Spatio-temporal wave propagation in photonic crystals: a Wannier-function analysis

Stefano Longhi
Dipartimento di Fisica, Politecnico di Milano and Istituto di Fotonica e Nanotechnologie del CNR, Piazza L. da Vinci 32, I-20133 Milan, Italy

A general analysis of undistorted propagation of localized wavepackets in photonic crystals based on a Wannier-function expansion technique is presented. Different kinds of propagating and stationary spatio-temporal localized waves are found from an asymptotic analysis of the Wannier function envelope equation.

I. INTRODUCTION

Spatio-temporal broadening of localized wavepackets with finite energy due to the effects of diffraction and dispersion is a universal and challenging phenomenon in any physical context involving wave propagation. If the finite energy constraint is left, special spatio-temporal waves with a certain degree of localization in space and/or in time, capable of propagating free of diffraction and/or temporal dispersion, can be constructed. Localized waves of this type include, among others, Bessel beams, focus-wave modes, X-type waves, pulsed Bessel beams [1, 2, 4, 5]. Though these waves can be only approximately realized in practice, several experiments in acoustic and optical fields have been reported so far showing nearly-undistorted localized wave propagation. As the existence of undistorted progressive localized waves in vacuum has been known since many years and lead to long-standing studies [1, 2, 3, 4, 5], and remarkably the spontaneous generation of localized and nonspreading wavepackets mediated by optical nonlinearity has been predicted [6] and experimentally observed [7] using standard femtosecond pulsed lasers. Very recently, in a few works [8, 9, 10, 11] the issue of spatial or spatio-temporal wave localization in periodic media has been addressed, and the possibility of exploiting well-established anomalous dispersive and dispersive properties of photonic crystals (PCs) [11, 12, 13] to induce novel spatio-temporal wave localization mechanisms has been proposed. Specifically, these studies have been concerned with localization of Bose-Einstein condensates in a one-dimensional optical lattice without any trapping potential [8, 9], with two-dimensional (2D) spatial Bessel X waves in weakly-coupled 2D waveguide arrays showing bi-dispersive properties [10] and with three-dimensional (3D) out-of-plane X-wave localization in 2D PCs [11]. Spatio-temporal waves considered in these works rely on some specific models and often use ad-hoc approximations, e.g. reduced coupled-mode equations, paraxiality, weak-coupling limit, continuum approximations. So far, a general framework to capture spatio-temporal wave localization and propagation in PCs and the derivation of a general wave equation, valid regardless of the specific system under investigation and with a wide range of applicability, is still lacking.

The aim of this work is to provide a general analytical framework to study spatio-temporal wave propagation in 2D and 3D PCs based on the use of Wannier-functions, which have been introduced in the context of PCs to treat localized modes, such as the bound states of impurities or lattice defects [13, 14]. A general asymptotic analysis of the envelope equation for the Wannier functions allows one to capture the existence and properties of localized nonspreading wavepackets in PCs in terms of localized solutions of canonical wave equations, such as the Schrödinger equation, the Helmholtz equation and the Klein-Gordon equation.

II. WANNIER FUNCTION ENVELOPE EQUATION

The starting point of the analysis is provided by the vectorial wave equation for the magnetic field \( \mathbf{H} = \mathbf{H}(\mathbf{r}, t) \) in a PC with a periodic relative dielectric constant \( \varepsilon(\mathbf{r}) \),

\[
\nabla \times \left( \frac{1}{\varepsilon} \nabla \times \mathbf{H} \right) = -\frac{1}{c^2} \frac{\partial^2 \mathbf{H}}{\partial t^2}.
\]

where \( c \) is the speed of light in vacuum. To study the propagation of a spatio-temporal wavepacket, we can adopt the method of the Wannier function expansion, which is commonplace in the study of the quasi-classical electron dynamics in solids [13, 14] and recently applied to study localized modes and defect structures in PCs with defects [13, 14]. We refer explicitly to a 3D PC structure, however a similar analysis can be developed for a 2D PC. Let us first consider the monochromatic Bloch-type solutions to Eq.(1) at frequency \( \omega \),

\[
\mathbf{H}(\mathbf{r}, t) = \mathbf{H}_{k,n}(\mathbf{r}) \exp(-i\omega t),
\]

