Mode Interactions of the Tachyon Condensate

in $p$-adic String Theory

Joseph A. Minahan

Abstract

We study the fluctuation modes for lump solutions of the tachyon effective potential in $p$-adic open string theory. We find a discrete spectrum with equally spaced mass squared levels. We also find that the interactions derived from this field theory are consistent with $p$-adic string amplitudes for excited string states.

1 Introduction

Sen’s conjectures concerning tachyon condensation and D-brane decay have been widely tested using cubic string field theory or the superstring analog. There have also been many promising attempts to find an exact verification using cubic string field theory.

Field theory models of tachyon dynamics are also useful in understanding the qualitative picture of tachyon condensation. One such model was proposed in [6], which was constructed by looking for lump solutions with a discrete fluctuation spectrum. This model is in some sense a generalization of a purely cubic model and was later shown to be the two derivative limit of boundary string field theory. An analogous model was constructed for the superstring and it too was later shown to be the two derivative limit of an action derived from boundary string field theory.

The authors of [9] pointed out that the model in [6] can be obtained as the \( p \to 1 \) limit of \( p \)-adic string theory. The \( p \)-adic string describes tachyon dynamics in a vastly simpler context than the ordinary bosonic string. In particular, Ghoshal and Sen showed that the open string dynamics disappear at the stable vacuum. They also showed that the lump solutions of the effective field theory satisfy constant descent relations. One can ask how other ideas of tachyon condensation can be tested using the \( p \)-adic string.

The \( p \)-adic string tree amplitudes are found by replacing the integrals over real numbers normally found in bosonic string theory, with integrals over \( p \)-adic numbers. The resulting amplitudes are much simpler than in bosonic string theory. For example, the \( N \)-point tachyon amplitude only has tachyon poles. Using these amplitudes, the authors of [20] were able to construct the exact tree-level action for the tachyon field. This action is non-local, with a potential that is unbounded below, but with a local minimum. The equations of motion have non-trivial stationary classical solutions, where the tachyon field lies at the local minimum at spatial infinity. These solutions were later interpreted to be the analogs of D-branes.

Since the tachyon amplitude only has tachyon poles, one might think that a consistent \( p \)-adic string theory only needs the tachyon field. In fact, it is not clear that one can even put in many of the other fields familiar from bosonic string theory. For instance, there has been no successful attempt to put in gauge fields such that the resulting amplitudes are gauge invariant. Gauge invariance requires that the on-shell amplitudes be zero when a polarization vector \( \xi_\mu \) is replaced by the momentum vector \( k_\mu \). In bosonic string theory,
this works because the vertex operator for the gauge boson,

\[ V = \zeta \cdot \partial_t X e^{ik \cdot X} \]  \hspace{1cm} (1.1)

where \( \partial_t \) refers to the tangential derivative along the boundary of the world-sheet, becomes a total derivative. However, for the \( p \)-adic numbers, there is no well defined notion of a derivative operator [20], hence there is no guarantee that the amplitude is zero after \( p \)-adic integration. Indeed, if one considers the correlation functions of the vertex operators in (1.1), replacing the real number coordinates on the boundary of the string world sheet with \( p \)-adic numbers, then after \( p \)-adic integration one finds an amplitude that is not gauge invariant.

Instead of showing this explicitly, let us give another argument why gauge fields are likely to be absent. In [20] it was shown how to insert Chan-Paton factors into the \( p \)-adic tachyon amplitudes. In bosonic string theory, when Chan-Paton factors are inserted, nonabelian gauge poles appear in the tree amplitudes, since the tachyons have gauge indices. One can also show that these amplitudes are consistent with the tachyon-tachyon-gauge three point couplings. But in the \( p \)-adic amplitudes, even after inserting Chan-Paton factors, the only poles are tachyon poles. If a gauge vertex operator existed, then the three point coupling would be the same as for the bosonic string, since there is no integration over a number field. This would then lead to an inconsistency with the higher point amplitudes. Therefore, for the \( p \)-adic string, the Chan-Paton symmetries are global symmetries only.

