The Spectral Slope and Escape Fraction of Bright Quasars at 
z ∼ 3.8: the Contribution to the Cosmic UV Background

ABSTRACT
We use a sample of 1669 QSOs ($r < 20.15$, $3.6 < z < 4.0$) from the BOSS survey to study the intrinsic shape of their continuum and the Lyman continuum photon escape fraction ($f_{\text{esc},q}$), estimated as the ratio between the observed flux and the expected intrinsic flux (corrected for the intergalactic medium absorption) in the wavelength range 865-885 Å rest-frame. Modelling the intrinsic QSO continuum shape with a power-law, $F_{\lambda} \propto \lambda^{-\gamma}$, we find a median $\gamma = 1.30$ (with a dispersion of 0.38, no dependence on the redshift and a mild intrinsic luminosity dependence) and a mean $f_{\text{esc},q} = 0.75$ (independent of the QSO luminosity and/or redshift). The $f_{\text{esc},q}$ distribution shows a peak around zero and a long tail of higher values, with a resulting dispersion of 0.7. If we assume for the QSO continuum a double power-law shape (also compatible with the data) with a break located at $\lambda_{\text{br}} = 1000$ Å and a softening $\Delta \gamma = 0.72$ at wavelengths shorter than $\lambda_{\text{br}}$, the mean $f_{\text{esc},q}$ rises to 0.82.

Combining our $\gamma$ and $f_{\text{esc},q}$ estimates with the observed evolution of the AGN luminosity function (LF) we compute the AGN contribution to the UV ionizing background (UVB) as a function of redshift. AGN brighter than one tenth of the characteristic luminosity of the LF are able to produce most of it at $z \approx 3$, if the present sample is representative of their properties. At higher redshifts a contribution of the galaxy population is required. Assuming an escape fraction of Lyman continuum photons from galaxies between 5.5 and 7.6\%, independent of the galaxy luminosity and/or redshift, a remarkably good fit to the observational UVB data up to $z \sim 6$ is obtained. At lower redshift the extrapolation of our empirical estimate agrees well with recent UVB observations, dispelling the so-called Photon Underproduction Crisis.

Key words: cosmology: observation - early Universe - quasars: general - galaxies: active - galaxies: evolution

1 INTRODUCTION
After more than thirty-five years \cite{Sargent1980} the issue of the sources driving the reionization of the hydrogen in the Universe and keeping it ionized afterward does not appear to be settled. It is commonplace that galaxies should be able to produce the bulk of the UV emissivity at high redshift (see, for example, \cite{Robertson2015}), but the AGN population is also proposed as a relevant or dominant contributor \cite{Giallongo2015, Madau2015} (see also \cite{Fontanot2012} and \cite{Haardt2015} for different views).

A direct measurement of the 1-4 Ryd photons escaping the various types of sources is unpractical at $z \gtrsim 4.5$, due to the reduced mean free path of these photons in the intergalactic medium (IGM). At lower redshift direct observations of galaxies, after accounting for the statistical contamination of interlopers, have in general provided upper limits in the fraction of ionizing photons, produced by young stars, that are able to escape to the IGM ($f_{\text{esc},g}$, see \cite{Vanzella2012}). These limits tend to be significantly lower than the $\sim 20\%$ required at $z \approx 7$ to re-ionize the Universe with galaxies only \cite{Bouwens2011}, and an increasing $f_{\text{esc},g}$ with decreasing luminosity (possibly with a steep faint-end of the LF) has been invoked to circumvent this shortcoming \cite{Fontanot2014}. The corresponding $f_{\text{esc},q}$ for QSOs is typically assumed to be about 100\%.

In this paper we aim to obtain a precise measurement of the QSO contribution to the cosmic UV background in the range $3.6 < z < 4.0$, where the QSO LF is well determined and the IGM transmission not too low. Our strategy is first to estimate the instrin-
sufficiently extended domain to estimate the intrinsic QSO continuum shape.

The spectral energy distribution (SED) of each quasar has been adjusted using a linear multiplicative slope (in magnitude) in order to match the $g, r, i, z$ magnitudes from the SDSS photometric catalog and then corrected for galactic extinction according to the maps of Schlafly & Finkbeiner (2011) and the average Milky Way extinction curve of Cardelli et al. (1989).

