Abstract:

A green and sustainable approach to recycle the waste iron rust into a valuable $\alpha$ modification of Fe$_2$O$_3$ via simple grinding and calcination for application in hybrid supercapacitor is reported. The $\alpha$-Fe$_2$O$_3$ was coupled with conducting polymer carbon nanofibers (CNF) and Poly aniline (PANI) to form composite hybrid supercapacitor electrode materials. The conventional hydrothermal, electro-spinning processes were used to prepare composites. X-ray diffraction, Transmission Electron Microscopy (TEM), High Resolution Transmission Electron Microscopy (HRTEM), Selected Area Electron Diffraction (SAED), Scanning Electron Microscopy and Energy Dispersive X-Ray spectroscopy were used to study the structural, morphological and compositional properties of as synthesised $\alpha$-Fe$_2$O$_3$ and its composites with CNF and PANI. The $\alpha$-Fe$_2$O$_3$/CNF and $\alpha$-Fe$_2$O$_3$/PANI composites coated on carbon rod were used as electrodes in a three-electrode system to study Electrochemical Impedance Spectroscopy, Cyclic Voltammetry and Galvanostatic Charge-Discharge in 1M H$_2$SO$_4$. It is observed that $\alpha$-Fe$_2$O$_3$/PANI exhibit higher response as against $\alpha$-Fe$_2$O$_3$/CNF with
respect to specific capacitance; 192.29 Fg\(^{-1}\) (88.88 Fg\(^{-1}\)), energy density; 11.28 WhKg\(^{-1}\) (3.084 WhKg\(^{-1}\)) power density; 162.44 Wkg\(^{-1}\) (69.39 Wkg\(^{-1}\)) with capacitance retention of 80% (75%).

The heavy dispersion of α-Fe₂O₃ over long CNF and PANI fibres with intimate contact resulted in abundant active sites for electrochemical reactions leading to obtained result. The rust derived α-Fe₂O₃ with PANI offer excellent stability to act as potential candidate for sustainable hybrid supercapacitor application.

**Keywords:** Supercapacitor, Cyclic Voltammetry, Iron oxide, Electrospinning, PANI

1. Introduction

The past few decades have witnessed a rapid development in industrial automation, transportation and huge upsurge of modern household appliances. Ever growing industrialization and urbanization however, demands huge amount of electrical energy to work with [1]. Today, most of the energy demands are fulfilled by utilizing non-renewable resources. The renewable energy resources though clean, eco-friendly, plentily available, needs an efficient harvesting system to use. The utilization of former resources mostly leads to depletion and eventually finish of the reservoirs, global warming, pollution and climate change [2]. Whatever be the source of energy, the smart utilization strategy needs an efficient and clean energy storage device so that stored energy can be used as buffer power. With the global concern about the depleting fossil fuels and its post use environmental implications, the development of efficient and clean energy devices utilizing natural materials and a greener synthetic approach has become a challenge to the electrochemists [3,4]. Recently, a lot of interest in research is developed to fabricate energy storage materials for use in batteries, supercapacitors and fuel cells. Among them, supercapacitor have emerged as an eco-friendly and safe means of energy storage device due to its characteristics such as comparatively small size, high power density (5-10 kWkg\(^{-1}\)), long cycle life (>5,00,000 cycles), long shelf life, high efficiency (95%), wide operating temperature range (-40 to +70 C) etc. It is being considered as a future’s energy storage system that probably complements or even replace conventional batteries and fuel cells [5].

The basic energy storage mechanism in supercapacitor involves either charge separation at the electrode-electrolyte interface (electric double layer capacitors, EDLC) or the Faradic redox reactions between the electrolyte and electro-active surface of the electrode material (pseudo capacitors). The carbon-based materials such as graphene, carbon nanofibers, activated carbon
and carbon nanotubes serve as the main electrode materials in EDLC [6,7]. Among them, one dimensional carbon mesoporous nanofibers are popular [8].