Nevertheless, the existence of lump solutions must lead to other \( p \)-adic string states. If one examines the effective field theory around the lump solution, one finds fluctuation modes and the question is how do these modes fit into the \( p \)-adic string picture. The lowest such mode is a tachyon [22, 14], while the next mode is the scalar zero-mode [14].

In this paper we will show that the remaining modes lie in an infinite tower of states, with a discrete spectrum and evenly spaced mass squared levels, for any value of \( p \). From the tachyon effective action, one can compute the effective action for the fluctuation modes. From this effective action one can directly compute tree-level scattering amplitudes.

In [23] it was conjectured that in bosonic string theory the fluctuations of the tachyon field about a codimension \( d \) lump solution correspond to the open string states

\[ \prod_{i=1}^{d} (\alpha_{-1}^i)^{m_i} |0\rangle, \]  \hspace{1cm} (1.2)
where the product is over the transverse directions to the brane. The \( m_i \) are nonnegative integers and \( \alpha_i - 1 \) is a string oscillator transverse to the brane. One way to test the conjecture of \( [23] \) is to compute the amplitudes for the states in (1.2) using \( p \)-adic integration, and compare this to the amplitudes found from the \( p \)-adic effective action. We do this and find agreement between the two results.

In section 2 we study the fluctuation modes about the \( p \)-adic lump solutions and find their spectrum and compute their interactions. In section 3 we compute the \( p \)-adic string amplitudes for the vertex operators in (3.1). In doing this we keep track of combinatoric factors and simply borrow the results from \( [13, 17, 18, 19, 20, 21] \) for tachyonic amplitudes, without encountering any new types of \( p \)-adic integrals. In section 4 we give a brief discussion.

### 2 Mode interactions from the tachyon field theory

The starting point for this analysis is the tachyon effective action for the \( p \)-adic string \( [20] \)

\[
S = -\frac{1}{g^2} \frac{p^2}{p-1} \int d^p x \left[ \frac{1}{2} \phi p^{-\frac{1}{2}} \phi - \frac{1}{p+1} \phi^{p+1} \right]. \tag{2.1}
\]

While this action was derived for \( p \) a prime number, it appears that \( p \) can be continued to any positive real number. The equation of motion for the \( \phi \) field is easily derived from (2.1) and is

\[
p^{-\frac{1}{2}} \phi = \phi^p. \tag{2.2}
\]

The perturbative open string vacuum is at \( \phi = 1 \), while the solution at the local minimum \( \phi = 0 \) has no open string fluctuations, since all poles are absent. One advantage of studying the \( p \)-adic string is that the strong coupling problems that arise at the local minimum in boundary string field theory \( [24] \) are not a problem here \( 2 \) so long as \( p \) is an integer greater than 1 \( \mathbb{N} \).

There are also nontrivial static solutions of (2.2). In particular, there are codimension \( d \) lump solutions \( [20, 14] \)

\[
\phi(x_i) = \prod_{i=1}^{d} f(x_i), \tag{2.3}
\]

2Nevertheless, one could argue that the problem is alleviated by going to the weak string coupling limit. If the coupling is absorbed into the tachyon field \( \phi \), then the potential is \( V(\phi) = -\frac{1}{4} \phi^2 \ln(g^2 \phi^2) \). Hence the mass of the field near the local minimum is roughly \( -\frac{1}{4} \ln(g^2 \phi^2) \) while the coupling terms have no \( g \) dependence. Hence, we can have a large mass and small couplings by keeping \( \phi \) large, but \( g \phi \) small.
where \( f(x) \) is the gaussian

\[
f(x) \equiv p^{\frac{1}{2p-1}} \exp \left( -\frac{1}{2} \frac{p-1}{p} \ln p \ x^2 \right).
\]  