All the spectra have been visually inspected and their systemic redshifts calculated. We have adopted the offsets of $-310$ km/s and $+177$ km/s, respectively assigned to the CIV 1549 and SiIV 1398 lines (Tytler & Fan 1992) to derive the systemic redshift. A small fraction ($\lesssim 1\%$) of spectra showing problems in terms of the observed S/N ratio have been excluded from the subsequent analysis. The resulting sample consists of 1669 objects and the associated redshift distribution is shown in Fig. 1. The number of QSOs declines from about 300 per $\Delta z = 0.05$ bin in the interval $3.6 < z < 3.7$ to about 100 at $z \simeq 4$, following the general trend of the BOSS Survey. The distribution of the recomputed redshifts shows a small systematic difference with respect to the SDSS data, $<\Delta z > = <z_{corr} - z_{SDSS}> = -0.008$, with a dispersion of 0.012.

### 3 ESTIMATE OF THE QSO SPECTRAL ENERGY DISTRIBUTION

In order to estimate the QSO production of UV ionizing photons it is necessary to model their intrinsic spectral shape. Customarily this is achieved by fitting a power-law, $F_\lambda \propto \lambda^{-\gamma}$, in the region redward of the Lyman-α emission, selecting windows free of emission lines and extrapolating it in the region blueward of the Lyman-α (e.g. Fig. 2). Previous works by Zheng et al. (1997), Telfer et al. (2002), Shull et al. (2013), Stevans et al. (2014) at relatively low redshift ($z \lesssim 1.5$), where the IGM absorption is minimized, have identified a break in the spectral distribution with a softening of the slope at wavelengths shorter than $\lambda_{Ly\alpha} \sim 1000$ Å.

In the following we have chosen to fit the continuum spectrum of each quasar both with a single and with a broken power-law. In both cases five windows, listed in Tab. 1, have been used for the fit as emission-line-free regions. In the case of the broken power-law fit we have imposed a flattening in the spectral slope blueward of 1000 Å of $\Delta \gamma = 0.72$ with respect to the power-law at longer wavelengths, as reported by Stevans et al. (2014). Pixels affected by absorption lines have been iteratively rejected on the basis of a three sigma k-clipping. We have checked that the results are not sensitive to the particular choice of the windows.

As a check of the goodness of the assumptions, we have stacked all the spectra after dividing them by the continuum slope and by the expected mean transmission of the IGM according to the procedure described in Sect. 2.

### Table 1. Regions used for the continuum fitting

| Region | start | end |
|--------|-------|-----|
| 1      | 1990  | 2020|
| 2      | 1690  | 1700|
| 3      | 1440  | 1465|
| 4      | 1322  | 1329|
| 5      | 1284  | 1291|

![Figure 1. Redshift distribution of the QSOs in the present sample shown in bins of $\Delta z = 0.05$. $z_{corr}$ on the x-axis indicates the redshift estimated according to the procedure described in Sect. 2.](image)
QSOs contribution to the UVB

Figure 2. Two illustrative cases for the estimate of the continuum power-law and the escape fraction. The upper panels show a QSO of redshift 3.815 with a $f_{esc, q} \sim 1$, the lower panels a QSO of redshift 3.726 with a $f_{esc, q} \sim 0$. Left column: the two spectra are plotted in black. Note that the region blueward of the Lyman-$\alpha$ has been divided by the average transmission of the IGM estimated (see Sect. 4) according to Inoue et al. (2014) in order to show where the average continuum should be located. The green line shows the uncertainty of the flux. The red line shows the fitted power-law continuum.

Right column: the two observed spectra are plotted in black, the expected position of the power-law continuum multiplied by the average IGM transmission is in red and the uncertainty of the observed flux in green. The cyan portion of the spectrum is the region where the escape fraction of the UV photons produced by the QSO has been estimated.