where \( k \) lies in the first Brillouin zone of the reciprocal \( \mathbf{k} \) space, \( \omega = \omega_n(\mathbf{k}) \) is the dispersion curve for the \( n \)-th band, and \( \mathbf{H}_{k,n}(\mathbf{r}) \) are the band modes, satisfying the condition \( \mathbf{H}_{k,n}(\mathbf{r} + \mathbf{R}) = \mathbf{H}_{k,n}(\mathbf{r}) \exp(i\mathbf{k} \cdot \mathbf{R}) \) for any lattice vector \( \mathbf{R} \) of the periodic dielectric function. The Bloch functions \( \mathbf{H}_{k,n}(\mathbf{r}) \) are normalized such that \( \langle \mathbf{H}_{k,n} | \mathbf{H}_{k',n'} \rangle = \delta_{n,n'} \delta(\mathbf{k}' - \mathbf{k}) \), where \( V_{BZ} = (2\pi)^3/V \) is the volume of the first Brillouin...
zone in the reciprocal space and $V$ is the volume of the real-space unit cell. For each band of the PC, one can construct a Wannier function $W_n(r)$ as a localized superposition of Bloch functions of the band according to:

$$W_n(r) = \frac{1}{V_{BZ}} \int_{BZ} \text{d}k \, H_{k,n}(r). \tag{2}$$

In the superposition, the phase of Bloch functions $H_{k,n}$ can be chosen such that the Wannier function $W_n(r)$ is strongly localized around $r = 0$ with an exponential decay far from $r = 0$. The Wannier functions satisfy the orthogonality conditions $\langle W_n(r - R') | W_n(r - R) \rangle = \delta_{n,n'} \delta_{R,R'}$, and the following relationship can be easily proven:

$$\langle W_n(r - R') \big| \nabla \times \left( \frac{1}{\epsilon} \nabla \times \right) | W_n(r - R) \rangle = \delta_{n,n'} \theta_n R - R', \tag{3}$$

where $\theta_{n,R}$ is the Fourier expansion coefficient of the dispersion curve $\omega_n(k)$ of the band, $\theta_{n,R} = (1/V_{BZ}) \int_{BZ} \text{d}k \, \omega_n^2(k) \exp(-i k \cdot R)$, i.e.

$$\omega_n^2(k) = \sum_R \theta_{n,R} \exp(i k \cdot R).$$

We then look for a spatio-temporal wavepacket, which is a solution to Eq.\,(1), as a superposition of translated Wannier functions localized at the different lattice points $R$ of the periodic structure, with amplitudes $f(R,t)$ that depend on the lattice point $R$ and can vary in time, i.e. we set:

$$H(r,t) = \sum_R f(R,t) W_n(r - R). \tag{4}$$

Note that, as we consider a pure periodic structure without defects and neglect perturbation terms in Eq.\,(1) (e.g. nonlinearity), coupling among different bands does not occur and in Eq.\,(4) the sum can be taken over a single band, of index $n$. Coupled-mode equations for the temporal evolution of the amplitudes $f(R,t)$ of Wannier functions at different lattice points can be obtained after substitution of Eq.\,(4) into Eq.\,(1), taking the scalar product with $W_n(r - R)$ and using the orthogonality conditions of Wannier functions, together with Eq.\,(3). One obtains:

$$\frac{\partial^2 f(R,t)}{\partial t^2} + \sum_{R'} \theta_{n,R'} R - R f(R',t) = 0. \tag{5}$$

The solution to the coupled-mode equations (5) can be expressed as $f(R,t) = f(r = R, t)$, where the continuous function $f(r,t)$ of space $r$ and time $t$ satisfies the partial differential equation:

$$\frac{\partial^2 f(r,t)}{\partial t^2} + \sum_{R'} \theta_{n,R'} R - R f(r',t) = 0, \tag{6}$$

and $\omega_n^2(-i \nabla_r)$ is the operator obtained after the substitution $k \rightarrow -i \nabla_r$ in the Fourier expansion of $\omega_n^2(k)$. It should be noted that the differential equation for the continuous envelope $f(r,t)$ of the Wannier function wavepacket [Eq.\,(4)], as given by Eq.\,(6), is exact, and for any band of the PC an envelope equation can be written, the specific details of the band entering both in the dispersion curve $\omega_n^2(k)$ and in the shape of the corresponding Wannier function $W_n$ [Eq.\,(2)].