(2.4)

This follows from the identity

\[
A f(x) = (f(x))^p, \quad A \equiv p^{-\frac{1}{2} \frac{\partial^2}{\partial x^2}}.
\]  

(2.5)

Plugging the solution in (2.3) back into (2.1) one can compute the tension of the lump solutions. In particular, one finds that the ratio of tensions satisfies the descent relation

\[
\frac{T_{D-d-1}}{T_{D-d-2}} = \left( \frac{2\pi p^{\frac{2p}{p-1}} \ln p}{p^2 - 1} \right)^{-1/2}.
\]  

(2.6)

Note that this ratio, as well as all tree amplitudes are invariant under \( p \rightarrow 1/p \) [21]. One can show this by taking the equation of motion in (2.2) and substituting \( \phi = \chi^{1/p} \). Then one finds the same equation for \( \chi \), but with \( p \) replaced by \( 1/p \).

Next consider the fluctuations about the lumps. For what follows, we will assume that \( d = 1 \), but the generalization for arbitrary \( d \) is straightforward. Hence, to quadratic order in the fluctuations, the action in (2.1) becomes

\[
S_f = -\frac{1}{2} \frac{p^2}{g^2 (p-1)} \int d^{D-1}y dx \left[ \frac{1}{2} \partial || + \frac{\partial^2}{\partial x^2} - p(f(x))^{p-1} \right] \tilde{\phi}(y, x),
\]  

(2.7)

where \( y \) are the coordinates along the lump world-brane, \( \tilde{\phi}(y, x) = \phi(y, x) - f(x) \), and \( \Box || \) is the d’Alembertian along the lump world-brane coordinates. To find the eigenmodes, we use the following identity

\[
[A, x] = -\ln p \frac{\partial}{\partial x} A.
\]  

(2.8)

Thus we find

\[
A x^n f(x) = p^n Q_n(x)(f(x))^p,
\]  

(2.9)

where \( Q_n(x) \) is a polynomial of the form

\[
Q_n(x) = x^n + C_{n-2} x^{n-2} + C_{n-4} x^{n-4} + \ldots.
\]  

(2.10)

Hence, using (2.9), (2.10) and the fact that \( A \) is a hermitian operator, we see that

\[
A H_n(\alpha x) f(x) = p^n H_n(\alpha x)(f(x))^p,
\]  

(2.11)
where
\[ \alpha = \sqrt{\frac{1 - p^2}{2p \ln p}}, \] (2.12)
and where \( H_n(\xi) \) are the Hermite polynomials with the usual normalization
\[ \int_{-\infty}^{+\infty} d\xi \exp\left(-\xi^2\right) H_n(\xi) H_m(\xi) = \pi^{\frac{1}{2}} 2^n n! \delta_{nm}. \] (2.13)

We now write the \( \tilde{\phi} \) fields in the form
\[ \tilde{\phi}(y, x) = \sum_{n=0}^{\infty} \psi_n(y) 2^{-\frac{n}{2}} H_n(\alpha x) f(x), \] (2.14)
therefore, (2.7) becomes
\[ S_f = \frac{1}{g^2} \frac{p^2}{p - 1} \left[ \frac{2\pi p \ln p}{p^2 - 1} \right]^{\frac{1}{2}} \int d^{D-1}y \sum_n \frac{n!}{2} \psi_n(y) \left[ p^{(\frac{n}{2} - \frac{1}{2})} - p \right] \psi_n(y). \] (2.15)

Hence, the fluctuation modes \( \psi_n(x) \) have masses squared given by
\[ m^2 = 2(n - 1). \] (2.16)
As in the normal bosonic string, the spectrum is discrete with equally spaced levels. The lowest such mode has \( n = 0 \) and is a tachyon, as was first discussed in [22]. Its mass squared is the same as the effective tachyon mass in (2.1). The next highest mode is at \( n = 1 \), and is the massless mode discussed in [14].

