**Abstract:** Dietary nitrate has several beneficial effects, including blood pressure reduction and improved oxygen consumption efficiency, but in order to do so it must first be reduced to nitrite by oral bacteria. *Veillonella* spp., a strictly anaerobic group, are the most prevalent nitrate-reducing bacteria in the oral cavity. In response to some early studies that have hinted at inter- and intra-individual variation in salivary nitrate-nitrite conversion capacity, the purpose of the present study was to investigate the incidence of and variation in the *Veillonella* species *V. atypica*, *V. dispar*, and *V. rogosae* by direct PCR and to assess salivary nitrate-nitrite conversion capacity and its reproducibility after dietary nitrate consumption in 24 elderly individuals. *V. atypica*, *V. dispar*, and *V. rogosae* were detected in 10 (41.7%), 24 (100%), and 14 (58.3%) participants, respectively. The coefficients of correlation between the first and second experiments on increased nitrate/nitrite were 0.637 and 0.583, respectively, both of which were statistically significant ($P < 0.01$). In both experiments, 6 participants produced relatively low levels of nitrite (<0.5 mM Δ nitrite) while 7 produced relatively high levels (>1.0 mM Δ nitrite). The data suggested that *V. dispar* was the most prevalent species, being present even in individuals producing low levels of salivary nitrite.

**Keywords:** salivary nitrate; salivary nitrite; *Veillonella*; inter- and intra-individual variation.

**Introduction**

In humans, dietary nitrate is obtained primarily from vegetables such as lettuce and spinach (1). Historically, ingestion of nitrate has been considered deleterious because it is rapidly reduced by oral microbial activity to toxic nitrite, which is a possible cause of infant methemoglobinemia and is linked to the formation of carcinogenic N-nitrosamine (1). Over the past two decades, however, it has also become clear that nitrate/nitrite also has beneficial effects such as reduction of blood pressure (2-4) and oxygen consumption (5), and antibacterial activity in the oral cavity (6-8) and upper intestinal tract (9). Nitric oxide produced through the reduction of dietary nitrate to nitrite by oral bacteria may have a vasodilatory effect, as does endogenous nitric oxide (NO) derived from L-arginine (10).

Ingested nitrate is absorbed rapidly into the bloodstream from the upper intestine. Approximately 75% of circulating nitrate is excreted by the kidneys, while the rest is concentrated in the salivary glands by the active transport system, increasing its concentration there to as much as 10 times the concentration found in plasma (11). Salivary levels of nitrate/nitrite can increase markedly after nitrate loading, those of nitrate rising from approximately 0.7 mM to >15 mM and those of nitrite from 0.3 mM to >2.0 mM (12). Previous studies examining the effect of dietary nitrate have also revealed great variation in salivary nitrate/nitrite conversion after nitrate loading, which is the result of inter-individual differences in nitrate...
metabolism. Some early studies published in the 1980s, for example, suggested a distinction between individuals with greater and lesser capacities for nitrate-nitrite conversion (13,14). Despite its physiological importance, however, the inter- and intra-individual variation in salivary nitrate/nitrite conversion after nitrate loading has received little attention to date.

Many oral facultative and strictly anaerobic bacteria possess nitrate and nitrite reductases (15-17). Veillonella spp., a strictly anaerobic group, are the most prevalent nitrate-reducing bacteria in the oral cavity, where they are considered to make a major contribution to nitrate reduction (16). So far, six Veillonella species have been isolated from humans; among these, V. atypica, V. dispar, and V. rogosae are predominant in the oral cavity (18).

Variations in microflora and the nitrate-nitrite-NO pathway seem to be matters of greater concern for middle-aged and older individuals because the management of cardiovascular disorders such as high blood pressure is more important for these age groups. The purpose of the present study was to assess the increase in salivary nitrate/nitrite that occurs after nitrate loading and its inter- and intra-individual variations, the distribution of the three dominant Veillonella spp., and the presence of any relationship between these factors in humans over 60 years of age.

Materials and Methods
Participants
For this study, 24 (12 male and 12 female) ambulatory non-smoking local residents with a mean age of 70.3 ± 6.0 (SD) years were enrolled. Participants were invited to enroll at a municipal job center or a local community organization. None of the participants had used antibiotics or mouthwash in the last three months. Their prescription notebooks were handed in at the first visit. Written informed consent was obtained from all participants, and the study protocol was approved by the Human Ethics Committee of Iwate University (No. 201407).