### III. SPATIAL AND SPATIO-TEMPORAL LOCALIZED WAVES

The most general solution to the Wannier-function envelope equation (6) is given by a superposition of functions $\psi(r,\pm t)$, where $\psi(r,t)$ is a solution to the wave equation:

$$\frac{\partial \psi}{\partial t} = \omega_n(-i \nabla_r) \psi. \tag{7}$$

We are now interested on the search for localized solutions to Eq.\,(7) such that $|\psi|$ corresponds to a wave propagating undistorted with a group velocity $v_g$. To this aim, let us set $\psi(r,t) = g(r,t) \exp(i k_0 \cdot R - \Omega t)$, where $k_0$ is chosen inside the first Brillouin zone in the reciprocal space and the frequency $\Omega$ is chosen close to (but not necessarily coincident with) $\omega_0 = \omega_n(k_0)$. The envelope $g$ then satisfies the wave equation

$$i \frac{\partial g}{\partial t} = [\omega_n(k_0 - i \nabla_r) - \Omega] g. \tag{8}$$

We first note that, if $g$ varies slowly with respect to the spatial variables $r$, at leading order one can expand $\omega_n(k_0 - i \nabla_r)$ up to first order around $k_0$: taking $\Omega = \omega_0$, one obtains $\partial g/\partial t + \nabla k_0 \omega_n \cdot \nabla r g = 0$, i.e. one retrieves the well-known result for which an arbitrary 3D spatially-localized wavepacket travels undistorted, at leading order, with a group velocity given by $\nabla k_0 \omega_n$. Nevertheless, higher-order terms are generally responsible for wavepacket spreading, both in space and time. In order to find propagation-invariant envelope waves even when dispersive terms are accounted for, let us assume, without loss of generality, that $(\partial \omega_n/\partial k_y)k_0 = (\partial \omega_n/\partial k_z)k_0 = 0$, i.e. we choose the orientation of the $x$ axis such that the wavepacket group velocity $\nabla k_0 \omega_n$ is directed along this axis, and let us look for a propagation-invariant solution to Eq.\,(8) of the form $g = g(x_1, x_2, x_3)$, with $x_1 = x - v_g t, x_2 = y$ and $x_3 = z$, traveling along the $x$ axis with a group velocity $v_g$, which is left undetermined at this stage. The function $g$ then satisfies the following equation:

$$-i v_g \frac{\partial g}{\partial x_1} = [\omega_n(k_0 - i \nabla_x) - \Omega] g, \tag{9}$$

whose solution can be written formally as:

$$g(x_1, x_2, x_3) = \int dQ dq Q_3 G(Q_2, Q_3) \exp(iQ \cdot x). \tag{10}$$

In Eq.\,(10), $x = (x_1 = x - v_g t, x_2 = y, x_3 = z), Q = (Q_1, Q_2, Q_3), G$ is an arbitrary spectral amplitude, and
$Q_1 = Q_1(Q_2, Q_3)$ is implicitly defined by the following dispersion relation:

$$\omega_n(k_0 + \mathbf{Q}) - \Omega - v_g Q_1 = 0. \tag{11}$$

To avoid the occurrence of evanescent (exponentially-growing) waves, the integral in Eq.(10) is extended over the values of $(Q_2, Q_3)$ such that $Q_1$, obtained after solving Eq.(11), turns out to be real-valued. We note that, for an arbitrary spectral amplitude $G$, Eq.(10) represents an exact solution of the Wannier-function envelope equation, which propagates undistorted with a group velocity $v_g$, once the proper band dispersion curve $\omega_n(k)$ of the PC and corresponding dispersion relation (11) are computed, e.g. by numerical methods. For some specific choices of the spectral amplitude $G$, in addition to undistorted wave propagation a certain degree of spatiotemporal wave localization can be obtained. It is worth to get some explicit examples, though approximate, of such 3D localized waves, admitting the integral representation given by Eq.(10), and relate them to already known localized solutions to canonical wave equations\cite{2}. To this aim, we develop an asymptotic analysis of Eq.(11) by assuming that the spectral amplitude $G$ is nonvanishing in a narrow interval around $Q_2 = Q_3 = 0$, so that, for $\Omega$ close to $\omega_0$, the value of $Q_1$, as obtained form Eq.(11), is also close to $Q_1 = 0$. In this case, an approximate expression for the dispersion relation $Q_1 = Q_1(Q_2, Q_3)$ can be obtained by expanding in Eq.(11) the band dispersion curve $\omega_n(k_0 + \mathbf{Q})$ at around $k_0$. We should distinguish two cases, depending on the value of the group velocity $v_g$, which is basically a free parameter in our analysis.

