Monocytic leukemia zinc-finger protein (MOZ), a MYST family histone acetyltransferase, is involved in the chromosome translocations associated with acute myeloid leukemia. MOZ acts as a transcriptional coactivator for AML1, which is essential for establishment of definitive hematopoiesis. To investigate the roles of MOZ in normal hematopoiesis, we generated MOZ-null mice. MOZ−/− mice died around embryonic day 15 (E15). In MOZ−/− E14.5 embryos, hematopoietic stem cells, lineage-committed progenitors, and B lineage cells were severely reduced. On the other hand, arrest of erythroid maturation and elevated myeloid lineage populations were observed. MOZ-deficient fetal liver cells could not reconstitute hematopoiesis of recipients after transplantation. Analysis using microarray and flow cytometry revealed that expression of thrombopoietin receptor (c-Mpl), HoxA9, and c-Kit was down-regulated. These results show that MOZ is required for maintenance of hematopoietic stem cells, and that it plays a role in differentiation of erythroid and myeloid cells. Some aspects of the MOZ−/− phenotype are similar to that observed in PU.1-deficient mice. MOZ was able to interact with PU.1 and activate PU.1-dependent transcription, thus suggesting a physical and functional link between PU.1 and MOZ.

Monocytic leukemia zinc-finger protein (MOZ) is a transcriptional coactivator with histone acetyltransferase activity [Champagne et al. 2001; Kitabayashi et al. 2001a]. MOZ was first isolated as a gene involved in chromosome translocation t(8;16) [p11;p13], which is associated with the FAB M4/M5 subtype of acute myeloid leukemia with monocytic arrest [Borrow et al. 1996]. This translocation results in the fusion of MOZ to transcription coactivator CBP. MOZ is also fused to CBP-like coactivator p300 and nuclear receptor coactivator TIF2 in leukemia-associated chromosome rearrangements t(8;22) [Chaffanet et al. 2000; Kitabayashi et al. 2001b], and inv(8) [Carapetis et al. 1998; Liang et al. 1998], respectively. In addition, MOZ is involved in the t(2;8) chromosome translocation found in myelodysplastic syndrome [Imamura et al. 2003]. In all of the leukemia-associated fusions, MOZ lacks the C-terminal region but retains some of its functional domains, including the histone acetyltransferase domain, PHD-type zinc-finger motif, and histone H1-like domain. MOZ–TIF2 fusion is able to confer properties of leukemic stem cells to committed hematopoietic progenitors, thus inducing acute myeloid leukemia in irradiated recipient mice after transplantation [Deguchi et al. 2003; Huntly et al. 2004]. MOZ–CBP inhibits differentiation of M1 myeloid precursor cells into macrophages [Kitabayashi et al. 2001a].

It has been reported that MOZ interacts with AML1, and acts as a transcriptional coactivator [Kitabayashi et al. 2001a]. AML1 [Runx1] is the most frequent target of chromosome rearrangements associated with acute leukemia. AML1 is essential for generation of hematopoietic stem cells [Okuda et al. 1996; Wang et al. 1996a], and is important for differentiation of megakaryocytes and lymphocytes [Ichikawa et al. 2004; Grownower et al. 2005]. AML1 forms a stable complex with CBFβ, which is also essential for definitive hematopoiesis [Sasaki et al. 1996; Wang et al. 1996b; Niki et al. 1997]. Although MOZ and p300/CBP act as coactivators for AML1, the leukemia-associated MOZ–CBP inhibits AML1-mediated transcription [Kitabayashi et al. 1998, 2001a; Bristow and Shore 2003]. The ETS family transcription factor PU.1 (Spi-1) is essential for maintenance of hematopoietic stem cells and development of myeloid and lymphoid lineages [Scott et al. 1994; McKercher et al. 1996; Kim et al. 2004; Iwasaki et al. 2005]. Recent studies of mice...
carrying hypomorphic PU.1 alleles have indicated that reduction in the expression of PU.1 is capable of predisposing mice to AML [Rosenbauer et al. 2004]. Zebrafish having a mutation in the MOZ gene exhibit defects in Hox expression and pharyngeal segmental identity [Miller et al. 2004]. Mice carrying a mutation in a gene encoding the MOZ-like protein MORF/Querkopf exhibited defects in bone and brain development [Thomas et al. 2000]. However, the role of zebrafish MOZ and mouse MORF in hematopoiesis has not been described.