So far, much effort has been devoted to develop carbon fibers using verities of methods. These methods involve more or less complexity in preparation process and costs high [9]. One of the methods, electrospinning method, working under the precisely controlled conditions, has emerged as a versatile, efficient, continuous and industrially viable method to evolve long nanofibers with different morphology having extremely high aspect ratio and large surface area to volume ratio [10]. Such fibers are highly desirable for use in energy storage applications since they exhibit transportation directionally and short ionic transport lengths [11]. The hydrothermal method, on the other hand, is facile, low-cost method that has advantages such as high yield of the products, control over morphology and reproducibility. So far, a number of metal oxides and hydroxides have been synthesized using hydrothermal technique for use as electrode materials in supercapacitors [12].

The supercapacitors based on EDLC exhibits long cycle life but produce relatively low specific capacitance, whereas, pseudo-capacitor have high specific capacitance but shows slow charge kinetics [13]. The hybrid capacitor, comprising of EDLC and pseudo-capacitor, combine their advantages, namely high energy and power densities and long cycle life. The metal oxides coupled conducting polymers are often employed as pseudo capacitor electrode materials [14]. A huge research literature is available on synthesis of nanofibers and or polymer coupled metal oxides exhibiting better performance in supercapacitance. For instance, electro spun- TiO$_2$/CNF exhibited a high specific capacitance 280.3 Fg$^{-1}$ at current density 1Ag$^{-1}$[15], hydrothermally grown V$_2$O$_5$/CNF composite exhibits a high capacitance of 227 F g$^{-1}$ for at current density 1 A g$^{-1}$[16], Zhi et al could achieve specific capacitance of 311 Fg$^{-1}$ at scan rate of 2 mV/s for MnO$_2$/CNF [17], while ZnO/CNF displayed specific capacitance of 178.2 Fg$^{-1}$ as reported by Kim et al [18]. Among oxides, iron oxide (Fe$_2$O$_3$) is considered as an important electrochemical electrode materials due to i) its existence in several morphologies and crystallographic modifications [19], ii) ease in variations in oxidation state (Fe$^{+2}$$\leftrightarrow$Fe$^{+3}$) iii) outstanding theoretical specific capacitance (3625 F g$^{-1}$), iv) high thermal stability v) high corrosion resistance, vi) abundance in nature and environmental friendliness[20,21,22]. and vii) use as positive as well as negative electrode. Like many other electrodes, Fe$_2$O$_3$, also suffers from poor electrical conductivity leading to lower capability and cycling stability [23]. However, the electrical conductivity can be improved by introducing carbon/ conducting polymer materials into Fe$_2$O$_3$ forming composites [24]. A good number of literature is available
wherein a thermodynamically stable form of iron oxide, \( \alpha-\text{Fe}_2\text{O}_3 \) (Hematite), coupled with carbon nano fiber via methods like hydrothermal [25,26,27], electrospinning [28,29], vapour growth [30], gel templating [31] and mechanical press [32] has been utilized as efficient negative electrode in Li ion/ Na ion batteries and or as supercapacitor in the potential range from -1.2 to 0 V. There are some reports where \( \alpha-\text{Fe}_2\text{O}_3 \) hybrid materials is utilised as positive electrode in aqueous electrolytes [33,34]. In all the cases, electrode material fabrication methods have involved the use of toxic, expensive chemicals and complicated chemical and physical treatments that can lead to environmental implications with cost. There are only two reports available in literature on the greener synthesis of \( \alpha-\text{Fe}_2\text{O}_3 \), wherein \( \alpha-\text{Fe}_2\text{O}_3 \) was obtained by chemical and physical treatments on up-cycled industrial mill scale waste [35] and in another case, annealing of a mixture of iron hydroxide and dextran chemicals at various temperatures [36]. However, to the best of our knowledge, there are no reports on the use of rust derived nano \( \alpha-\text{Fe}_2\text{O}_3 \) for application as hybrid supercapacitor. The rusting process called corrosion is a weathering phenomenon capable of giving aggregates of nano scaled iron oxide, a rust product [37].