First case. The first case corresponds to the choice of a group velocity $v_g$ different from (and enough far form) $\partial \omega_n/\partial k_x$. In this case, the leading-order terms entering in Eq.(11) after a power expansion of $\omega_n(k_0 + \mathbf{Q})$ are quadratic in $Q_2, Q_3$ and linear in $Q_1$; precisely, one has:

$$\left( \frac{\partial \omega_n}{\partial k_1} - v_g \right) Q_1 + \omega_0 - \Omega + \frac{1}{2} \sum_{i,j=1}^{3} \frac{\partial^2 \omega_n}{\partial k_i \partial k_j} Q_i Q_j = 0, \tag{12}$$

where $k_i = k_{x,y,z}$ for $i = 1, 2, 3$ and the derivatives of the band dispersion curve are calculated at $k = k_0$. If the approximate expression of $Q_1$, given Eq.(12), is introduced into Eq.(10), one can easily show that the envelope $g(x_1, x_2, x_3)$ satisfies the differential equation:

$$i \left( \frac{\partial \omega_n}{\partial k_1} - v_g \right) \frac{\partial g}{\partial x_1} = (\omega_0 - \Omega) g - \frac{1}{2} \sum_{i,j=1}^{3} \frac{\partial^2 \omega_n}{\partial k_i \partial k_j} \frac{\partial^2 g}{\partial x_i \partial x_j}. \tag{13}$$

Since the matrix $\partial^2 \omega_n/\partial k_i \partial k_j$ is symmetric, after a suitable rotation of the $(x_2, x_3)$ axes by the transformation $x'_j = R_{ji} x_i \ (i, j = 2, 3)$, where $R_{ji}$ is the orthogonal matrix that diagonalizes $\partial^2 \omega_n/\partial k_i \partial k_j$, assuming without loss of generality $\Omega = \omega_0$, Eq.(13) can be written in the canonical Schrödinger-like form:

$$i \left( \frac{\partial \omega_n}{\partial k_1} - v_g \right) \frac{\partial g}{\partial x_1} = -\frac{1}{2} \alpha_2 \frac{\partial^2 g}{\partial x_2^2} - \frac{1}{2} \alpha_3 \frac{\partial^2 g}{\partial x_3^2}, \tag{14}$$

where $\alpha_2$ and $\alpha_3$ are the eigenvalues of the $2 \times 2$ matrix $\partial^2 \omega_n/\partial k_i \partial k_j \ (i, j = 2, 3)$. 3D localized waves to Eq.(14) are expressed in terms of well-known Gaussian-Hermite functions, which are in general anisotropic for $\alpha_2 \neq \alpha_3$. These 3D localized waves, which exist regardless of the sign of $\alpha_2$ and $\alpha_3$, represent Gaussian-like beams, with exponential localization in the transverse $(y, z)$ plane and algebraic localization, determined by the beam Rayleigh range, in the longitudinal $x$ direction (and hence in time). These beams propagate undistorted along the $x$ direction with an arbitrary group velocity $v_g$, either subluminal or superluminal, provided that $v_g \neq \partial \omega_n/\partial k_x$. Such pulsed propagating Gaussian beams represent an extension, in a PC structure, of similar solutions found in vacuum (see \cite{17} and references therein). In particular, the special case $v_g = 0$ leads to stationary (monochromatic) Gaussian-like beams; note that the condition $v_g \neq \partial \omega_n/\partial k_x$ implies that such steady Gaussian beams do not exist in a PC close to a bandgap edge, where $\partial \omega_n/\partial k_x$ vanishes. Other solutions to Eq.(14), leading to spatial 2D localized and monochromatic waves in the transverse $(y, z)$ plane (but delocalized in the longitudinal $x$ direction), can be search in the form $g(x_1, x_2, x_3) = s(x_2, x_3) \exp(i x_1 \lambda)$, where $\lambda$ is a propagation constant. If $\alpha_2$ and $\alpha_3$ have the same sign, the function $s(x_2, x_3)$ satisfies a 2D Helmholtz equation, admitting well-known Bessel-beam solutions in cylindrical coordinates. For $\alpha_2 \neq \alpha_3$, such solutions are anisotropic, and again they represent a generalization to a PC of well-known spatial Bessel beams in vacuum. If $\alpha_2$ and $\alpha_3$ have opposite sign, one obtains a hyperbolic 2D equation (or, equivalently, a 1D Klein-Gordon equation), which admits of 2D X-type localized solutions involving modified Bessel functions recently studied in \cite{7} (see Eqs.(3a) and (4) of Ref. \cite{3}; see also \cite{18}).