In order to clarify the physiological role of MOZ, we generated mutant mice that completely lack expression of MOZ. Involvement in leukemia-associated chromosome rearrangements and interaction with AML1 suggest critical roles of MOZ in hematopoiesis. Thus, we focused on analysis of the hematopoietic system in MOZ-null mice.

Results

MOZ deficiency is embryonic lethal

In order to clarify the roles of MOZ in hematopoiesis, we generated MOZ-deficient mice by homologous recombination in embryonic stem (ES) cells using a gene-targeting vector, in which the MOZ exon 2 containing the first ATG was replaced with the neo gene cassette [Fig. 1A]. Western blot analysis showed no detectable MOZ in homozygous embryos and decreased expression of MOZ in heterozygous embryos [Fig. 1B]. Western blot analysis using antibodies to detect N-terminal and C-terminal MOZ, and RT–PCR using different sets of primers on the 5′, central, and 3′ regions indicated that no truncated MOZ protein or mRNA was present in MOZ−/− embryos (Supplementary Fig. S1B). MOZ +/+ mice were born and were fertile, exhibiting no morphological abnormalities [Fig. 1C]. On the other hand, MOZ−/− pups were not seen. To identity the stage of embryonic development at which the MOZ mutation is lethal, embryonic day 12.5–16.5 (E12.5–E16.5) embryos were analyzed for genotype. MOZ−/− embryos remained alive until E14.5; however, after E15.5, viable MOZ-deficient fetuses were not detected [Fig. 1C]. MOZ−/− embryos at E14.5 were pale, and the fetal liver, which is the major hematopoietic organ at this stage, was smaller than that of wild-type or heterozygous littermates [Fig. 1D]. Some MOZ−/− embryos exhibited hemorrhaging, subcutaneous edema, and bent tail. Gross histological analysis of wild-type and null-mutant littermates revealed that MOZ−/− embryos have no other notable defects or abnormalities [Fig. 1E]. Two independent targeted lines were produced, and exhibited essentially the same phenotype.

Decreased colony-forming cells in MOZ-deficient fetal liver

The morphological features of MOZ−/− embryos suggest defects in fetal liver hematopoiesis. The total number of fetal liver cells was decreased by 40% in E14.5 MOZ−/− embryos [Fig. 2A]. To examine the presence of hematopoietic progenitors, colony-forming cells (CFCs) were analyzed. Fetal liver cells were cultured in methylcellulose medium, and myeloid, erythroid, and mixed-lineage colonies were scored on the basis of standard morphological criteria after 12 d of culture. The total number of CFCs in MOZ−/− fetal liver cells was decreased by fivefold to 10-fold. However, the ratio of lineage-committed CFCs was not affected [Fig. 2B]. These results suggest that the hematopoietic progenitor population was reduced in MOZ-deficient embryos. No significant differ-
Reduction of hematopoietic stem cells and progenitors in MOZ-deficient fetal liver

In order to analyze hematopoietic progenitors and stem cells directly, we performed flow cytometry. Analysis of c-Kit, a common marker for hematopoietic progenitors, revealed that the population of cells expressing high levels of c-Kit (Lin− c-Kithi) was severely decreased in MOZ−/− fetal liver, while the population of cells expressing low levels of c-Kit was not strongly affected [Fig. 3A]. The population of Lin− Sca-1− c-Kit+ cells, which includes hematopoietic stem cells (HSCs), was severely reduced in MOZ−/− embryos when compared with wild-type controls [Fig. 3B]. Reductions were also observed in lineage-committed progenitors, such as common lymphoid progenitors (CLPs, Lin− IL-7Ra− Sca-1+ c-Kitlo) [Fig. 3B], common myeloid progenitors (CMPs, Lin− Sca-1− c-Kit− CD34+FcγR III/IIlo), granulocyte/macrophage progenitors (GMPs, Lin− Sca-1− c-Kit− CD34+FcγR III/II−), and megakaryocyte/erythroid progenitors (MEPs, Lin− Sca-1− c-Kit− CD34+FcγR III/IIlo) [Fig. 4A]. The number of HSCs and progenitors was also reduced in E12.5 MOZ−/− fetal liver as compared with those in wild-type littermates, but the reductions were milder than those observed in E14.5 embryos [Supplementary Fig. S2]. These data suggest that generation or maintenance of HSCs and progenitors was disrupted in MOZ−/− embryos, and the number of HSCs and progenitors was slightly reduced in MOZ−/− embryos.