Let us next consider the interaction terms. To this end we make the substitution
\[ \phi(y, x) = f(x) + \sum_n \psi_n(y) 2^{-\frac{n}{2}} H_n(\alpha x) f(x) \] (2.17)
into the interaction term in (2.1). Therefore, the interacting part of the lump action is
\[ S_{\text{int}} = \frac{1}{g^2} \frac{p^2}{p - 1} \left[ \frac{2\pi p \ln p}{p^2 - 1} \right]^{\frac{1}{2}} \int d^{D-1}y \sum_{\ell=3}^{p+1} \frac{p!}{\ell! (p + 1 - \ell)!} \sum_{n_1} \cdots \sum_{n_\ell} A_{n_1 n_2 \cdots n_\ell} \prod_{i=1}^{\ell} \psi_n(y), \] (2.18)
where
\[ A_{n_1 n_2 \cdots n_\ell} = \left[ \frac{2\pi p \ln p}{p^2 - 1} \right]^{\frac{1}{2}} \int_{-\infty}^{+\infty} dx \exp\left(-\frac{1}{2} \frac{p^2 - 1}{p \ln p} x^2\right) \prod_{i=1}^{\ell} 2^{-\frac{n_i}{2}} H_{n_i}(\alpha x). \] (2.19)

To evaluate the expression in (2.19), we note that \( H_n(\alpha x) \) can be written in operator form.
\[ 2^{-\frac{\bar{n}}{2}} H_n(\alpha x) = : (a + a^\dag)^n : \]  

(2.20)

where

\[ a = \alpha x + \frac{1}{2\alpha} \frac{\partial}{\partial x}. \]  

(2.21)

Therefore

\[ [a, a^\dag] = 1 \]  

(2.22)

and the equation in (2.19) becomes

\[ A_{n_1 n_2 \ldots n_\ell} = \langle 0 | \prod_{i=1}^{\ell} : (a + a^\dag)^{n_i} : | 0 \rangle, \]  

(2.23)

where the oscillator vacuum state is normalized to be

\[ \langle 0 | 0 \rangle = 1. \]  

(2.24)

Therefore, the coefficient \( A_{n_1 n_2 \ldots n_\ell} \) essentially counts the number of possible ways to contract the \( \ell \) fields together. To see this more explicitly, let \( N_{ij} \) be the number of contractions between \( : (a + a^\dag)^{n_i} : \) and \( : (a + a^\dag)^{n_j} : \) in (2.23). Since the operators are normal ordered \( N_{ii} = 0 \). The \( N_{ij} \) satisfy the \( \ell \) constraint conditions

\[ n_i = \sum_{j \neq i} N_{ij} \]  

(2.25)

and for fixed \( N_{ij} \), the total number of different ways to have this set of contractions is

\[ \frac{\prod_i n_i !}{\prod_{i<j} N_{ij} !}. \]  

(2.26)

Hence, the coefficients can be expressed as

\[ A_{n_1 n_2 \ldots n_\ell} = \sum_{N_{ij}} \frac{\prod_i n_i !}{\prod_{i<j} N_{ij} !}, \]  

(2.27)

where the sum over all \( N_{ij} \) is subject to the constraints in (2.25).

\( ^3 \) The form for \( H_n(\alpha x) \) in (2.20) follows from the fact that \( : (a + a^\dag)^n : \) commutes with \( x = \frac{1}{2\alpha} (a + a^\dag) \) and that \( : (a + a^\dag)^n : | 0 \rangle = (a^\dag)^n | 0 \rangle \).
3  \( p \)-adic amplitudes for excited modes

In this section we consider the \( N \)-point amplitudes for excited \( p \)-adic string modes. There are certain points to keep in mind when constructing these amplitudes. First, the number of excited modes that could correspond to fluctuation modes for a tachyon field is much smaller than the number of string modes in ordinary bosonic string theory. This suggests two possibilities. Either an infinite number of fields need to be put in by hand for the full effective field theory, or the number of string modes for \( p \)-adic string theory is vastly reduced from ordinary bosonic string theory. The second possibility seems more likely, given the problems previously discussed for gauge fields.