Second case. The second case corresponds to the choice $v_g = \partial \omega_n/\partial k_x$. In this case, the leading-order approximation to the dispersion relation [Eq.(11)] should include also second-order derivatives with respect to $x_1$ of the band dispersion curve $\omega_n(k_0 + \mathbf{Q})$, yielding:

$$\omega_0 - \Omega + \frac{1}{2} \sum_{i,j=1}^{3} \frac{\partial^2 \omega_n}{\partial k_i \partial k_j} Q_i Q_j = 0, \tag{15}$$

where the derivatives of the band dispersion curve are calculated at $k = k_0$. If the approximate expression of $Q_1$, implicitly defined by the quadratic equation (15), is introduced into Eq.(10), one can easily show that the envelope $g(x_1, x_2, x_3)$ satisfies this time the differential equation:

$$\omega_0 - \Omega g - \frac{1}{2} \sum_{i,j=1}^{3} \frac{\partial^2 \omega_n}{\partial k_i \partial k_j} \frac{\partial^2 g}{\partial x_i \partial x_j}. \tag{16}$$

Since the matrix $\partial^2 \omega_n/\partial k_i \partial k_j$ is symmetric, after a suitable rotation of the $(x_1, x_2, x_3)$ axes by the transformation $x'_j = R_{ji} x_i \ (i, j = 1, 2, 3)$, where $R_{ji}$ is the orthogonal matrix that diagonalizes $\partial^2 \omega_n/\partial k_i \partial k_j$, Eq.(16) takes
the canonical form:

$$(\omega_0 - \Omega) g = \frac{1}{2} \left( \alpha_1 \frac{\partial^2 g}{\partial x_1^2} + \alpha_2 \frac{\partial^2 g}{\partial x_2^2} + \alpha_3 \frac{\partial^2 g}{\partial x_3^2} \right),$$

where $\alpha_i$ $(i = 1, 2, 3)$ are the eigenvalues of the $3 \times 3$ matrix $\partial^2 \omega_n/\partial k_i \partial k_j$ $(i, j = 1, 2, 3)$. The sign of the eigenvalues $\alpha_i$ basically determines the elliptic or hyperbolic character of Eq.(17), and hence the nature of their solutions (see, e.g., \cite{2, 0}). If $\alpha_i$ have the same sign, e.g. they are positive, for $\Omega < \omega_0$ Eq.(17) reduces, after a scaling of axis length, to a 3D Helmholtz equation, which in spherical coordinates admits of localized solutions in the form of sinc-shaped waves (see, e.g., \cite{6, 0}). If, conversely, there is a sign discordance among the eigenvalues $\alpha_i$, one obtains a 2D Klein-Gordon equation, which admits of 3D localized X-type waves which have been lengthily discussed in many works (see, e.g., \cite{6, 0, 0}) and references therein. In some special cases, one of the eigenvalues $\alpha_i$ may vanish, which may yield further nonspreading wavepacket solutions. Notably, if $\alpha_1 = 0$, the solution to Eq.(17) is given by $g(x_1, x_2, x_3) = h(x_1) \varphi(x_2, x_3)$, where $h$ is an arbitrary function of $x_1 = x - v_2 t$ and $\varphi$ satisfies a 2D Helmholtz equation for $\alpha_2 \alpha_3 > 0$, admitting Bessel beam solutions, or a 1D Klein-Gordon equation for $\alpha_2 \alpha_3 < 0$, admitting 2D X-type solutions. For these special solutions a cancellation of temporal dispersion is attained. As the former case ($\alpha_2 \alpha_3 > 0$) extends to a PC structure the so-called pulsed Bessel beams found in homogeneous dispersive media \cite{6}, the latter case ($\alpha_2 \alpha_3 < 0$) is rather peculiar for a PC structure, which realizes a bi-diffractive propagation regime \cite{6}, i.e. positive and negative diffraction along the two transverse directions $y$ and $z$. Instead of pulses with a transverse Bessel beam profile, in this case one obtains a transverse X-shaped beam with an arbitrary longitudinal (temporal) profile that propagates without spreading.

As a final remark, we note that, though our analysis has been focused to a 3D PC, similar results can be obtained \textit{mutatis mutandis} for the lower-dimensional case of a 2D PC. In this case, not considering out-of-plane propagation, the fields depend solely on the two spatial variables $x$ and $y$ defining the PC plane, and Eqs.(14) and (17) are still valid provided that the terms involving the derivatives with respect to the $x_3 = z$ coordinate are dropped. In this case, Eq.(14) corresponds to a 1D Schrödinger equation, whereas Eq.(17) corresponds to either a 2D Helmholtz equation or to a 1D Klein-Gordon equation.

IV. CONCLUSIONS

In conclusion, a general analysis of wavepacket propagation in PCs, based on a Wannier function expansion approach, has been presented, and an exact envelope equation describing undistorted propagation of spatio-temporal localized waves has been derived. An asymptotic analysis of the envelope equation shows that a wide class of localized (either spatial or spatio-temporal) waves exist, including propagating Gaussian beams, 2D and 3D X-type waves, sinc-shaped waves, pulsed Bessel beams and pulsed 2D X waves, some of which have been recently studied with reference to some specific models \cite{8, 9}.