Reduction of B lymphocytes, but not granulocytes and monocytes, in MOZ-deficient fetal liver

In order to assess differentiated hematopoietic cells in fetal liver, we investigated cells expressing a B lineage marker, CD19, and myeloid lineage markers, Gr-1 and Mac-1 by flow cytometry. CD19+ cells were reduced in MOZ−/− embryos when compared with wild-type embryos [Fig. 3C]. In contrast, cell numbers of Mac-1+, Gr-1lo granulocytes and Mac-1+ Gr-1lo monocytes were

Figure 3. Decrease in hematopoietic stem cells and progenitors in MOZ−/− fetal liver. (A) Population of c-Kithi and c-Kitlo cells. Cells were prepared from E14.5 fetal liver cells, stained with Lineage-Biotin-streptavidin-PerCP-Cy5.5 and c-Kit-APC. Populations of c-Kithi and c-Kitlo cells in Lin− fractions were analyzed by flow cytometry. The filled area exhibits background staining. (B) Population of HSCs and CLPs. Cells from E14.5 fetal liver cells were stained with Sca-1-FITC, IL-7R−PE, Lin−/H9251, Gr-1, Ter119)-Biotin-streptavidin-PerCP-Cy5.5 and c-Kit-APC. Populations of c-Kitlo and c-Kithi cells in Lin− fractions were analyzed by flow cytometry. (C) Population of B lymphocytes. Cells from E14.5 fetal liver cells were stained with CD19-PE and Gr-1-APC. CD19+ B lineage cells and Gr-1 + myeloid lineage cells were analyzed by flow cytometry. (D) Numbers of c-Kitlo cells, c-Kithi cells, HSCs, CLPs, CD19+ B lineage cells, and Gr-1 + myeloid lineage cells. Results represent average values for the relative number of cells per embryo. E14.5 MOZ−/− [n = 6], MOZ−/− [n = 22] and MOZ−/− [n = 9] fetal livers were used for analysis of HSCs and CLPs. E14.5 MOZ−/− [n = 8], MOZ−/− [n = 10], and MOZ−/− [n = 4] fetal livers were used for B lineage and myeloid cells. P-values were calculated by two-tailed unequal-variance t-test as compared with MOZ−/+ embryos. (*) P < 0.05; (**) P < 0.01; (***) P < 0.005.
granulocyte/macrophage progenitors (GMPs, Lin<sup>−</sup>) and monocytic MOZ progenitors (CMPs, Lin<sup>−</sup>PerCP-Cy5.5, and c-Kit-APC. Populations of common myeloid (Gr-1 hi/Mac-1+) and also analyzed cells in the thymus, spleen, and bone marrow demonstrated that the KLSF fraction before and after cultured in liquid medium. After culture in liquid medium with cytokines for 4 d, the majority of KLSFs and CMPs differentiating into either granulocytes or macrophages, although the differentiation of KLSFs was somewhat perturbed compared with that of GMPs. No significant differences in differentiation between wild-type and MOZ<sup>−/−</sup> cells were observed in the KLSF and GMP fractions before and after cultured in liquid medium. However, MOZ<sup>−/−</sup> GMPs and KLSFs exhibited poor proliferation and colony formation activity compared with those from wild-type fetal liver [Supplementary Fig. S5]. These results suggest that KLSFs contain not-yet characterized myeloid lineage cells that are relatively resistant to differentiation.

**Defects in erythropoiesis in MOZ-deficient fetal liver**

In order to investigate erythroid lineage differentiation, E14.5 fetal liver cells were simultaneously stained for transferrin receptor (CD71) and erythroid antigen Ter119, and were analyzed by flow cytometry [Solovovsky et al. 2001]. While differentiated red cells [Ter119<sup>−</sup> CD71<sup>+</sup>] were severely reduced, late-stage erythroblasts [Ter119<sup>−</sup> CD71<sup>−</sup>]) were elevated in MOZ<sup>−/−</sup> fetal liver when compared with wild-type or MOZ<sup>+/−</sup> controls [Fig. 4C]. Morphological analysis of fetal liver cells indicated that erythroblasts were markedly accumulated in MOZ<sup>−/−</sup> embryos when compared with wild-type embryos [Supplementary Fig. 8]. These data suggest that MOZ is indispensable for maturation of erythroid cells.

