We study the relation between quasi-normal modes (QNM) and transmission resonances (TR) in one-dimensional (1D) disordered systems. We show for the first time that while each maximum in the transmission coefficient is always related to a QNM, the reverse statement is not necessarily correct. There exists an intermediate state, where only part of the QNM are localized and these QNM provide a resonant transmission. The rest of the solutions of the eigenvalue problem (denoted as strange quasi-modes) are never found in regular open cavities and resonators, and arise exclusively due to random scatterings. Although these strange QNM belong to a discrete spectrum, they are not localized and not associated with any anomalies in the transmission. The ratio of the number of the normal QNM to the total number of QNM is independent of the type of disorder, and deviates only slightly from the constant \( \sqrt{2/5} \) in rather wide ranges of the strength of a single scattering and the length of the random sample.

Wave processes in open systems can be described in terms of quasi-normal modes (QNM), which are a generalization of the notion of normal modes for closed systems, to open structures. The corresponding eigen-frequencies are complex, so that the imaginary parts characterize the lifetime of the quasi-normal states. Regarding the transmission of radiation through random media, it is more appropriate to use an alternative approach based on transmission resonances (TR): open channels, through which the radiation transmits with high efficiency.

Recently, physicists came to realize that focusing radiation into such channels could not only enhance the total intensity transmitted through strongly-scattering media, but also significantly improve images blurred by random scattering, facilitate the detection and location of objects, provide optical tomography at very large depths, etc. To efficiently excite transmission resonances, it is preferable to treat them as superpositions of QNM, with which the incident signal can be coupled by a properly-shaped wavefront. The great potential of such algorithms for a host of practical applications is obvious. This is why the relation between transmission resonances and QNM have recently attracted particular attention of both the physical and mathematical communities.

It is now universally accepted that in open systems (e.g., quantum potential wells, optical cavities, or microwave resonators) each maximum in the transmission coefficient (i.e., transmission resonance) is associated with a QNM, so that the resonant frequency is close to the real part of the corresponding eigenvalue. QNM and TRs are often considered identical. For example, the solutions of the eigenvalue problem (with no incoming waves), which in physics are unambiguously called QNM, in the mathematical community dealing with the scattering inverse problem, are termed transmission eigenvalues. However, the connection between QNM and TR is not that simple and, despite extensive research and much recent progress, still needs a better physical understanding and mathematical justification, at least for disordered systems.

To this end, it is instructive to look for insights the 1D limit because its spectral and transport properties are better understood. It is well-known that the transmission of a long enough 1D disordered system is typically (for most of the frequencies) exponentially small. At the same time, there exists a set of frequencies where the transmission coefficient has local maxima (resonances in transmission), some of them close to one. Each resonance is a transmission channel and is always associated with a QNM determined in a standard way as a solution of a scattering problem. The reverse statement, that each QNM manifests itself as a transmission resonance, although never has been questioned, is usually taken as obvious and self-evident, perhaps because it is always the case in all regular (homogeneous or periodic) quantum-mechanical and optical open structures.

Here we show, both numerically and analytically, that in 1D disordered systems there exist two types of QNM: ordinary QNM, that provide resonance transmission peaks, and “strange” QNM unrelated to any anomalies in the transmission spectrum. These strange modes exist exclusively due to random scatterings and arise already in the ballistic regime with weak disorder. Although they belong to the discrete spectrum, their eigenfunctions are not localized. The imaginary parts of the strange QNM eigenfrequencies vary with increasing disorder in a highly unusual manner. Indeed, typically, the stronger the disorder is, the more confined the system becomes, which implies that the eigenfrequencies should approach the real axis. However, the imaginary part of a strange mode’s eigenfrequency either increases from the onset of disorder, or goes down anomalously slowly. Most
surprisingly, up to rather strong disorder, the average ratio of the density (in the frequency domain) of strange modes to the total density of QNMs, being independent of the type of disorder, remains close to the constant $\sqrt{2/5}$ in wide ranges of the strength of disorder and of the total length of the system. The value $\sqrt{2/5}$ follows from the general statistical properties of random trigonometric polynomials \[31\]. As the disorder keeps growing, eventually all strange quasimodes turn normal. Therefore these results can be interpreted as a manifestation of the existence (in 1D random systems, at least) of an intermediate regime, at which in any finite-frequency interval, only a part of the quasimodes are localized and provide resonant transmission.