Study protocol
All participants were asked to refrain from eating vegetables at dinner on the eve of each sampling day and to skip breakfast. They arrived at the laboratory prior to 7:30 a.m. for each experiment and rested for 10 min before the experiment began. Just before the nitrate load was consumed, blood pressure was measured using an EW-BW13 (Panasonic, Osaka, Japan) with the participant in a sitting position. Hypertension was defined as a systolic blood pressure of ≥140 mmHg and/or a diastolic blood pressure ≥90 mmHg (Ministry of Health, Labour, and Welfare) or current medication for hypertension. A 1.0-mL whole saliva and bacteria sample was also collected. The dorsal surface of the tongue in each participant was swabbed five times using a sterile cotton-wool stick to collect bacteria; the surface of the tongue is the major area where nitrate reduction occurs in the oral cavity (16). The stick was immediately placed in 1 mL of phosphate-buffered saline (PBS) solution to create a bacterial suspension. Following baseline collection, participants consumed 100 mL of beetroot juice (James White Drinks Ltd., Ashbocking, UK), which is equivalent to 372 mg of nitrate. Afterwards, blood pressure was measured at 15-min intervals and saliva samples were collected at 30-min intervals for 90 min. Bacterial and saliva samples were stored at −20°C immediately after collection. The procedure was repeated twice with a one-week interval.

Analysis of salivary nitrate and nitrite
Our method of salivary nitrite measurement has been described previously (7). Each whole saliva sample was diluted 200-400-fold using distilled water and filtered using an ADVANTEC Grade No. 2 filter for nitrate/nitrite analysis. A standard colorimetric method involving diazotization with sulphanilamide coupled with N-(1-naphthyl)ethylendiamine to form an azo-dye was used, and the samples were tested spectrophotometrically at 540 nm. Nitrate was measured after reduction to nitrite by passing it through a cadmium-copper column.

Direct polymerase chain reaction (PCR) protocol
The following species-specific forward primers in the rpoB gene were used for identification of the three bacterial species: ATYF (5’-TCTCTTTGGAGAAGAATTGAACGC-3’) for V. atypica, DISF (5’-AACGC-GTTGAATTTCTCGATGAC-3’) for V. dispar, and RGF (5’-ATTGCAAGATGTAACATGAGC-3’) for V. rogosae. In addition, the reverse primer VR (5’-GTGTAACAGGGAGTACGGACC-3’) was used for all species (19). The expected molecular weights of the PCR products were 384 bp for V. atypica, 321 bp for V. dispar, and 604 bp for V. rogosae (20). The primers were synthesized by BEX Co. Ltd. (Tokyo, Japan).

The PCR mixture (50 µL) was composed of 24 µL H2O, 12 µL bacterial slurry serially diluted 10-fold with PBS (10⁻¹ and 10⁻²), 12 µL direct PCR kit (KAPA2G Robust HotStart ReadyMix with dye, Kapa Biosystems, Cape Town, South Africa), and 1 µL of each primer (50 pmol/µL). This PCR polymerase offers high amplification efficiency even in the presence of an inhibitor and is a useful tool for forensic samples (20).
PCR was performed in a thermal cycler (Model TP600, Takara Bio Inc., Otsu, Japan). The reaction mixture was predenatured at 95°C for 3 min, followed by 30 cycles of denaturing at 95°C for 15 s, annealing at 60°C for 15 s, and extension at 72°C, with a final extension at 72°C for 10 min. The 12 µL of PCR products were analyzed using electrophoresis in 1.0% agarose gel (Lonza, Rockland, ME, USA) on a submarine-type apparatus (Mupid-2 plus, Mupid Co., Ltd, Tokyo, Japan). Precisely 10 µL of a 250-bp DNA ladder was used as a size marker (Takara Bio Inc.). After electrophoresis, the gel was stained with 50 µg/100 mL ethidium bromide solution.

**Data analysis**

Data were reported as mean ± SD or median (range) when not normally distributed. Linear regression analysis was used to examine the relationship between the increases in salivary nitrate/nitrite concentrations after nitrate loading (Δ nitrate/nitrite) obtained in the first and second experiments. The differences were analyzed by non-paired t-test or Mann-Whitney U test. Statistical significance was set at P < 0.05. All statistical analyses were carried out by Kaleidagraph 3.6 (HULINKS, Tokyo, Japan).

**Results**

Table 1 shows the participants’ age, first and second measurements of the baseline nitrate/nitrite concentration, and Δ nitrate/nitrite concentration after nitrate loading. The numbers of normotensive, grey-zone, and hypertensive participants were 10, 2, and 12, respectively.