**MOZ is required for reconstituting the hematopoietic system**

We performed competitive reconstitution assay in order to determine whether MOZ-deficient embryos possess functional HSCs. Fetal liver cells (2 x 10<sup>6</sup> cells) from E13.5–E14.5 MOZ<sup>−/−</sup>, MOZ<sup>+/−</sup>, and MOZ<sup>+</sup> (Ly5.2<sup>+</sup>) embryos were injected into lethally irradiated normal recipients mice [Ly5.1<sup>−</sup>/Ly5.2<sup>+</sup>] and Ly5.1<sup>−</sup>/Ly5.2<sup>−</sup> embryos. Engraftment of recipient mice was monitored for 2, 4, 8, or 12 wk after transplantation by flow cytometry analysis of Ly5 allotype expression in peripheral blood cells. As shown in Figure 5A, MOZ<sup>−/−</sup> and MOZ<sup>+/−</sup> Ly5.2<sup>−</sup> cells were detected in the recipient mice. However, MOZ<sup>−/−</sup> cells were not detected at any of the time points examined [Fig. 5B]. The population of MOZ<sup>−/−</sup> cells was lower than that of wild-type cells. We also analyzed cells in the thymus, spleen, and bone marrow at 12 wk after transplantation and found that Ly5.2<sup>−</sup> cells derived from MOZ<sup>−/−</sup> embryos were not present in any organs tested [Fig. 5C].
In order to determine whether loss of reconstitution activity was due to reductions in the number of HSCs or loss of HSC self-renewal activity, competitive reconstitution assay was performed using increasing numbers of donor cells [threefold and ninefold] (Fig. 5D). Results represent the average values for the population of Ly5.2+ cells. These results suggest that MOZ functions as a transcriptional coactivator for PU.1.

Expression levels of these genes were then investigated in HSCs by sorting HSC-enriched Lin−/Sca-1− fetal liver cells from E14.5 wild-type and MOZ−/− embryos, and preparing total RNAs. Semiquantitative RT–PCR analysis showed that expression levels of HoxA9 and c-Mpl were apparently reduced in MOZ−/− fetal liver cells [Fig. 6B]. Among the latter 163 genes, reduced expression of c-Kit was also observed in MOZ−/− fetal liver cells [Supplementary Fig. S6].

Expression levels of these genes with altered expression levels in MOZ−/− fetal liver cells, total RNAs were extracted from E12.5 MOZ+/+, MOZ−/−, and MOZ−/− fetal livers. Analysis by oligonucleotide microarray identified 48 and 163 genes exhibiting changes in expression of more than twofold [Fig. 6A] and 1.5-fold [Supplementary Fig. S6], respectively. Among the former 48 genes, down-regulation of the homeobox transcription factor HoxA9 and the thrombopoietin receptor c-Mpl are likely to be associated with defects in hematopoiesis. Semiquantitative RT–PCR also showed that expression levels of HoxA9 and c-Mpl were apparently reduced in MOZ−/− fetal liver cells [Fig. 6B]. Among the latter 163 genes, reduced expression of c-Kit was also observed in MOZ−/− fetal liver cells [Supplementary Fig. S6].

**Reduced expression of HoxA9 and c-Mpl in MOZ−/− fetal liver cells**

In order to identify genes with altered expression levels in MOZ−/− fetal liver cells, total RNAs were extracted from E12.5 MOZ+/+, MOZ−/−, and MOZ−/− fetal livers. Analysis by oligonucleotide microarray identified 48 and 163 genes exhibiting changes in expression of more than twofold [Fig. 6A] and 1.5-fold [Supplementary Fig. S6], respectively. Among the former 48 genes, down-regulation of the homeobox transcription factor HoxA9 and the thrombopoietin receptor c-Mpl are likely to be associated with defects in hematopoiesis. Semiquantitative RT–PCR also showed that expression levels of HoxA9 and c-Mpl were apparently reduced in MOZ−/− fetal liver cells [Fig. 6B]. Among the latter 163 genes, reduced expression of c-Kit was also observed in MOZ−/− fetal liver cells [Supplementary Fig. S6].