We consider a generic 1D system composed of $N+1$ scatterers separated by $N$ intervals and attached to two semi-infinite leads. Two problems are associated with such systems. The first one is finding solutions $\psi(x,t)$ of the wave equation satisfying the outgoing boundary conditions, which means that there are no right/left-propagating waves in the left/right lead. The eigenfunction solution $\psi_n(x,t)$ of this problem is the superposition of two counter-propagating monochromatic waves $\psi_n(x)^{\pm} e^{-i\omega_n t}$. In any $j$th layer $\psi_n^{(\pm)}(x) = \psi_{n,j}^{(\pm)}(x) = a_{n,j}^{(\pm)} e^{\pm ik_n x}$. The amplitudes $a_{n,j}^{(\pm)}$ in adjacent layers are connected by a transfer matrix. The wave numbers $k_n$ are complex-valued and form the discrete set (poles of $k$). The amplitudes $a_{n,j}^{(\pm)}$ between them are characterized by the reflection coefficients $r$ and $d$.

The wave intensity, defined as $I_{n,j} = |\psi_{n,j}^{(+)}|^2 + |\psi_{n,j}^{(-)}|^2$ is distributed along the system as $I_n(x_j) \propto \cosh[2k^0(x_j - x^*)]$, where $x^* = L/\ln(|r_R|/|r_L|)/\ln(|r_R|r_L)|/2$. When $|r_L| = |r_R|$, the minimum of the intensity is located at the centre of the system, and in an asymmetric case shifts to the boundary with a higher reflection coefficient. This property will be used when analyzing the behavior of the QNMs when the disorder parameter $s$ grows.

It is easy to show that when $s = 0$ the wave numbers $k_n^{(res)}$ of the transmission resonances coincide with the real parts $k'_n$ given by Eq. (1). Thus, in the homogeneous resonator, there is a one-to-one correspondence between QNMs and TRs. The same correlation exists also in periodic systems (periodic sets $r_i$ and $d_i$).

The question now is whether this relationship survives in the disordered system, when $s \neq 0$. There is strong evidence that for every resonance there is a corresponding QNM. However, as we show below, the reverse statement is not valid: there are certain QNMs which cannot be associated with any resonance.

Figure 1 shows the evolution of the eigennumbers $k_n^{(mod)}$ in the complex plane ($k', k''$) as $s$ grows. Initially, when $s = 0$, all eigennumbers are equidistantly located on the line $k'' = \text{const.}$, in agreement with Eqs. (1,2). As soon as disorder arises ($s \neq 0$) and increases, the eigenvalues separate into two essentially different types. Indeed, with $s$ increasing, the points #1-3,5,7,8,10,12,13 in Fig. 1 move towards the real axis ($k''$ decreases) with approximately the same “velocity” (ordinary QNMs). The rest of the points (strange QNMs) either shift down substantially more slowly (#0,6,9) or, even more surprisingly, move away from the real axis (points 4 and 11). The latest modes are highly unusual because disorder makes them more leaky. This is quite the opposite to the hitherto observed and well understood increase of the lifetime of the eigenstates due to multiple scattering.

The difference between the ordinary and strange QNMs goes beyond the evolution of the eigenvalues and manifests itself also in the spatial distribution of the QNM intensity inside the system. As an example, the spatial distributions along the system of the intensities $I_{5,j}$ and $I_{6,j}$ of QNMs #5 and 6 are presented in Fig 2 for different values of $s$. Note that the difference be-
between the imaginary parts \( k'' \) of the eigenvectors 5 and 6 increases as \( s \) increases (see Fig. 1). Despite the fact that the initial (\( s = 0 \)) distributions are identical, even small disorder (\( s = 0.05 \)) deforms the distributions \( I_{5,j} \) and \( I_{6,j} \) in very different ways. The distribution \( I_{5,j} | s = 0.05 \) is similar to \( I_{5,j} | s = 0 \), but has a much less pronounced minimum. By analogy with a homogeneous resonator, this can be interpreted as the growth of the effective reflection coefficients \( r_L \) and \( r_R \), which agrees well with the statement that the wave lifetime increases when disorder becomes stronger. For larger \( s \), \( I_{5,j} \) tends to manifest the behaviour typical for QNM in the localized regime. In contrast, the intensity evolution of QNM #6 is similar to that in the homogeneous resonator, whose right wall becomes more transparent. QNMs #4 and 11 also demonstrate the same behaviour, but the effective transparency of one of the “walls” increases much faster when the degree of disorder \( s \) grows.