In the present paper, we propose a scalable, simple, smart strategy to evolve nano-scaled \( \alpha-\text{Fe}_2\text{O}_3 \) with an aim to recycle huge pure iron rust waste available. The method is truly greener, cost effective and requires no chemicals and other expensive treatments. The as synthesised \( \alpha-\text{Fe}_2\text{O}_3 \) was further coupled with CNF and PANI to get binary positive electrode material.

2. Experimental details

2.1 Extraction of nano-\( \alpha-\text{Fe}_2\text{O}_3 \) from iron rust

The iron rust from moderately rusted pure iron pipes/ iron bars was hand peeled and collected. The collected iron rust was grinded for a couple of hours, washed with deionised water for several times, dried naturally and annealed at 550 °C for 5 hours. After the heat treatment, the collected powder was further grinded to fine powder for an hour and again annealed for an hour at 550 °C. Finally, it is cooled and subjected to characterization.

2.2 Fabrication of carbon nanofibers (CNF)

For CNF preparation, the solution used for electrospinning was prepared by dissolving 10 wt % of polyacrylonitrile (PAN, Sigma Aldrich) in Dimethylformamide (DMF, Sigma Aldrich with a constant magnetic stirring for 2 hours at 70°C. The solution was loaded into 10 ml syringe for electrospinning, the distance between needle tip of syringe and fibers collector
plate was maintained at 15 cm, the injecting solution flow rate was kept at 0.8 ml/h. The applied voltage between metallic syringe and collector plate was 20kV. The as-prepared electro spun PAN fibers were further transferred to horizontal tube furnace for carbonization process. In this process, initially the PAN fibers were stabilized at 220 °C for one hour and then the carbonization was carried out at 600 °C in nitrogen atmosphere for further one hour, finally the temperature was reduced to 400 °C to activate CNF for another one hour. After natural cooling, the fibers were collected and stored in a dry desiccator.

2.3 Preparation of α-Fe₂O₃/CNF composite by hydrothermal

For hydrothermal process, the CNF was mixed in deionised water and sonicated for 3 hours to get uniform dispersion. To this, α-Fe₂O₃ was added and mixed under magnetic stirring for an hour. In order to get heavy decoration, the weight ratio of CNF and α-Fe₂O₃ was taken in 1:2 proportions. This mixture was subsequently transferred into a Teflon coated stainless steel autoclave for 8 hours at 140°C. Finally, after natural cooling of autoclave, the content was removed, washed centrifugally and the final product was dried at 70 °C overnight to obtain α-Fe₂O₃/CNF.

2.4 Preparation of α-Fe₂O₃/PANI composite

A mixture of 25 ml of 1M HCl (Sigma Aldrich) solution and 5 ml 0.25M APS (Ammonium peroxy disulphate, E Merk), after magnetic stirring for an hour, was filled in a burette. A 25 ml of 1M HCl and 5 ml 0.25M aniline (Sigma Aldrich), taken in a beaker was stirred magnetically for 30 minutes, to this 50 mg of α-Fe₂O₃ was added and sonicated for 30 minutes. It is then transferred to an ice bath. To this, APS solution was added dropwise from a burette. After polymerization, solution was centrifugally washed several times with water and dried at 80 °C in vacuum oven.

2.5 Electrode preparation method

For electrochemical testing, Graphite rod coated with a slurry, prepared by mixing α-Fe₂O₃/CNF or PANI: Poly Vinylidene Difluoride (PVDF): Carbon black taken in 85:10:5 ratio was used as electrodes. After dip coating, the carbon rod was removed and dried at 80°C in an oven. The PVDF was used as a binder while carbon black to maintain electrical conductivity.