Expression levels of these genes was then investigated in HSCs by sorting HSC-enriched Lin−/Sca-1− fetal liver cells from E14.5 wild-type and MOZ−/− embryos, and preparing total RNAs. Semiquantitative RT–PCR analysis showed that expression levels of HoxA9 and c-Mpl were apparently reduced in MOZ−/− fetal liver cells [Fig. 6C].

Expression levels of these genes was then investigated in HSCs by sorting HSC-enriched Lin−/Sca-1− fetal liver cells from E14.5 wild-type and MOZ−/− embryos, and preparing total RNAs. Semiquantitative RT–PCR analysis showed that expression levels of HoxA9 and c-Mpl were apparently reduced in MOZ−/− fetal liver cells [Fig. 6C].

Interaction of MOZ with PU.1

The defects in hematopoiesis in MOZ-null mice are similar to those observed in PU.1−/− mice. In PU.1−/− fetal liver, HSCs and progenitors, in particular, the population of c-Kit+ Lin− cells is severely reduced [Kim et al. 2004; Iwasaki et al. 2005]. These similarities suggest a functional link between MOZ and PU.1. To test whether MOZ interacts with PU.1, we performed coimmunoprecipitation analysis. HA-tagged MOZ was transfected with Flag-tagged PU.1, AML1, C/EBPα, and C/EBPγ. Cell lysates were prepared, and were immunoprecipitated with anti-Flag antibodies. Western blot analysis of the immunoprecipitates indicated that MOZ was coprecipitated with PU.1 and AML1, but not with C/EBPα and C/EBPγ [Fig. 7A]. Reciprocal immunoprecipitation analysis indicated that PU.1 was coprecipitated with MOZ [Fig. 7B]. To test the interaction between endogenous MOZ and PU.1, we performed coimmunoprecipitation analysis using lysates of E14.5 fetal liver cells. Endogenous MOZ was detected in immunoprecipitates of endogenous PU.1 [Fig. 7C]. These results suggest that MOZ is able to physically interact with PU.1. To test the effects of MOZ on PU.1-regulated transcription activity, reporter analysis was performed. MOZ strongly stimulated PU.1-mediated transcriptional activation [Fig. 7D]. These results suggest that MOZ functions as a transcriptional coactivator for PU.1.
Discussion

In this study, we generated MOZ-deficient mice and demonstrated that MOZ is essential for definitive hematopoiesis. HSCs and progenitors were decreased, and maturation of erythroid cells was inhibited in MOZ-deficient fetal liver. In competitive repopulation assay, MOZ−/− fetal liver cells did not exhibit any activity to reconstitute hematopoietic system. These results indicate that MOZ is essential for maintenance of HSCs. Intermediate phenotypes in the number of HSCs and progenitors as well as in reconstitution activity were observed in MOZ+/− fetal liver cells, thus suggesting a gene dosage requirement for MOZ. Gene expression profiles showed that expression of HoxA9, c-Mpl, and c-Kit was diminished. Immunoprecipitation analysis and reporter analysis suggest that MOZ functions as a coactivator for PU.1 as well as AML1.

Targets of MOZ

Expression levels of HoxA9, c-Mpl, and c-Kit were significantly decreased in MOZ−/− fetal liver cells and HSC-enriched Lin−/Sca-1− cells. HoxA9 has key roles in hematopoiesis (Lawrence et al. 1997; So et al. 2004) and leukemia pathogenesis (Kroon et al. 1998; Calvo et al. 2000). It has been reported that loss of HoxA9 reduces the proliferation and repopulating potential of hematopoietic stem cells, although HoxA9 is not essential for the maintenance of HSCs (Lawrence et al. 2005). The TPO receptor c-Mpl is important for megakaryocyte development (Carver-Moore et al. 1996) and for HSC activity in reconstituting hematopoietic organs in irradiated recipients (Kimura et al. 1998). c-Kit-mutated Vickid and KitW+/-W+/- mice also exhibited reduced HSC repopulating activity (Waskow et al. 2002; Antonchuk et al. 2004). Moreover, reduced progenitors and repopulating activities, as well as defects in erythropoiesis, were exacerbated in c-Mpl- and c-Kit double-deficient mice (Antonchuk et al. 2004). In addition, the c-Mpl ligand, TPO, induces HOXA9 nuclear localization (Kirito et al. 2004). Therefore, it is possible that defects in HSC repopulating activity and erythropoiesis in MOZ−/− mice are due to the synergistic effects of decreased expression of these factors.