Nevertheless, while massless gauge fields and many other fields might not exist, scattering amplitudes for certain string modes with polarizations transverse to the brane do appear to be consistent. For one thing, these are not gauge fields, so there is no gauge invariance restriction. For a second thing, the existence of tachyon lumps, which follows from the effective action derived from tachyon scattering amplitudes seems to require the existence of such modes.

In \cite{23} it was suggested that for the two derivative truncation of boundary string field theory, the tachyon field condensed to a codimension \( d \) brane has fluctuations that correspond to the open string states in \cite{12}. The vertex operator for such a mode is

\[
V = \prod_{i=1}^{d} (\partial_n X^i)^{m_i} e^{ik \cdot X},
\]

where \( \partial_n \) refers to the normal derivative from the boundary of the string worldsheet. It is important to note that \( k_\mu \) points along the brane coordinates, therefore correlation functions between vertex operators of this sort do not have contributions from the contractions of \( \partial_n X^i \) with \( e^{ik \cdot X} \) terms.

Let us now specialize to the case where \( d = 1 \) and let us consider the \( N \)-point correlator

\[
\langle \prod_i^N (\partial X(x_i))^{n_i} e^{ik_i \cdot X(x_i)} \rangle.
\]

(3.2)

Using the fact that

\[
\langle X(z_i)X(z_j) \rangle = -\log |z_i - z_j|
\]

(3.3)

we find that the correlator in (3.2) is

\[
\sum_{N_{ij}} \prod_i^N n_i! \prod_{i<j} \frac{1}{N_{ij}} |x_{ij}|^{k_i k_j - 2N_{ij}},
\]

(3.4)
where $N_{ij}$ counts the number of contractions of $\partial X(x_i)$ with $\partial X(x_j)$. As in the previous section, the $N_{ij}$ are subject to a constraint

$$n_i = \sum_{j \neq i} N_{ij}. \quad (3.5)$$

Therefore, the $N$-point amplitude for these excited states is a sum over tachyon like amplitudes, where each term in the sum has the combinatoric prefactor in (2.26) and where $k_i \cdot k_j$ is replaced with $k_i \cdot k_j - 2N_{ij}$. We can then use information about $p$-adic tachyon amplitudes to find the $p$-adic excited state amplitudes.

The $p$-adic amplitudes are made up of a constant term independent of the particles momenta and a sum over terms with poles \[20\]. The constant term directly corresponds to the $N$-point interaction term in (2.18). Since, it is independent of $k_i \cdot k_j$, the constant term is unchanged if $k_i \cdot k_j$ is replaced by $k_i \cdot k_j - 2N_{ij}$. Thus each term in the sum in (3.4) has the same constant term. Hence, the general $N$-point interaction term has an extra factor of

$$\sum_{N_{ij}} \frac{\prod_{i} N_{i}!}{\prod_{i < j} N_{i j}!} = A_{n_1 n_2 \ldots n_N}, \quad (3.6)$$

precisely matching the result of the field theory analysis.

To complete the proof, we need to show that the poles in the amplitude derived from the correlator in (3.2) factorize consistently with the action in (2.13) and (2.18). We proceed using an induction argument. If we isolate the amplitude to a particular pole term, then the propagator divides the Feynman diagram into two parts (see figure 1).