2.6 Materials Characterization

X-ray diffraction (XRD) of α-Fe₂O₃, CNF and α-Fe₂O₃/CNF, α-Fe₂O₃/PANI composites were performed on Rigaku D/MAX-RB X-ray diffractometer with Cu-Kα radiation at scan rate
1°/min. The surface morphology and compositional analysis of CNF, α-Fe$_2$O$_3$, α-Fe$_2$O$_3$/CNF and α-Fe$_2$O$_3$/PANI composites were investigated using Scanning Electron Microscope (Carl Zeiss EVO-18) equipped with energy dispersive X-ray spectroscopy (EDAX). The detailed morphology, microstructures and crystalline nature of α-Fe$_2$O$_3$ was further investigated using Transmission Electron Microscopy (TEM), High Resolution Transmission Electron Microscope (HRTEM) and Selected Area Electron Diffraction (SAED) were performed on TEM (JEOL 3010) and HRTEM (Tecnai G2, F30). The electrochemical performances of composite electrodes were measured on AutoLab electrochemical workstation (PGSTAT204) using three electrode system at room temperature in 1 M H$_2$SO$_4$ electrolyte. For cyclic voltammetry, α-Fe$_2$O$_3$/CNF and α-Fe$_2$O$_3$/PANI composites coated on graphite rods were used as working electrode, platinum wire as counter electrode and calomel as the reference electrode. The electrochemical measurements were performed at scan rate 5–100 mV/s in a potential range of 0–1 V. The capacitance of the electrode was galvano-statically measured in the potential range of 0-1 V at current density of 1-10 A g$^{-1}$. Electrochemical impedance spectroscopy was performed under open circuit potential with frequency ranging from $10^{-2}$ to $10^5$ Hz.

3. **Results and discussion**

3.1 **Evolution of nano α-Fe$_2$O$_3$**

In order to understand feasibility of formation of rust in to nanosized Fe$_2$O$_3$, we look into the theory of corrosion and role of mechanical grinding and annealing. The rust formation process, under ambient environment in presence of water and oxygen involves formation of local electrochemical/ concentration cells on the surface of iron structures, with formation of cathodes and anodes. The products of reactions at cathode and anode are Fe$^{+2}$ and OH$^-$ ions respectively, migrates toward each other and meet in between to form molecular, hydrous Fe(OH)$_2$, FeOOH as initial products of corrosion. These molecular particles grow further via combinations of Fe$^{+2}$ and OH$^-$ ions to get clusters, where nanosized particles are loosely held together via weak Vander-Waals and Hydrogen bondings [37,38]. The corrosion product is porous, so that corrosion continues further till access of environmental water and oxygen is present that follows exponential decay. The natural ageing and drying converts Fe(OH)$_2$ and FeOOH to FeO xH$_2$O and Fe$_2$O$_3$ clusters. Thus, simple annealing is sufficient to evaporate coordinated water molecules from remaining FeOOH, FeO xH$_2$O to form Fe$_2$O$_3$, while strong mechanical grinding could break loosely held cluster to nanoscale range Fe$_2$O$_3$ particles. It is
to be noted that the usual chemical formation is a precipitation process that involves nucleation, growth and termination steps, that usually results into hard grains and clusters.

3.2 X-ray diffraction (XRD)

XRD patterns of as-obtained $\alpha$-$\text{Fe}_2\text{O}_3$, CNF, $\alpha$-$\text{Fe}_2\text{O}_3$/CNF and $\alpha$-$\text{Fe}_2\text{O}_3$/PANI are shown in Fig. 1. XRD pattern of as prepared $\alpha$-$\text{Fe}_2\text{O}_3$ shows presence of sharp diffraction lines matching exactly with the pattern displayed in JCPDS card No. 33-0664, confirming the presence of only Rhombohedral modification of $\alpha$-$\text{Fe}_2\text{O}_3$. The presence of sharp diffraction lines indicates good crystallinity of $\alpha$-$\text{Fe}_2\text{O}_3$ sample. The diffraction peaks at 20 values of 24.10, 33.20, 35.60, 40.90, 49.50, 54.10, 57.60, 62.40 and 64.00 degree have been assigned to the reflections originating from (012), (104), (110), (113), (024), (116), (018), (214), (300) planes of $\alpha$–$\text{Fe}_2\text{O}_3$ respectively [12].