In E14.5 MOZ−/− fetal liver, populations of HSCs and all lineages of hematopoietic progenitors were reduced, particularly progenitors expressing high levels of c-Kit. These phenotypes were, at least in part, similar to those observed in PU.1−/− mice. In PU.1−/− fetal liver, HSCs and progenitors, except for MEPs, were severely reduced (Kim et al. 2004; Iwasaki et al. 2005). The population of Lin− c-Kit− cells was particularly low, thus suggesting that expression of c-Kit is positively regulated by PU.1. We showed here that MOZ is able to interact with PU.1 and activates PU.1-dependent transcription, which suggests that MOZ is a coactivator of PU.1 and that it regu-
lates transcription of PU.1-target genes. PU.1−/− mice show more severe reductions in HSCs and hematopoietic progenitors than MOZ−/− mice. MOZ is a transcription coactivator, and thus the difference may be because PU.1 transcription activity is not completely abolished in MOZ−/− mice. Therefore, MORF, which is highly homologous to MOZ, may compensate for some MOZ functions. In contrast to MOZ−/− embryos, PU.1-null embryos have no myeloid cells [Kim et al. 2004; Iwasaki et al. 2005]. However, increases in myeloid cells were observed in mice carrying hypomorphic PU.1 alleles, in which PU.1 expression was decreased to 20% of wild-type levels [Rosenbauer et al. 2004] as observed in MOZ−/− embryos. Thus, the MOZ−/− mouse phenotype, except for defects in erythropoiesis and reductions in MEPs, can be explained by reduced PU.1 activity.

We previously showed that MOZ forms a complex with AML1 and acts as a potent coactivator of AML1 [Kitabayashi et al. 2001a]. HoxA9 expression is reduced in AML patients with chromosome translocations t(8;21) and inv(16) [Debernardi et al. 2003]. In such leukemia cells, AML1 is inhibited by AML1-ETO and CBFβ-MYH11, respectively. Expression of c-Mpl is also reduced in patients having familial platelet disorder with predisposition to acute myeloid leukemia [FPD/AML], which has a mutation in AML1 [Heller et al. 2005]. These studies indicate that expression of HoxA9 and c-Mpl can be regulated by AML1. Thus, it is likely that reduced expression of HoxA9 and c-Mpl in MOZ−/− fetal liver arises from the inactivity of AML1 in the absence of its coactivator, MOZ.

**Figure 7.** Interaction between MOZ and PU.1. (A) MOZ interacts with PU.1 and AML1 but not with C/EBPα and C/EBPε. 293T cells were cotransfected with HA-tagged MOZ, together with control vector, Flag-tagged AML1, PU.1, C/EBPα or C/EBPε. (Top) Expression of MOZ in the lysates of transfected cells was detected by immunoblotting using anti-HA antibody (3E10) antibody. Proteins were immunoprecipitated with anti-Flag [M2] antibody. Immuno precipitates were analyzed by immunoblotting using anti-HA [middle] and anti-Flag [bottom] antibodies. (B, top) Reciprocal coimmunoprecipitation of PU.1 and MOZ. 293T cells were cotransfected with PU.1 together with control vector, Flag-tagged p300, or MOZ. Expression of PU.1 in the lysates of transfected cells was detected by immunoblotting using anti-PU.1 antibody. Flag-tagged p300 and MOZ were immunoprecipitated with anti-Flag (M2) antibody. (Bottom) Immunoprecipitates were analyzed by immunoblotting using anti-PU.1 antibody. (C) Interaction of endogenous PU.1 and MOZ. Cell lysates were prepared from E14.5 fetal liver cells (5 x 10⁷) and PU.1 was immunoprecipitated with anti-PU.1 antibody. Cell lysates and immunoprecipitates were then analyzed by immunoblotting with anti-PU.1 antibody (N). (D) MOZ activates PU.1-mediated transcription. SaOS2 cells were transfected with 100 ng of M-CSFR-luc, 50 ng of CMV-PU.1, indicated amounts (in micrograms) of LNCX-MOZ, and 2 ng of phRL-cmv. Cell lysates were prepared at 24 h after transfection, and were analyzed for luciferase activity.

