6} & a_0 > a_1', \end{cases}
\]

\[
a_1' = \left( \frac{c}{r_e \omega} \right)^{1/4} \sim 3 \times 10^3, \quad r_e = \frac{e^2}{m_e c^2}.
\]

(II) If \( \omega_p > \omega' \) and the wave has strength \( a_0 < a_1' \approx (c \omega_p^2 / r_e \omega a_0^3)^{1/2} \), the particle motion becomes simple Larmor rotation in \( B_{bg} \) with frequency \( \omega' = \omega_p / \gamma' < \omega' \) (with superimposed subdominant \( \omega' \) oscillations in the wave). The Larmor rotation is pumped because the particle experiences a resonance with the wave every Larmor period, as shown in detail in B21. As a result, the particle’s Lorentz factor is quickly pushed to the radiation reaction limit (RRL),
\[
\gamma_{RRL} = \left( \frac{c}{r_e \omega a_0} \right)^{3/8} \left( \frac{\omega_p}{\omega'} \right)^{1/4}
\]

\(^3\omega_p > \omega' \) does not prevent particle acceleration by \( E_0 > B_{bg}' \). The wave accelerates the particle to a high \( \gamma' \) and reduces its Larmor frequency \( \omega_L' = \omega_p / \gamma' \) before the particle has a chance to complete one gyration in \( B_{bg} \) (B21).
Their spectrum has a peak with a half-width in photons with characteristic $g\omega_L$ are not modulated by Larmor rotation; $c\omega \gg \omega$ and the avalanche creates $e^\pm$ pairs. With increasing $\gamma_{sc}$, the plasma bulk acceleration expands the pink region.

and the resulting scattering cross section is

$$\frac{\sigma_{sc}}{\sigma_T} \sim \gamma_{RRL} \sim 2 \times 10^8 \frac{[\gamma_p(1 + \beta_p)]^{1/4} \mu_{33}^{1/2}}{\frac{R_9^{7/4}L_{42}^{3/4}}{\nu_9^{1/4}}}. \quad (20)$$

The condition $a_0 < a_{sc}'$ implies $\sigma_{sc}' > a_0^2 \sigma_T$. It is satisfied for FRBs with $L \lesssim 10^{31} \gamma_{53}^2$ erg s$^{-1}$, as seen from the relation

$$a_{sc}' \sim \frac{\gamma_p(1 + \beta_p)\mu_{33}^{1/2}}{2.3 \frac{R_9^{7/4}L_{42}^{3/4}}{\nu_9^{1/4}}}. \quad (21)$$

These results for $\sigma_{sc}'$ hold for a wave packet with a characteristic frequency $\omega$ (numerical examples in B21 used a modulated sine wave). Note also that the approximate Equations (17) and (20) do not match at $\omega_B' = \omega'_p$ — there is a sharp change of $\sigma_{sc}'$ across this transition.

The above expressions for $\sigma_{sc}'$ assume that the radio wave propagates with vacuum speed $c$. Deviations from $c$ are small, as follows from the dispersion relation $\omega^2 = c^2 k^2 + \omega_B'^2$, where $k'$ is the wavenumber of a Fourier mode.5 Phase speed $v_{ph}' = \omega'/k' > c$ and group speed $v_{gr}' = d \omega'/dk' < c$ are related by $v_{ph}' v_{gr}' = c^2$, and their deviations from $c$ are small if $v_{gr}' \equiv (1 - v_{gr}'^2/c^2)^{1/2} \gg 1$. In particular, in regime II we find (using $\gamma_\gamma' \sim \gamma_{RRL}'$)

$$\sigma_{sc}' \sim \frac{\gamma_p'}{\omega_p'} \sim \frac{1}{\gamma_{RRL}'} \frac{\gamma_p(1 + \beta_p)}{R_9^{7/4}L_{42}^{3/4}} \frac{5 \times 10^3}{\mu_{33}^{3/8} \nu_9^{5/8}}. \quad (22)$$

where we substituted $n_0 = \tau_{sc}/R \sigma_{sc}'$ and $\sigma_{sc}' \sim \gamma_{RRL}' \sigma_T$. The huge $\gamma_{sc}'$, at $\tau_{sc}$ = 1 shows that scattering of the wave is a much stronger effect than dispersion. (Strong dispersion of the wave packet would require time $\sim \gamma_{B}^2 T'$, far exceeding the burst age in frame $K'$, $t' \sim R/c\gamma_{p}'$.) It also justifies the use of $v_{ph}' = c$ in the calculation of $\sigma_{sc}'$.