Let us assume that there are $M$ vertices on one side of the propagator and $L = N - M$ vertices on the other side. By assumption, the part of the amplitude containing this pole factorizes to the form

$$A(n_1, k_1; n_2, k_2; \ldots n_M, k_M; n_I, k_I) \frac{1}{n_I! p^{n_I + k_I^2/2}} \frac{1}{-p} \frac{1}{A(n_I, k_I; n_{M+1}, k_{M+1} \ldots n_N, k_N)}, \quad (3.7)$$

where $A(n_1, k_1; n_2, k_2; \ldots n_M, k_M; n_I, k_I)$ and $A(n_I, k_I; n_{M+1}, k_{M+1} \ldots n_N, k_N)$ refer to the lower point amplitudes derived from (2.13) and (2.18) and $n_I$ and $k_I$ refer to the mode number and momentum of the internal state. Hence the momentum going through the propagator is

$$k_I = \sum_{i=1}^{M} k_i = -\sum_{i=M+1}^{N} k_i, \quad (3.8)$$

and so

$$k_I^2 = \sum_{i=1}^{M} k_i^2 + 2 \sum_{i<j} k_i \cdot k_j = 2 \sum_{i} (1 - n_i) + 2 \sum_{i<j} k_i \cdot k_j$$
Figure 1: Factorization of the amplitude with incoming momenta $k_i$ and mode number $n_i$ about a pole with momentum $k_I$ and mode number $n_I$.

\[
2M + 2 \sum_{i<j} (k_i \cdot k_j - 2M_{ij}) - 2 \sum_i \sum_j \tilde{N}_{ij} \quad (3.9)
\]

where

\[
M_{ij} = N_{ij} \quad i, j \leq M
\]
\[
\tilde{N}_{ij} = N_{i,j+M} \quad i \leq M, \quad j \leq L. \quad (3.10)
\]

Comparing to a pure tachyon amplitude, which only has tachyon poles, it is clear that the mass squared of the pole is given by

\[
m_I^2 = -2 + \sum_i \sum_j \tilde{N}_{ij} \quad (3.11)
\]
and so the mode number for the pole is
\[ n_I = \sum_i \sum_j \tilde{N}_{ij}. \]  
(3.12)

By momentum conservation, we also have that
\[ k_i^2 = 2L + 2 \sum_{i<j}^L (k_i \cdot k_j - 2L_{ij}) + \sum_i^M \sum_j^L \tilde{N}_{ij}, \]  
(3.13)
and hence we have the relation that
\[ M + \sum_{i<j}^M (k_i \cdot k_j - 2M_{ij}) = L + \sum_{i<j}^L (k_i \cdot k_j - 2L_{ij}). \]  
(3.14)

There are \( N(N-1)/2 \) separate \( N_{ij} \) terms. However, the constraint in (3.5) reduces the number of independent terms to \( N(N-3)/2 \). Since we are isolating the amplitude to a particular pole, \( n_I \) is fixed, reducing the number of independent terms by 1. Finally, fixing all \( M_{ij} \) and \( L_{ij} \) reduces the number of independent \( N_{ij} \) terms by \((M+1)M/2 - (M+1)\) and \((L+1)L/2 - (L+1)\), leaving \((M-1)(L-1)\) independent terms. These independent terms are the \( \tilde{N}_{ij} \), subject to the constraints
\[ M_{iI} \equiv n_i - \sum_{k \neq i} M_{ik} = \sum_k \tilde{N}_{ik} \quad \text{and} \quad L_{jI} \equiv \hat{n}_j - \sum_{k \neq k} L_{kj} = \sum_k \tilde{N}_{kj}, \]  
(3.15)
where \( \hat{n}_i = n_i + M \). The terms \( M_{iI} \) and \( L_{iI} \) count the contractions of the external states with the internal state, and impose \( M + L - 1 \) constraints.