The average crystallite size of the as prepared $\text{Fe}_2\text{O}_3$ nanoparticles was about 28 nm, calculated from the Debye–Scherrer equation based on the measurements of the FWHM of the strongest (110) peaks. No diffraction peaks due to unknown impurities/contaminant have been observed indicating high purity of sample. XRD patterns of CNF displays a characteristic broad peak due to (111) plane of carbon material corresponding to interlayer packing of hexagonal carbon sheets. When $\alpha$-$\text{Fe}_2\text{O}_3$ is coupled with CNF, the crystal phase of $\alpha$-$\text{Fe}_2\text{O}_3$ did not changes and the diffraction peak at (111) of carbon also present in the XRD pattern of $\alpha$-$\text{Fe}_2\text{O}_3$/CNF. Thus, the composite $\alpha$-$\text{Fe}_2\text{O}_3$/CNF keep the characteristics of peak pattern of both of the material with the diminishing intensity of (111) peak of the carbon material due to introduction of $\alpha$-$\text{Fe}_2\text{O}_3$ nanoparticles. Similar observations are indicated by $\alpha$-$\text{Fe}_2\text{O}_3$/PANI composite. It displays prominent peak corresponding to Polyaniline (Emeraldine hydrochloride, JCPDS No 49-2500) and those corresponding to $\alpha$-$\text{Fe}_2\text{O}_3$. 
Figure 1: XRD patterns of α-Fe$_2$O$_3$, Carbon fibers, α-Fe$_2$O$_3$/CNF and α-Fe$_2$O$_3$/PANI composites.

Scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX)

The SEM image of CNF, α-Fe$_2$O$_3$, α-Fe$_2$O$_3$/CNF and α-Fe$_2$O$_3$/PANI are shown in Fig. 2(a-d) respectively. Fig. 2(e,f) displays EDAX of α-Fe$_2$O$_3$/ PANI and α-Fe$_2$O$_3$/CNF respectively. The morphology of CNF exhibits continuous network type of fibers with average diameter of 300-350 nm (Fig 2a). The CNF fiber was able to maintain its long and continuous structure even after carbonisation giving large aspect ratio with moderate interconnectivity among the fibers. Such type of structure is desirable as it provides transportation directionality with short ionic length during charge storage [18]. Fig 2b shows the SEM image of as prepared α-Fe$_2$O$_3$, displaying nano-cluster, made up of large number of interconnected α-Fe$_2$O$_3$ nanoparticles having somewhat irregular shapes. The SEM image of α-Fe$_2$O$_3$/CNF composite (Fig 2c) shows quite heavy decoration of α-Fe$_2$O$_3$ particles over carbon fibers with some segregated α-Fe$_2$O$_3$ nano particles forming tiny plate-like clusters. The SEM of α-Fe$_2$O$_3$/PANI (Fig.2d) displays quite uniform dispersion of α-Fe$_2$O$_3$ over PANI fibers. The intimate and heavy junction between α-Fe$_2$O$_3$ and conducting CNF/PANI is essential for a fast redox reaction during the electrochemical process. The EDAX pattern of α-Fe$_2$O$_3$/CNF displayed in Fig.2f confirm the
presence of carbon, iron and oxygen with no other elemental impurities whereas that of \( \alpha-\text{Fe}_2\text{O}_3/\text{PANI} \) (Fig.2e) displays presence of nitrogen in addition to carbon, iron and oxygen without impurities.

![SEM images of CNF(a), \( \alpha-\text{Fe}_2\text{O}_3 \) (b), \( \alpha-\text{Fe}_2\text{O}_3/\text{CNF} \) (c), \( \alpha-\text{Fe}_2\text{O}_3/\text{PANI} \) (d), EDX spectrum of \( \alpha-\text{Fe}_2\text{O}_3/\text{PANI} \) (e) and \( \alpha-\text{Fe}_2\text{O}_3/\text{CNF} \) (f)](image)