We have then analyzed the ensemble properties of the quasars in our sample. The median (mean) spectral index of the population for the single power-law case (and for the region with $\lambda > 1000$ Å for the broken power-law) is $\gamma = 1.30$ (1.24), with a dispersion of 0.38, computed as half of the difference between the 84.13 and 15.87 percentiles (Fig. 5). A KS test on the two samples above and below redshift $z = 3.8$ does not show any significant difference in the two distributions (see also Fig. 4 and 5). We have checked that selecting QSOs with $3.4 < z < 3.6$ (and $r < 20.15$) we would obtain a value of $\gamma$ significantly lower than the one we measure in the range $3.6 < z < 4.0$, confirming the above mentioned bias found by Prochaska et al. (2009). The dependence of the spectral index on the SDSS $r$ magnitude has also been analyzed by splitting the sample in two halves: $r \leq 19.69$ and $r > 19.69$. The corresponding median spectral indices turn out to be $\gamma = 1.36$ and $\gamma = 1.22$, respectively, with fainter objects generally characterized by “redder” spectral indices. A KS test rejects with a high significance the hypothesis that the two subsamples have the same distribution function. We interpret this effect as a property of the SEDs of the QSOs analyzed, rather than a bias introduced by the fitting procedure, since a corresponding difference is present in the measured colors of the QSOs: the average $(r - i)$ is 0.115 for objects brighter than $r = 19.69$ and 0.138 for the fainter ones.

The median (mean) value of the spectral index for the full sam-
4 THE AVERAGE ESCAPE FRACTION OF THE QSO POPULATION AT $3.6 < Z \leq 4.0$

The fraction of the UV ionizing photons produced by each QSO leaking to the IGM has been estimated by dividing the observed average flux in the region $865 - 885 \, \text{Å}$ rest frame by the expected average flux in the same region, as estimated either with the single or with the broken power-law, convolved with the average transmission of the IGM at the given redshift (Inoue et al. 2014). The interval $856 - 885 \, \text{Å}$ has been chosen since its is expected to be a “true continuum” window (see Fig.6 in Shull et al. 2012 and Fig.5 in Stevans et al. 2014). Besides, it represents a convenient compromise: on the one hand at wavelengths close to the Lyman edge the measurement can be affected by errors in the determination of the emission redshift of the QSO, on the other hand the IGM transmission is progressively decreasing at shorter and shorter wavelengths with a consequent increase of the measurement uncertainty. The resulting value of the $f_{\text{esc},q}$ has been checked to be largely independent of the specific choice of the limits of the interval.

The estimated $f_{\text{esc},q}$ is an effective escape fraction, i.e. is expected to include the escape fraction of the UV photons from the QSO host galaxy and all the extra absorption due to clustered neutral hydrogen in the vicinity of the QSO that is not accounted for in the model of Inoue et al. (2014), which applies to the average, intervening IGM.

The average escape fraction in the redshift interval $3.6 < z \leq 4.0$, measured on the ensemble of 1669 objects of our sample turns out to be $f_{\text{esc},q} = 0.75$ and $f_{\text{esc},q} = 0.82$ in the case of the single and broken power-law respectively. As shown in Fig.6 and 7, a rather large dispersion is observed, 0.7, computed as half of the difference between the 84.13 and 15.87 percentiles, in a kind of bimodal distribution with a narrower peak around the value zero and a larger dispersion around the value 1. In each object $f_{\text{esc},q}$ is computed by comparing the observed flux shortward of the Lyman edge and the expected flux on the basis of an average correction for the IGM absorption. It is not surprising therefore that for some objects our measured $f_{\text{esc},q}$ turns out to be larger than one - besides the measurement errors - due to lines of sight with an actual transmission larger than the average estimate from the Inoue et al. (2014) computation.

Fig.6 shows the escape fraction measured in the QSO spectra as a function of the redshift. In the intervals $3.6 < z \leq 3.8$ and $3.8 < z \leq 4.0$ the result is similar: $f_{\text{esc},q} = 0.73$ and $f_{\text{esc},q} = 0.78$, respectively for the single power-law, $f_{\text{esc},q} = 0.80$ and $f_{\text{esc},q} = 0.85$, respectively, for the broken power-law.

Splitting the sample in two halves, brighter and fainter than $r = 19.69$ does not show any significant difference in the mean $f_{\text{esc},q}$ and a KS test cannot reject the hypothesis that the parent
5 SYNTHESIS OF THE IONIZING BACKGROUND

We use the results of the previous section to estimate the QSO contribution to the observed photon volume emissivity (Fig. 8 upper panel) and photoionization rate (lower panel), adopting the same formalism as in Fontanot et al. (2014).