The mean ages of the normotensive and hypertensive participants were significantly different (65.1 ± 4.1 vs. 74.3 ± 4.0 years, P < 0.001). There were no significant differences in salivary Δ nitrate/nitrite after nitrate loading between the normotensive and hypertensive participants (Fig. 1). Blood pressure did not change after nitrate loading (data not shown).

Table 2 shows the incidence of Veillonella spp. and Δ nitrate/nitrite concentrations according to blood pressure. V. atypica, V. dispar, and V. rogosae were detected in 10 (41.7%), 24 (100%), and 14 (38.3%) participants, respectively. A clear band of V. dispar was even seen in

Data are expressed as mean ± SD or median (range).
participants who produced low amount of salivary nitrite (Fig. 2).

The relationship between the salivary Δ nitrate/nitrite concentration are depicted in Figure 3. The correlation coefficients were 0.637 for nitrate and 0.583 for nitrite, both of which were statistically significant ($P < 0.01$).

Six participants (Nos. 4, 9, 16, 17, 19, and 24) produced relatively low levels of nitrite (<0.5 mM Δ nitrite), while seven (Nos. 1, 5, 7, 14, 20, 21, and 23) produced relatively high levels (>1.0 mM Δ nitrite) (Table 2).

**Discussion**

There were no significant differences in Δ nitrate/nitrite after nitrate loading between normotensive and hyperten-

sive participants. The significantly higher age (9.2 years) of the hypertensive group indicates that nitrate-nitrite conversion capacity does not change with aging. Blood pressure is primarily determined by genetics, aging, diet, and other lifestyle-related factors, and the contribution of the nitrate-nitrite-NO pathway to it is relatively small.

In the present study, large inter-individual variation in saliva nitrate/nitrite concentration was seen, levels after nitrate loading ranging from slightly higher to more than 10 times the baseline level. The nitrate-nitrite-NO pathway is a non-mammalian metabolic process that can be completely abolished by the use of chlorhexidine-based mouthwash, although salivary nitrate concentration is little affected by such mouthwashes (12). The large inter-individual variation in salivary nitrate/nitrite concentration probably occurs because of differences in the capacity for absorption of nitrate in the small intestine, its excretion by the kidneys, and its concentration by the salivary glands, and also the distribution of oral nitrate-reducing microflora.

As shown in Fig. 3, statistically significant relationships were seen between individual participants’ salivary Δ nitrate/nitrite levels in the first and second experiments.

To our knowledge, only one previous study (14) has examined intra-individual variation in salivary nitrate/nitrite. In that study, 100 mL of beetroot juice and almost the same level of potassium nitrate (2.0 mM) was administered to participants, and a distinction between subjects with consistently high and low rates of nitrite conversion was suggested. While large day-to-day variations were observed, our results were largely consistent with those previous ones. Our 6 low nitrite-producing participants would certainly have had a lower nitrate-reducing capacity.

In previous studies, cultivable _V. atypica_, _V. dispar_, and _V. rogosae_ were isolated from the dorsal surface of the tongue using _rpoB_ sequencing in 91.0%, 81.8%, and 72.7% of 11 healthy adults, respectively (18), and in 74.0%, 55.5%, and 66.7% of 27 young adults, respectively (21). In a recent study of 89 Thai children, the incidence rates of these _Veillonella _spp. were 3.4%, 3.4%, and 9.0%, all being lower than those found previously (22). In our present study, _V. dispar_ was the most prevalent species (100%) with marked DNA bands, while _V. atypica_ and _V. rogosae_ were detected in 40-60% of participants. We adopted the direct PCR method because...
it is easy, fast, and low-cost, as it does not require culture. Larger-scale research will be needed to determine how the incidence of Veillonella spp. in the oral cavity relates to aging, race, and oral hygiene.

As Fig. 2 shows, clear bands of V. dispar DNA were seen in one subject with low salivary nitrite production (No. 16), while all three Veillonella species were detected in a subject with abundant production (No. 21). Many bacteria in the oral cavity have nitrate/nitrite reductases (15-17), indicating that they may be involved in the nitrate-nitrite-NO pathway. Although the medical community’s interest in this pathway has been increasing recently, the organisms that participate in these processes remain poorly understood. To improve our understanding of nitrate metabolism in the intestinal tract and its effects on the human body, more information on oral nitrate-reducing bacteria is required.

In conclusion, V. dispar was detected even in participants with a reduced capacity for nitrate-nitrite conversion. The conversion of salivary nitrate-nitrite is not affected by aging or blood pressure. This inter- and intra-individual variation may affect how individuals receive the benefits of dietary nitrate, such as through lower blood pressure and efficient oxygen consumption.