3. Avalanche of Pair Creation

A magnetospheric particle exposed to the strong radio wave radiates the power $\dot{E}_s = \sigma_{sc}' E''$ in photons with characteristic frequency $\omega_s' = (3/2)\gamma_0^3 c/r_s$, where $r_s = (3E_s/2ce^2\gamma_{53})^{1/2}$ is the curvature of the particle’s trajectory. Using the results of B21, we find in regime I

$$\epsilon_{s}' \equiv \frac{h\omega_s'}{m_e c^2} \approx \frac{a_0^3}{m_e c^2} \approx \frac{100}{\gamma_p(1 + \beta_p)} \frac{L_{42}^{1/2}}{R_9^{7/4} \nu_9^{1/2}}. \quad (23)$$

and in regime II

$$\epsilon_{s}' \approx \frac{1}{\alpha} \left( \frac{r_s \omega_B'^2 \rho_0}{c \omega_p'} \right)^{1/4} \approx 44 \left( \frac{\gamma_p(1 + \beta_p)\mu_{33}^{1/2} L_{42}^{1/8}}{R_9^{7/4} \nu_9^{1/2}} \right). \quad (24)$$

where $\alpha = e^2/\hbar c$. We conclude that the wave generates $\gamma$-rays with $\epsilon_{s}' \gg 1$. Their spectrum has a peak with a half-width extending from $0.01 \epsilon_{s}'$ to $1.5 \epsilon_{s}'$ (e.g., Longair 2011). This broad peak extends over the MeV band where photon–photon collisions $\gamma + \gamma \rightarrow e^+ + e^-$ occur with cross section $\sigma_{sc} \sim 0.1 \sigma_T$.

It is convenient to view $e^\pm$ creation in frame $K'$, where the emitted $\gamma$-rays are quasi-isotropic.\(^5\) The energy emitted as the wave expands to radius $R$, $E_{s}' = E_s'/\gamma_{p}'$, occupies radial thickness $\Delta R' \sim R/\gamma_{p}'$, so the $\gamma$-rays have energy density

$$U_{\gamma} \approx \frac{\tau_{sc} E_s}{4\pi R^2}. \quad (25)$$

They exit behind the wave on a timescale comparable to the wave duration $T' = \gamma_p'(1 + \beta_p')T$, and a fraction of $\gamma$-rays convert to $e^\pm$ pairs before exiting. The number of converting $\gamma$-rays per primary particle is

$$M_\pm = \frac{\delta \gamma T'}{m_e c^2} \frac{E_{s}' T'}{m_e c^2} \approx \zeta \frac{T}{R} \frac{\sigma_{sc}'}{\tau_{sc}}, \quad (26)$$

where

$$\zeta \equiv \frac{\sigma_T E_{s}'}{4\pi R^2 m_e c^2} \approx 66 \frac{E_{s}'}{R_9^2}, \quad (27)$$

and $\sigma_{sc}' \equiv \zeta \tau_{sc}$ is an effective cross section for $\gamma\gamma$ collisions. The numerical factor $\zeta$ may be found by integrating the $\gamma\gamma$ reaction rate over the spectrum of curvature emission. It depends on $\epsilon_{s}'$ and varies around $\zeta \sim 10^{-2}$ at radii where $\epsilon_{s}' > 1$.

---

4 Density $n'$ and the corresponding $\omega_p'$ are not modulated by Larmor rotation in $B_{bg}$ even in regime II, where particle motion is dominated by gyration with $\omega_L' \ll \omega'$. The plasma accelerated in the wave initially forms a thin stream in the phase space, but it quickly broadens as particles develop chaos in $\gamma'$ (B21).

5 In regime I with $a_0 > a_0'$, the emission has a backward beaming in frame $K'$; however, this regime is not relevant for most FRBs.
The $e^\pm$ created by $\gamma$-rays oscillate in the wave and emit secondary $\gamma$-rays just like the primary particles do. An avalanche of $e^\pm$ creation develops if $M_\pm \gg 1$, boosting the plasma density by $e^{M_+}$. One can see that $M_\pm$ is large, even if one chooses a low-density $n_0 = n_{\text{crit}}$,

$$M_\pm \sim \frac{10^8 \zeta}{R_0} E_3^{-3/2} T_3^{-3} \sigma_T^2 \gtrsim 1,$$

where $\sigma_\pm = \sigma_{\text{crit}} / 10^8 \sigma_T$. The wave becomes immersed in the exponentially enriched $e^\pm$ plasma with $\tau_{\text{sc}} \gg 1$.