We consider functional forms for the AGN LF \( \Phi(L, z) \) as a function of luminosity and redshift and we use them to compute the rate of emitted ionizing photons per unit comoving volume as a function of the redshift:

\[
\dot{N}_{\text{ion}}(z) = \int_{\nu_{\text{up}}}^{\nu_{\text{up}}} \frac{\rho_\nu}{h_\nu c} d\nu
\]

where \( \nu_{\text{up}} \) is the frequency corresponding to 912 Å and \( \nu_{\text{up}} = 4\nu_H \) (i.e. we consider that more energetic photons will be mainly absorbed by He II atoms), while \( \rho_\nu \) is the monochromatic comoving luminosity density brighter than \( L_{\text{min}} \). The redshift evolution of the corresponding photoionization rate \( \Gamma \) is computed solving the following equations (see e.g. Haardt & Madau (2012) and references therein):

\[
\Gamma(z) = 4\pi \int_{\nu_H}^{\nu_{\text{up}}} \frac{J(\nu, z)}{h_\nu c} \sigma_{HI}(\nu) d\nu
\]

where \( \sigma_{HI}(\nu) \) is the absorbing cross-section for neutral hydrogen and \( J(\nu, z) \) is the background intensity:

\[
J(\nu, z) = c/4\pi \int_0^{\nu_{\text{up}}} \epsilon_{\nu_1}(z_1) e^{-\tau_{\nu_1}(1+z_1)^3} \frac{dt}{dz_1} \frac{dz_1}{dz_2} f(N_{HI}, z_2)(1-e^{-\tau_{\nu_2}(z_2)})
\]

where \( \tau_{\nu_1} \) is the continuum optical depth through an individual absorber at frequency \( \nu_2 = \frac{\nu_{\text{up}}}{1+z_1} \) and \( f(N_{HI}, z) \) is the bivariate distribution of absorbers. For the latter quantity, we consider different functional forms available in the literature, namely those proposed by Haardt & Madau (2012), Becker & Bolton (2013) and Inoue et al. (2014). In the following, we adopt Becker & Bolton (2013) as a reference, because we want to compare our predictions for the photon volume emissivity and photoionization rate in particular with their dataset, which covers a redshift range encompassing our sample. We consider two different estimates for the AGN-LF, namely the luminosity function at 145 nm (see Fig. 9) defined in the framework of the Hopkins et al. (2008) bolometric LF and the Hard X-ray LF from Fiore et al. (2012). We use the resulting space densities in Eq. 2 and 3 using the median spectral index from Sect. 5 and using the corresponding \( L_{145} \) as a normalization. In Fig. 8 the solid line represents predictions corresponding to the Hopkins et al. (2008) 145 nm LF at \( z < 4 \) (and its extrapolation at higher redshifts), while dashed line refers to the Fiore et al. (2012) LF (\( z > 3.5 \)), assuming a single power-law SED. We adopt as \( L_{\text{min}} \) one tenth of the characteristic luminosity of the LF (i.e. \( L_{\text{min}} = 0.1 L_* \) ).. Cowie et al. (2008) have shown, in fact, that most of the ionizing flux is produced by broad-line QSOs straddling the break luminosity. Although our formulation allows for a luminosity and redshift dependent escape fraction, we assume a fixed \( f_{\text{esc},QSO} = 0.75 \), consistently with the results in Sect 4.

In Fig. 8 we use hatched and grey areas to highlight the effect of two of the main uncertainties involved in the estimate of the photon volume emissivity and photoionization rate. In particular, the hatched orange area represents the variation corresponding to different functional forms for the column density distribution (Haardt & Madau 2012, Becker & Bolton 2013, Inoue et al. 2014), while the grey area refers to the difference between the single and the double estimates of the QSO LF.

Figure 6. Escape fraction measured in the QSO spectra as a function of the redshift. The mean values in the intervals \( 3.6 < z \leq 3.8 \) and \( 3.8 < z \leq 4.0 \) are shown as continuous red segments, with the dispersion estimated as half of the difference between the 84.15 and 15.87 percentiles.