**Figure 2:** SEM images of CNF(a), \( \alpha-\text{Fe}_2\text{O}_3 \) (b), \( \alpha-\text{Fe}_2\text{O}_3/\text{CNF} \) (c), \( \alpha-\text{Fe}_2\text{O}_3/\text{PANI} \) (d), EDX spectrum of \( \alpha-\text{Fe}_2\text{O}_3/\text{PANI} \) (e) and \( \alpha-\text{Fe}_2\text{O}_3/\text{CNF} \) (f)

### 3.3 TEM, HRTEM and SAED of \( \alpha-\text{Fe}_2\text{O}_3 \)

The detailed morphology and microstructure of as prepared iron rust have been further investigated by TEM and HRTEM. Figure 3 (a,b) shows TEM images of as prepared iron rust at different resolutions, it can be seen that the iron rust is made up of aggregations of numbers of nanoparticles with size ranging from 20 to 50 nm, further the interplanar distance measured out in HRTEM image of 0.25 nm (Fig 3c) can be indexed to the lattice fringes of \( \alpha-\text{Fe}_2\text{O}_3 \) (110) planes, which is a prominently consistent with the results of XRD. Figure 3d shows the SAED pattern of \( \alpha-\text{Fe}_2\text{O}_3 \)NP’s with bright spots in the diffraction circles confirming the crystalline nature of \( \alpha-\text{Fe}_2\text{O}_3 \) nanoparticles.
Figure 3(a-d): TEM images of $\alpha$-Fe$_2$O$_3$ (a,b), HRTEM image of $\alpha$-Fe$_2$O$_3$, SAED pattern of $\alpha$-Fe$_2$O$_3$ (d).

3.5 Electrochemical performance of $\alpha$-Fe$_2$O$_3$/CNF

The electrochemical measurements were performed in 1M H$_2$SO$_4$ electrolyte in a three-electrode cell configuration with platinum rod (counter electrode), saturated calomel electrode (reference electrode) and individual working electrodes consisting of $\alpha$-Fe$_2$O$_3$/CNF and $\alpha$-Fe$_2$O$_3$/PANI composites deposited on carbon rod. The potential window was kept between 0 – 1V. Figure 4(a,c) displays CV profile before cycling, whereas, fig (b,d) displays CV profile after 5000 cycles for $\alpha$-Fe$_2$O$_3$/CNF and $\alpha$-Fe$_2$O$_3$/PANI at 5,10,20,30,40,50,75 and 100 mV/s scan rates respectively.

The approximately symmetrical, rectangular appearance of the CV profile with distinct redox peaks demonstrates the pseudo-capacitive behaviour. A couple of well-defined redox peaks can be found within 0.2 – 0.8 V due to faradic redox reactions corresponding to the reversible conversions between Fe$^{3+}$ and Fe$^{2+}$ [20]. The $\alpha$-Fe$_2$O$_3$/PANI exhibited much larger captive current (180 mA) (Fig 4c) than Fe$_2$O$_3$/CNF (3mA) (Fig 4a) as against bare $\alpha$-Fe$_2$O$_3$, which did not show any comparable current. The highest electrochemical performance of $\alpha$-
Fe$_2$O$_3$/PANI has been resulted from the well-designed nano-structure, excellent interconnectivity among PANI fibers and the synergistic effect between the two-components.

The nanosized α-Fe$_2$O$_3$ particles provide fast faradic process resulting in high pseudo-capacitance contributing to much higher specific capacitance. It is evident that with the increase in the sweep rate, the peak current notably increases keeping the CV profiles intact. A slight potential shift of the redox peaks can be ascribed to the internal charge transfer resistance [39]. With the increase of scan rate, the specific capacitance was found to diminish gradually as usual and considered as normal behaviour due to faster diffusion of ions at lower scan rate than higher [40]. After 5000 cycling (Fig.4 b,d), the area under the curve has decreased for α-Fe$_2$O$_3$/CNF and α-Fe$_2$O$_3$/PANI electrodes indicating decrease in specific capacitance of both materials.