4. Discussion

We have found $\tau_{\text{sc}} \gg 1$ for FRBs emitted deep inside the magnetosphere and attempting to escape through the outer magnetosphere. This result is obtained for a given strong radio burst, not including the feedback of energy losses on its luminosity $L$. In reality the burst luminosity must drop to satisfy $\tau_{\text{sc}} \lesssim 1$, respecting energy conservation $\mathcal{E}_{\text{sc}} \lesssim \mathcal{E}$. Alternatively, the condition $\tau_{\text{sc}}(L, R) \sim 1$ may be used to define a minimum emission radius for a given $L$. Our results imply that observed FRBs cannot be released deep inside the magnetospheres of magnetars at radii $R \ll 10^{10}$ cm. This conclusion is based on established laws of electrodynamics and should be robust.

A similar constraint should hold for FRBs with any temporal structure, including e.g., double FRBs. The first burst will accelerate and displace the outer magnetosphere outside $R \sim 10^3$ cm (Equation (11)). Yet this displacement creates no holes that could save the second burst from scattering—it still must pass through the quasi-static magnetosphere just outside $R_0$ and then through the expanding layers at $R \gtrsim 10^7$ cm. Note that the magnetospheric outflow launched by the scattering of the first FRB has a smooth radial profile: its speed increases from $v_p \approx n_0$ in the inner layers to $v_p \sim c$ in the outer layers, and such smooth outflows do not develop holes. In addition, the outflow will get loaded with $e^\pm$ plasma created by gamma-rays trailing the first FRB. Then, the perturbed magnetosphere will begin to relax toward a new equilibrium. Thus, the burst will fail to clear out an escape route and save subsequent FRBs from scattering.

Interestingly, lowering $L$ may not help FRBs escape, because $\sigma_{\text{crit}} \propto L^{-3/8}$ grows at lower $L$ (Equation (20)), and $\epsilon_{\gamma}$ weakens. The main helping effect of lowering $L$ is the growth of $R_0 \propto L^{1/4}$ (Figure 1). When $L \lesssim 10^{46}$ erg s$^{-1}$, $R_0$ reaches $\sim 10^{10}$ cm, the zone of strong particle acceleration $1 < a_0 < \omega_0 / c$ disappears, and the wave scattering practically vanishes. The FRBs detected from SGR 1935+2154 are close to this transition.

We conclude that the scenario of a radio source confined in the inner magnetosphere is not satisfactory for FRBs in a broad range of observed luminosities. A remaining possibility for FRB emission by magnetars is a magnetic explosion—the ejection of a large-scale electromagnetic pulse from the inner magnetosphere. The pulse has a size of $10^7 - 10^8$ cm and is much more energetic than the observed GHz burst. Beloborodov (2017, 2020) proposed that the pulse drives an ultrarelativistic shock in the magnetar wind and the shock emits coherent radio waves by the synchrotron maser mechanism. A version of this model (a shock striking slow ion ejecta) was developed by Metzger et al. (2019).

Alternatively, Lyubarsky (2014, 2020) argued that the ejected pulse will freely propagate through the magnetar wind, like a vacuum electromagnetic wave (this can happen under certain conditions that will be discussed elsewhere). The field in the pulse is expected to have small-scale perturbations, and they may be released at a large radius as escaping radio waves (Lyubarsky 2020).

Calculations of wave scattering in this Letter focused on the closed magnetosphere at $R < R_{\text{LC}}$. In a similar way, one can evaluate $\tau_{\text{sc}}$ in the wind at radii $R > R_{\text{LC}}$, where $n_0 \sim N_0 / R_{\text{LC}} R^2$, $B_0 \approx \mu / R_{\text{LC}} R$, and scattering occurs in regime I ($\omega_0' < \omega_1'$) with $\sigma_{\text{crit}}' \approx a_0^2 \sigma_T$. With increasing radius, $\omega_0' \approx a_0 \omega_0$ quickly falls below $m_e c^2$, so secondary $e^\pm$ creation becomes suppressed, and one finds

$$\tau_{\text{sc}} \sim \frac{a_0^2 \sigma_T N}{R_{\text{LC}} R} \approx \frac{0.7 L_{52} N_{57}^2}{R_0^3 v_0^2 (P/1 \text{ s})} (R > 10^{10} \text{ cm}).$$

In particular, $\tau_{\text{sc}}$ is negligible if the observed FRBs are emitted by blast waves in the magnetar wind, which generate coherent radio emission at $R \sim 10^{13} - 10^{14}$ cm, although induced scattering could still be important in this model (Beloborodov 2020).

I thank Yuri Levin, Brian Metzger, and the referee for comments that helped improve the manuscript. This work is supported by NSF grant AST 2009453, Simons Foundation grant #446228, and the Humboldt Foundation.