Figure 7. Normalized probability distributions of the escape fraction \( f_{\text{esc},QSO} \) for QSOs in the redshift interval \( 3.6 < z \leq 4.0 \). The black continuous line shows the full sample. The red dashed line corresponds to objects with \( r < 19.69 \), while the blue dashed line refers to objects with \( r > 19.69 \).
the broken power-law assumption for the AGN spectral shape. To the zeroth order, adopting a single power-law with a 0.75 $f_{\text{esc}}$ or a broken power-law with a 0.82 $f_{\text{esc,q}}$ is degenerate from the point of view of the UV background: the assumption of the SED type is compensated by the resulting $f_{\text{esc,q}}$ and the same flux is predicted at the Lyman Limit. The difference between the two predictions arises from the extrapolation of the flux up to 4 Ryd with different slopes.

Our estimates are then compared with a collection of observational results for the photon volume emissivity (Wyithe & Bolton 2011; Becker & Bolton 2013) and photoionization rate (Calverley et al. 2011; Adams et al. 2011; Becker & Bolton 2013; Shull et al. 2015; Gaikwad et al. 2016). It is worth stressing that our estimates do not exactly correspond to the predictions of the Haardt & Madau (2012) model. The main difference lies in the assumption by Haardt & Madau (2012) of a QSO emissivity based on the Hopkins et al. (2007) LF with a contribution of relatively bright ($M_B < -27$) QSOs only. Here, we are considering objects down to 0.1 $L_\star$, which implies a fainter (and variable with redshift) limiting magnitude.

![Figure 8](image8.png)

**Figure 8. Upper panel:** predicted photon volume emissivity. Observed data from Wyithe & Bolton (2011) (asterisks) and Becker & Bolton (2013) (diamonds). Lower Panel: predicted hydrogen photoionization rate. Observations from Becker & Bolton (2013, diamonds), Calverley et al. (2011 pentagons), Shull et al. (2015, stars) and Gaikwad et al. (2016, empty circles). In both panels, solid and dashed lines (in blue) represent the predictions corresponding to the AGN-LF from Hopkins et al. (2007) and Fiore et al. (2012, respectively, integrated up to 0.1 $L_\star$, assuming a single power-law quasar SED. The grey area extends down to the double power-law results, to show the deriving systematic uncertainty, while the hatched orange area represents the uncertainty relative to the shape of the assumed column density distribution (see text). The short thick segments (in green) in the redshift range $3.6 < z < 4$, show the contribution of QSOs brighter than $M_{\text{UV}} \sim -27.49$ roughly corresponding to the absolute magnitude limit in the present sample, assuming the Hopkins et al. (2007) bolometric LF. The dot-dashed red lines show the total UV background and photoionization rate adding to the blue solid line a contribution of the galaxy population estimated assuming an $f_{\text{esc,q}} = 5.5\%$ (see text for more details).

Our predictions are consistent with a number of observational constraints, and in particular with the data at $2 < z < 3$ from Becker & Bolton (2013): this suggests both that sources brighter than 0.1 $L_\star$, account for the observed ionizing photons and, conversely, that objects fainter than 0.1 $L_\star$ should provide a negligible contribution to the ionizing photon budget. It will be therefore of interest to test with future observations the $f_{\text{esc,q}}$ for low-luminosity QSOs to check whether smaller values with respect to the present sample are measured. There is already an indication from the observations of Cowie et al. (2009) that this is indeed the case. The thick green segments in Fig. 8 spanning the redshift range of the present sample represent the integration of the Hopkins et al. (2007) LF up to $M_{\text{UV}} \sim -27.49$, roughly corresponding to the absolute magnitude limit in our QSO sample, in the range $3.6 < z < 4.0$. They lie $\sim 0.8$ dex below the solid lines, highlighting that the QSOs in the present sample account for less than one sixth of the full background and, again, observations of fainter objects would be advisable in order to avoid extrapolations. The prediction obtained with the luminosity function by Fiore et al. (2012) highlights the effect of the uncertainties in the LF estimate and the need for a better determination of this distribution at high-$z$.