We now write the combinatoric factor in (2.26) as
\[ \prod_i n_i! \prod_{i \leq j} N_{ij}! = \prod_i^M n_i! \prod_i^L \hat{n}_i! \prod_{i \leq j}^M M_{ij}! \prod_{i \leq j}^L L_{ij}! \prod_{i,j} \tilde{N}_{ij}!. \]  
(3.16)

Since \( \tilde{N}_{ij} \) enters into the factorized amplitudes only through the \( M_{iI} \) and \( L_{iI} \) terms, the complete factorized amplitude should consist of a sum over all \((M-1)(L-1)\) independent \( \tilde{N}_{ij} \). It is convenient to use as the independent terms \( \tilde{N}_{ij} \) with \( i < M \) and \( j < L \). Then the dependent terms can be written as
\[ \tilde{N}_{iL} = n_i - \sum_k \tilde{N}_{ik} - \sum_k M_{ik} \]
\[ \tilde{N}_{Mj} = \hat{n}_j - \sum_k \tilde{N}_{kj} - \sum_k L_{kj} \]  
(3.17)
\[ \tilde{N}_{ML} = n_M - \sum_{k}^{L-1} \tilde{N}_{Mk} - \sum_{k} M_{Mk} \]
\[ = n_M - \sum_{k}^{L-1} \tilde{n}_k + \sum_{m}^{M-1} \sum_{k}^{L-1} \tilde{N}_{mk} - \sum_{k} M_{Mk} + \sum_{jk} L_{jk}. \]

Thus, using this way to choose the dependent terms, we see that the factor in (3.16) dependent on \( \tilde{N}_{ij} \) is
\[ \frac{1}{\tilde{N}_{ij}! \tilde{N}_{iM}! \tilde{N}_{iL}! \tilde{N}_{ML}!}. \]
(3.18)

Starting with the sum over \( \tilde{N}_{11} \), we have
\[ \sum_{\tilde{N}_{11}} \frac{1}{\tilde{N}_{11}! \tilde{N}_{M1}! \tilde{N}_{1L}! \tilde{N}_{ML}!} = \sum_{\tilde{N}_{11}} \left( \frac{\tilde{N}_{11} + \tilde{N}_{1L}}{\tilde{N}_{1L}} \right) \left( \frac{\tilde{N}_{M1} + \tilde{N}_{ML}}{\tilde{N}_{1L}} \right) \frac{1}{(\tilde{N}_{11} + \tilde{N}_{1L})(\tilde{N}_{M1} + \tilde{N}_{ML})!}. \]
(3.19)

Note that \( (\tilde{N}_{11} + \tilde{N}_{1L}) \) and \( (\tilde{N}_{M1} + \tilde{N}_{ML}) \) on the rhs of (3.19) are independent of \( \tilde{N}_{11} \).
Using the identity
\[ \sum_{m} \left( \begin{array}{c} N_{1} \\ m \end{array} \right) \left( \begin{array}{c} N_{2} \\ N_{3} - m \end{array} \right) = \left( \begin{array}{c} N_{1} + N_{2} \\ N_{3} \end{array} \right), \]
(3.20)

we can write (3.19) as
\[ \frac{(\tilde{N}_{11} + \tilde{N}_{1L} + \tilde{N}_{M1} + \tilde{N}_{ML})!}{(\tilde{N}_{11} + \tilde{N}_{M1})!(\tilde{N}_{1L} + \tilde{N}_{ML})!(\tilde{N}_{11} + \tilde{N}_{1L})!(\tilde{N}_{M1} + \tilde{N}_{ML})!}. \]
(3.21)

The last two terms in the denominator of this expression have \( \tilde{N}_{12} \) dependence. Hence, after dividing (3.21) by \( \tilde{N}_{12}! \tilde{N}_{M2}! \) and using (3.20), the sum over \( \tilde{N}_{12} \) gives
\[ \frac{(\tilde{N}_{11} + \tilde{N}_{12} + \tilde{N}_{1L} + \tilde{N}_{M1} + \tilde{N}_{M2} + \tilde{N}_{ML})!}{(\tilde{N}_{11} + \tilde{N}_{M1})!(\tilde{N}_{12} + \tilde{N}_{M2})!(\tilde{N}_{1L} + \tilde{N}_{ML})!(\tilde{N}_{11} + \tilde{N}_{12} + \tilde{N}_{1L})!(\tilde{N}_{M1} + \tilde{N}_{M2} + \tilde{N}_{ML})!}. \]
(3.22)