**Figure 4:** Cyclic voltammetry at different scan rates for CNF-Fe$_2$O$_3$ in 1M H$_2$SO$_4$ before cycling (a) and after 5000 cycling (b) and for PANI-Fe$_2$O$_3$ in 1M H$_2$SO$_4$ before cycling (c) and after cycling and (d)

Figure 5(a,b) show Nyquist plot of α-Fe$_2$O$_3$/CNF and α-Fe$_2$O$_3$/PANI within the frequency range of 0.01 to $10^5$ Hz at open circuit potential before (black data) and after 5000 cycles (red data).
data) respectively. As can be seen from EIS spectra, α-Fe$_2$O$_3$/CNF exhibits one depressed semicircle (Fig.5a) in the high frequency range (due to charge transfer process, Rct) and a sloped straight line in the low frequency region (due to diffused limited process, W). The absence of a linear portion in low frequency range before and after cycling indicates presence of negligible surface Warburg resistance in the electrolyte due to poor conductivity of α-Fe$_2$O$_3$ so that the charge transfer resistance becomes high to make electrochemical reaction too slow to enable diffusion process not a rate control step, therefore, the Warburg impedance becomes insignificant thus the straight-line portion at the low frequency range is not obvious anymore [1].

![Figure 5: Cyclic voltammetry curves measured at different scan rates for PANI-Fe$_2$O$_3$ in 1M H$_2$SO$_4$ (a) before cycling and (b) after 5000 cycling; (c) EIS before and after cycling and (d) Galvanostatic charge-discharge curves at different current densities](image)

On the other hand, the Faradic interfacial charge-transfer resistance rises slowly with cycling (red data) ascribing to the fact that the partial deformation/destruction of nanostructure and the corrosion of the current collector was occurred during the redox reaction, yielding low conductivity after cycling [20]. The notable reduction in semicircle diameter for α-Fe$_2$O$_3$/PANI (Fig 5b, black data) than α-Fe$_2$O$_3$/CNF display outstanding electrical conductivity.
of α-Fe$_2$O$_3$/PANI, contributing much superior electrochemical performance. A straight line
versus a high angle to the Z’ axis before and after cycling have been noticed, suggesting co-
existence of abundant ions diffusion path-ways and their rapid movement in the active
materials leading to differential capacitance [22,40].

Figure 5(c,d) shows GCD curves of α-Fe$_2$O$_3$/CNF and α-Fe$_2$O$_3$/PANI recorded at different
current density respectively. A presence of a perfect triangular shaped charge/discharge curves
implies presence of pure EDLC type capacitance, however, the GCD curves of both the
electrodes shows a plateau at about 0.3-0.4V along with triangle indicating the presence of
pseudo-capacitive faradic feature in addition. As displayed in Fig 5(c,d), α-Fe$_2$O$_3$/PANI
exhibited a longer discharge time (520 sec) than α-Fe$_2$O$_3$/CNF composites (330 sec).

Figure 6(a) displays the comparison of CV of α-Fe$_2$O$_3$/CNF and α-Fe$_2$O$_3$/PANI at 5 mV/s.
It clearly shows much larger area for α-Fe$_2$O$_3$/PANI cycle than Fe$_2$O$_3$/CNF indicating high
captive nature of α-Fe$_2$O$_3$/PANI than Fe$_2$O$_3$/CNF composites. The specific capacitance of both
the composites have been calculated from GCD curves at different current density using
equation (1),

\[
C_s = \frac{i \times \Delta t}{m \times \Delta V}
\]

... (1)

Where, $C_s$ is the specific discharge capacitance, $i$ is the current density, $\Delta t$ is the discharge time,
$\Delta V$ is the potential during discharge.