We confirm that the QSO cannot dominate the ionizing photons production at $z > 4$: in fact none of our predictions reproduces the observational data, typically underestimating them, thus highlighting the need for additional ionizing sources at these redshifts (e.g. galaxies, dot-dashed red lines in Fig. 8). The contribution from galaxies has been computed from the LF of Lyman Break Galaxies (Bouwens et al. 2011) using eq. 1-5, assuming the redshift-dependent spectral emissivity as in Haardt & Madau (2012), the column density distribution as in Becker & Bolton (2013) and a constant value for the $f_{\text{esc,q}}$ (i.e. independent of either the luminosity or the redshift). The corresponding LFs have been integrated.
up to a limiting redshift-dependent faint magnitude computed as in Fontanot et al. (2014), their Fig. 3).

If we limit the analysis to the photon volume emissivity shown in the upper panel of Fig. 5 and fix the contribution of the QSO population to the above determined \( \text{f}_{\text{esc}, q} \) amount (shown by the blue solid line), then in the case of a single power-law quasar SED the best fit to the observational data (with a \( \chi^2 = 2.3 \) for six points and one free parameter) turns out to be \( \text{f}_{\text{esc}, g} = 6.9^{+6.4}_{-4.2} \% \), with the confidence interval estimated for \( \Delta \chi^2 = 1.1 \). If we apply the same analysis to the photonization rate (lower panel of Fig. 5) we obtain a best fit \( \text{f}_{\text{esc}, g} = 5.5^{+4.4}_{-1.2} \% \), with a \( \chi^2 = 9.8 \) for nine points and one free parameter). In the case of a double power-law quasar SED the best fit to the upper panel (with a \( \chi^2 = 2.1 \) for six points and one free parameter) turns out to be \( \text{f}_{\text{esc}, g} = 7.6^{+2.3}_{-2.1} \% \), and for the lower panel we obtain a best fit \( \text{f}_{\text{esc}, g} = 6.0^{+2.3}_{-1.2} \% \), with a \( \chi^2 = 8.9 \). It is interesting to note that all these values are fully compatible with the limits obtained by various authors with direct measurements of the \( \text{f}_{\text{esc}, g} \) (e.g. Vanzella et al. 2012; Bouwens et al. 2013; Reddy et al. 2016).

Finally, at \( z < 1 \) our estimates agree with the most recent determinations for the HI photoionization rate by Shull et al. (2015) and Gaikwad et al. (2016), based on HST-COS data (Danforth et al. 2014), giving origin to the so-called Photon Underproduction Crisis (PUC). Our computation shows that relatively bright QSOs at low redshift (i.e. brighter than \( 0.1 \text{L}_* \)) may account for the total photon budget required by observations. A similar result has been obtained by Khaire & Srianand (2015).

6 CONCLUSIONS

In this paper, we use a sample of 1669 QSOs with \( r < 20.15 \) in the redshift range \( 3.6 < z < 4.0 \), taken from the BOSS sample, to estimate the contribution of type I QSOs to the UV background. Each spectrum in the sample has been recalibrated to match the observed SDSS photometry, and the corresponding systemic redshift has been recomputed, taking into account the velocity shifts associated with the SiIV and CIV emission lines. For each QSO, we fit the intrinsic continuum spectrum, by means of five windows relatively free of emission lines, both with a single, \( F_{\lambda} \propto \lambda^{-g} \), and with a broken power-law with a break located at \( \lambda_{\text{br}} = 1000 \text{ A} \) rest-frame.

In order to constrain the Lyman continuum photon escape fraction, \( \text{f}_{\text{esc}, q} \) in our sample, we consider the spectral range \( 865 - 885 \text{ A} \) rest frame, close to the Lyman limit. We compute \( \text{f}_{\text{esc}, q} \) as the ratio between observed flux in this interval and the flux expected on the basis of the intrinsic quasar continuum and the average attenuation due to the IGM.

Using our reference sample, we estimate a median \( g = 1.30 \), with a dispersion of 0.38 in its distribution, and a mean \( \text{f}_{\text{esc}, q} = 0.75 \) in the case of the single power-law fit and \( = 0.82 \) for the broken power-law.