Following this same procedure for the sums of all \( \tilde{N}_{1j}, j < M \), results in the factor
\[ \frac{(\sum_{j}^{L} \tilde{N}_{ij} + \tilde{N}_{Mj})!}{(\sum_{j}^{L} \tilde{N}_{ij})!(\sum_{j}^{L} \tilde{N}_{Mj})! \prod_{j} \tilde{N}_{ij}! \tilde{N}_{Mj}! \tilde{N}_{ML}!}. \]
(3.23)

One can now continue in a similar fashion for all sums, where one uses the identity (3.20) for each sum. At the end, one finds that
\[ \sum_{\tilde{N}_{ij}} \prod_{i}^{M} \prod_{j}^{L} \frac{1}{\tilde{N}_{ij}!} = \frac{\left( \sum_{ij} \tilde{N}_{ij} \right)!}{\prod_{i} \left( \sum_{j} \tilde{N}_{ij} \right)! \prod_{j} \left( \sum_{i} \tilde{N}_{ij} \right)!} = \frac{n_{i}!}{\prod_{i} M_{i}! \prod_{j} L_{j}!}, \]
(3.24)
where we used (3.12) and (3.13) for the last equality. Thus, the amplitudes $A(n_1, k_1; n_2, k_2; \ldots n_M, k_M; n_I, k_I)$ and $A(n_I, k_I; n_{M+1}, k_{M+1} \ldots n_N, k_N)$ have combinatoric factors

$$\frac{\prod_{i}^{M} n_i!}{\prod_{i < j}^{M} M_{ij}} \cdot \frac{n_I!}{\prod_{i}^{M} M_{ii}!}$$

(3.25)

and

$$\frac{\prod_{i}^{L} \tilde{n}_i!}{\prod_{i < j}^{L} L_{ij}} \cdot \frac{n_I!}{\prod_{i}^{L} L_{ii}!}$$

(3.26)

respectively. Therefore, each part of the factorized amplitude has the same form for its combinatoric factors as the original amplitude. We can then continue factorizing poles until we are left with pole free amplitudes. These amplitudes then have the combinatoric factors in (3.6). This completes the proof.

4 Discussion

We have shown that the effective field theory for the tachyon fluctuations about a $p$-adic lump is consistent with tree-level $p$-adic string amplitudes. This analysis is further evidence for the identification of tachyon fluctuations with specific open string states. The analysis in [23] went further, conjecturing the identification of gauge fluctuations with other open string states. The apparent absence of gauge fields prevents us from testing this in the $p$-adic case.

There also have been attempts to generalize the closed string by replacing integrals over the complex plane with integrals over $p$-adics, or more precisely, with integrals over extensions of $p$-adic numbers [15, 16, 17, 18, 25]. The resulting amplitudes are almost identical to the open string amplitudes, and in fact an effective field theory was found for the tachyon, which is identical to the action in (2.1), except that the d’Alembertian has a factor of $1/4$ in front of it instead of $1/2$ [23]. But this means that this action has lump solutions with constant descent relations. If this is really a closed string theory, then it seems difficult to interpret the lumps as analogs of D-branes. A possible explanation is that this construction is the analog of the open string for extended $p$-adic fields.

If this is the case, then it begs the question of whether there is a $p$-adic closed string. The apparent absence of gauge fields on the $p$-adic worldsheet might provide a clue. It has been argued that in ordinary string theory, the closed strings are flux tubes coming from these gauge fields [26, 27, 28, 29, 30, 24, 31]. But if the gauge fields are absent, then there might not be any closed strings to be concerned about.
Acknowledgments: I thank Barton Zwiebach for many helpful discussions and for critically reading the manuscript. I also thank the CTP at MIT for hospitality during the course of this work. This work was supported in part by the NFR.