Figure 6(b) shows the relationship between the specific capacitance at different current
density. The specific capacitance of α–Fe$_2$O$_3$/CNF and α–Fe$_2$O$_3$/PANI composite were 88.88
and 192.29 Fg$^{-1}$ at 1A g$^{-1}$ current density, was dramatically decreased to 5.43 Fg$^{-1}$ (at current
density of 5 A g$^{-1}$) for α–Fe$_2$O$_3$/CNF and to 84.04 Fg$^{-1}$(at current density of 10 A g$^{-1}$)
respectively.
Both of the materials showed the same trend of decreasing specific capacitance with the increments in the discharge current density. The active surface of the electrodes may be probably becoming inapproachable for charge stockpile during the charge-discharge process, resulting in the comparatively inadequate Faradic redox reaction at higher discharge current densities, which accounts for the abatement of specific capacitance [41]. It is to be noted that Fe$_2$O$_3$ nano spindles, synthesised chemically via hydrothermal route, as positive electrode in 0.5 M K$_2$SO$_4$ electrolyte showed a specific capacitance of 159 F g$^{-1}$ at 0.1 A g$^{-1}$ current density [34]. The results are much comparable with mill scale derived Fe$_2$O$_3$ sprayed on large area current collector electrode (method reported as a greener synthetic route) which gave 92Fg$^{-1}$ capacitance at 5 mVs$^{-1}$ scan rate with 20% loss after 5000 cycles [35].

Fig. 5(c) shows the Ragone plot for $\alpha$–Fe$_2$O$_3$/CNF (black data) and $\alpha$–Fe$_2$O$_3$/PANI (red data) electrodes. It is seen that for $\alpha$–Fe$_2$O$_3$/CNF, increase in specific power from 69.39 to 410.63 WhKg$^{-1}$ the specific energy was decreased from 3.08 to 0.1WhKg$^{-1}$, whereas $\alpha$–Fe$_2$O$_3$/PANI showed a maximum specific energy of 11.28 WhKg$^{-1}$ at specific power density of
162.44 Wkg\(^{-1}\) and a maximum power density of 1623.78 Wkg\(^{-1}\) at a specific energy of 4.93 WhKg\(^{-1}\) indicating good power characteristics than \(\alpha \– \text{Fe}_2\text{O}_3/\text{CNF}\). The higher power output makes the material promising for applications where high-power output as well as high energy capacity is required. The cycling stability is considered as an effective element of supercapacitor for realistic application purpose. Figure 6(d) demonstrates long term cycling properties of the \(\alpha \– \text{Fe}_2\text{O}_3/\text{CNF}\) and \(\alpha \– \text{Fe}_2\text{O}_3/\text{PANI}\) composite tested by continuous GCD measurements at current density of 1 Ag\(^{-1}\) for 5000 cycles. The specific discharge capacitance of \(\alpha \– \text{Fe}_2\text{O}_3/\text{CNF}\) and \(\text{Fe}_2\text{O}_3/\text{PANI}\) electrodes drop by 25\% and 20\% of the initial capacitance respectively after 5000 cycles, displaying an excellent cycling performance for both the electrodes. The loss after 5000 cycling is attributed to the stacking and agglomeration of active sites in the process.

**Conclusions**

Decorations of \(\alpha \– \text{Fe}_2\text{O}_3\) synthesized from its waste iron rust on CNF and PANI were successfully done by using electrospinning and hydrothermal method. The \(\alpha \– \text{Fe}_2\text{O}_3/\text{CNF}\) and \(\text{Fe}_2\text{O}_3/\text{PANI}\) positive electrodes showed a maximum specific capacitance of 88.88 and 192.29 Fg\(^{-1}\) at 1 Ag\(^{-1}\), energy density of 3.08 and 11.28 Whkg\(^{-1}\) with power density of 69.39 and 162.44 Wkg\(^{-1}\) respectively. A loss of 25\% for \(\alpha \– \text{Fe}_2\text{O}_3/\text{CNF}\) and 20 \% \(\text{Fe}_2\text{O}_3/\text{PANI}\) in specific capacitance after 5000 continuous charge/discharge cycle indicate a highly stable cycling performance. The excellent electrochemical capacitance of the waste derived \(\alpha \– \text{Fe}_2\text{O}_3/\text{PANI}\) composite positive electrode makes it prospectively as a promising electrode material for energy storage in sustainable hybrid supercapacitor.