We also consider the propagation of a monochromatic wave through the same system. When \( s = 0 \), the number of resonances \( N_{\text{res}} \) is equal to the number of QNMs, \( N_{\text{mod}} \), and all \( k_{n,\text{res}} \) coincide with the real parts \( k_n \) of QNMs. When disorder is introduced, \( s \neq 0 \), each \( k_{n,\text{res}} \) remains close to the \( k_n \) of the corresponding ordinary QNM: \( k_{n,\text{res}}(s) \approx k_n(s) \). The spatial intensity distributions of QNM #5 and of the corresponding TR are also similar, up to small details (see Fig. 2).

However, the transmission resonances whose frequencies at \( s = 0 \) are equal to the real parts of the eigenvalues of the strange QNMs, disappear when the mean value of the reflection coefficients \( s \langle r_i \rangle \) becomes of the order of \( r_{L,R} \). Figure 3 demonstrates this behavior. Here, the role of the reflection coefficients \( r_{R,L} \) (\( r_R = r_L = 0.005 \)) in Figs. 2 and 3 is only to specify the TRs and QNMs at \( s = 0 \).

Thus, any TR has its partner among QNMs, but the reverse is not true: there are strange QNMs that are not associated with any maxima in the transmission, as it is shown in Fig. 1 and therefore do not have co-partners between resonances. In other words, in a given wave number interval \( \Delta k \), the statistically-averaged number of TRs, \( N_{\text{res}} \), is smaller than the statistically-averaged number of QNMs, \( N_{\text{mod}} = \Delta k L / \pi \), and does not depend on the degree of disorder. This fact was noticed in the numerical calculations in [28].

Surprisingly, when \( s \to 0 \), the ratio \( N_{\text{res}} / N_{\text{mod}} \) is an universal constant \( \sqrt{2/\pi} \), independent of the type of disorder, and remains practically independent on the degree of disorder and the length \( L \) of the system in a rather
where \( x_n \) is the coordinate of the \( n \)-th scatterer. The values \( N_{\text{res}} \), where the transmission coefficient, \( T(k) = 1 - |r(k)|^2 \), has local maxima, are defined as the zeros of the function \( f(k) \equiv d[r(k)]^2/dk = 2\Re[r(k)dr^*(k)/dk] \):

\[
f(k_{\text{max}}) = 4\Im \Sigma_{n=1}^{N} N_{n}^{2} e^{2ik_{\text{max}}x_{n} - x_{m}} = 0.
\]

Assuming first that \( \delta d_{l} = 0 \), then \( f(k) \) becomes

\[
f(k) \propto \Sigma_{n=1}^{N} N_{n}^{2} \sin \{2k(n - m)\sin (2kld) \sum_{l=1}^{N} \sin (2kld) a_{l} \}
\]

Eq. (5) is the trigonometric sum \( \Sigma_{n=1}^{N} N_{n}^{2} \sin (\nu k) \) with “frequencies” \( \nu_{l} = 2kd \) and random coefficients \( a_{l} \). The statistics of the zeros of random polynomials have been studied in [31], where it is shown that the statistically-averaged number of real roots \( N_{\text{root}} \) of the sum of this type at a certain interval \( \Delta k \) is

\[
N_{\text{root}} = \frac{\Delta k}{\pi} \sqrt{\frac{\Sigma_{n=1}^{N} N_{n}^{2} \sin (\nu k)}{\Sigma_{l=1}^{N} \sigma_{l}^{2}}},
\]

where \( \sigma_{l}^{2} = \text{Var}(a_{l}) \) is the variance of the coefficients

\[
a_{l} = \sum_{n=1}^{N-1} r_{n+l} r_{n} l + \sum_{n=1}^{N} r_{n} r_{n-l} l.\]