We do not find any evidence for a redshift dependence of both quantities. \( g \) shows a small dependence on the \( r \)-mag, which is likely due to an intrinsic effect, with the fainter sources having flatter continua \( (g = 1.36 \) for QSOs brighter than \( r = 19.69 \) and \( g = 1.22 \) for \( r > 19.69 \)). The statistical distribution of \( \text{f}_{\text{esc}, q} \) is characterized by a kind of bimodality: this shape suggests an interpretation of \( \text{f}_{\text{esc}, q} \) as a probabilistic distribution, rather than a mean value, with \( \sim 25 - 18 \% \) of the object characterized by a negligible escape fraction and the rest with roughly clear lines of sight. For comparison the percentage of BAL quasars in the BOSS survey has been estimated to be around 10 – 14\% (Péris et al. 2014; Allen et al. 2011). No dependence of \( \text{f}_{\text{esc}, q} \) with luminosity is present in our sample.

We have combined the observed evolution of the AGN/QSO-LF with our measurement of the escape fraction to compute the expected rate of emitting ionizing photons per unit comoving volume \( N_{\text{ion}} \) and photoionization rate \( \Gamma \), as a function of redshift. We show that, given our mean values for \( \text{f}_{\text{esc}, q} \), \( L > 0.1 \text{L}_* \) sources are able to provide enough photons to reproduce the reionization history in the redshift interval \( 2 < z < 3 \), while we confirm that at \( z > 4 \) additional sources of ionizing photons are required. However, the details on the reionization history are affected by the uncertainties in the QSO luminosity function evolution as estimated in the optical and X-ray bands.

Overall, our results imply that, at \( 2 < z < 4 \), the contribution to the ionizing background of AGNs fainter than the LF characteristic luminosity, \( 0.1 \text{L}_* \), should be negligible. Since our sample covers only magnitudes brighter than \( M_{\text{UV}} \sim -27.49 \), we also forecast that fainter QSOs (but still brighter than \( 0.1 \text{L}_* \)) should be characterized by an \( \text{f}_{\text{esc}, q} \) as large as those found in this work, in order for the QSO population to account for the whole photon budget at the redshift of interest.

Our predictions are perfectly compatible with the low redshift estimate of Shull et al. (2015); Gaikwad et al. (2016), suggesting that QSOs brighter than \( 0.1 \text{L}_* \) may account for the total photon budget at low redshift.

At \( z > 4 \) a contribution to the UV background from the galaxy population is needed. A good fit from \( z = 2 \) to \( z = 6 \) of the data is obtained assuming an escape fraction \( \text{f}_{\text{esc}, q} \) between 5.5 and 7.6\% (depending on the assumptions on the quasar SED and the comparison with the ionizing background or photoionization rate measurements), independent of the galaxy luminosity and/or redshift, added to the present determination of the QSO contribution.

On the basis of the present approach, future area of progress, besides the obvious direct determination of \( \text{f}_{\text{esc}, q} \), are linked to a better knowledge of the QSO luminosity function, the \( \text{f}_{\text{esc}, q} \) for fainter quasars (at least down to 0.1 \text{L}_*) and its possible dependence on the redshift, the intensity of the UVB, which in turn requires improved simulations of the IGM.

ACKNOWLEDGMENTS

We are grateful to A. Inoue, S. Cooper, E. Giallongo, F. Haardt, L. Hofstader, J. Japelj, I. Péris and H. Wolowitz, for providing unpublished material and enlightening discussions. We acknowledge financial support from the grants PRIN INAF 2010 “From the dawn of galaxy formation” and PRIN MIUR 2012 “The Intergalactic Medium as a probe of the growth of cosmic structures”. Funding for SDSS-III has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, and the U.S. Department of Energy Office of Science. The SDSS-III web site is http://www.sdss3.org/. SDSS-III is managed by the Astrophysical Research Consortium for the Participating Institutions of the SDSS-III Collaboration including the University of Arizona, the Brazilian Participation Group, Brookhaven National Laboratory, University of Cambridge, Carnegie Mellon University, University of Florida, the French Participation Group, the German Participation Group, Harvard University, the Instituto de Astrofísica de Canarias, the Michigan State/Notre Dame/JINA