When \( N \gg 1 \),

\[
\text{Var}(a_{l}) \approx 2(N - l)^{2} \sigma_{0}^{4},
\]

where \( \sigma_{0}^{2} = \text{Var}(r) \). The sums in Eq. (6) can be calculated using Eq. (7), which yields [32]:

\[
\Sigma_{l=1}^{N} \sigma_{l}^{2} \approx 2\sigma_{0}^{4} N^{4},
\]

\[
\Sigma_{l=1}^{N} \nu_{l}^{2} \sigma_{l}^{2} = 2\sigma_{0}^{4} N^{4} (N - l) \approx 15 \sigma_{0}^{4} N^{6} \sigma_{0}^{4}.
\]

From Eqs. (6) and (8) we obtain

\[
N_{\text{root}} = \frac{2\Delta k N d_{0}}{\pi} \sqrt{\frac{2}{5}} = \frac{2\Delta k L}{\pi} \sqrt{\frac{2}{5}},
\]

where \( L = N d_{0} \). Since the number of minima of the reflection coefficient is equal to the number of TRs, \( N_{\text{res}} = N_{\text{root}}/2 \), and the number \( N_{\text{mod}} \) of QNMs in the same interval \( \Delta k \) is \( N_{\text{res}} = \Delta k L/\pi \), from Eq. (9) it follows that

\[
N_{\text{res}}/N_{\text{mod}} = \sqrt{2/5}.
\]

This analytically-calculated relation agrees perfectly with the results of numerical calculations performed without assuming any periodicity of the scatterers. To calculate this ratio for more general situations, when the distances between the scatterers are also random (\( \delta d_{l} \neq 0 \)), the frequencies \( \nu = 2kd_{l} \) in Eq. (5) should be replaced by \( \nu = 2|x_{m} - x_{m+l}| \). Since the main contribution to the sums in Eq. (5) is given by the terms with large \( l \sim N \), the mean value of \( |x_{m} - x_{m+l}| \) can be replaced by \( kd_{l} \), in the case of a homogeneous distribution of the distances.
$d_n$ along the system. This ultimately leads to the same result Eq. [14].

In summary, it is well known that there is a one-to-one correspondence between the QNMs of a regular open system (wave resonator or quantum cavity) and its transmission resonances: each QNM is unambiguously associated with a TR, and vice versa. In this paper, we show for the first time that in 1D random structures, this reciprocity is broken: any weak disorder mutates part of the eigenstates so that the corresponding resonances in the transmission disappear and the density of TR becomes smaller than the total density of states. Although the strange modes belong to a discrete spectrum, the spatial structure of the eigenfunctions differs drastically from that of the ordinary states and show no sign of localization. It is significant that while the strange modes do not show up in the amplitude of the transmission coefficient, in the phase of the transmitted field they manifest themselves in just the same way as the ordinary modes do. Indeed, the numerical calculations show that the derivative of this phase with respect to the frequency gives the total density of QNMs, which includes both the normal ordinary and strange ones. When the disorder is weak (but strong enough to localize the ordinary modes), the ratio of the number of TRs to the total number of QNMs in a frequency interval $\Delta \omega \to \infty$ is independent of the type of disorder and anomalously weakly deviates from a universal constant, $\sqrt{2}/5$, when the strength of disorder and the length of the random sample increase. This constant coincides with the one analytically calculated in the weak single-scattering approximation ensemble-averaged ratio $N_{\text{res}}/N_{\text{mod}}$. If the strength $s$ of disorder grows, ultimately all strange quasimodes become ordinary. This means that in 1D random systems there exists an intermediate, so far unknown regime, at which in any finite-frequency interval, only a part of the quasimodes are localized and provide resonant transmission.

We gratefully acknowledge stimulating discussion with K. Bliokh. We especially thank M. Dennis who drew our attention to the paper [31].