**Roles of MOZ and MOZ fusion in myelogenesis and leukemia pathogenesis**

We observed increases in the populations of Mac-1+ Gr-1+ myeloid cells and in the uncharacterized myeloid cell fraction KLSF [Lin− Sca-1− c-Kit+ CD34− FcγR III/IIb] in MOZ-deficient fetal liver [Fig. 4A,B], although immature myeloid progenitors (CMP, GMP) were reduced. This may be because myeloid differentiation is inhibited around the KLSF stage in MOZ−/− mice, as MOZ has important roles in the regulation of this stage. Alternatively, accumulation of myeloid cells including KLSFs may be due to uncontrolled and abnormal differentiation of the myeloid lineage. Consistent with the latter hypothesis, analysis of the flow-sorted KLSF fraction indicated that KLSFs contained myeloid lineage cells showing less differentiation activity than GMPs [Supplementary Fig. S4]. Increases in myeloid cells were also observed in conditional AML1-KO mice [Growney et al. 2005] and in hypomorphic PU.1 mice [Rosenbauer et al. 2004]. Interestingly, KLSF cells were substantially elevated in mice with acute myeloid leukemia after transplantation of MOZ–TIF2-introduced bone marrow cells [Deguchi et al. 2003; Huntly et al. 2004]. In addition, monocytic blasts are often elevated in human leukemia patients who exhibit rearrangement of MOZ. Taken together with previous results [Deguchi et al. 2003; Huntly et al. 2004], the present study suggests that MOZ fusion modulates normal MOZ function in the pathogenesis of leukemia, and that the KLSF fraction plays a role in the development of acute myeloid leukemia. Recent studies have indicated that mice carrying hypomorphic PU.1 alleles in which PU.1 expression is decreased to 20% of wild-type levels develop acute myeloid leukemia [Rosenbauer et al. 2004]. The interaction between MOZ and
PU.1 suggests that MOZ fusion may affect function of PU.1 in the pathogenesis of leukemia.

Materials and methods

Generation of MOZ-deficient mice

MOZ genomic clones were isolated from a mouse genomic BAC library by PCR screening. We constructed a targeting vector containing an MOZ genomic fragment interrupted in exon 2, which contains the first methionine ATG, using a neomycin resistance gene (neo) cassette with a flanking diphtheria toxin A fragment gene [DT-A] cassette. The construct was electroporated into ES cells, and G418-resistant clones were selected by Southern blot analysis using 5’ and 3’ external probes. Nine clones containing the MOZ-disrupted allele were obtained. Two independent clones were injected into day 3.5 C57BL/6 JcL embryos, which were subsequently transferred to CD-1 recipient females. All animals were maintained under specific pathogen-free, temperature-controlled conditions throughout this study, in accordance with Institutional Guidelines. Written approval for all animal experiments was obtained from the local Animal Experiments Committee of the National Cancer Center Research Institute.

Histological procedures

Embryos were isolated at E14.5 and fixed in 4% paraformaldehyde in phosphate-buffered saline (PBS) for 48 h. Embryos were routinely processed for embedding in paraffin and 3-µm sections were cut for hematoxylin and eosin staining.

In vitro hematopoietic colony assays

Fetal liver cells from E14.5 embryos were dispersed into single-cell suspensions and cultured in 1% methylcellulose in Iscove’s modified Dulbecco’s medium (IMDM) containing 15% fetal bovine serum (FBS), 1% bovine serum albumin (BSA), 10 µg/mL rh insulin, 200 µg/mL human transferrin, 100 µM 2-mercaptoethanol, 2 mM L-glutamine, 50 ng/mL rm SCF, 10 ng/mL rm IL-3, 10 ng/mL rh IL-6, and 3 U/mL Erythropoietin (METHOCULT GF M3434) (Stemcell Technology, Inc.). Cultures were maintained at 37°C under humidified conditions with 5% CO₂. Colonies containing >50 cells were counted on day 12, and myeloid CFUs, erythroid burst forming units (BFU-E), and CFU-Mix were defined based on morphology.

Immunofluorescent staining and flow cytometric analysis

Fetal liver cells were dissected from E12.5 and E14.5 embryos, and drawn through 21- and 25-gauge needles to generate a single-cell suspension. Erythrocytes were lysed in ammonium chloride potassium buffer. One-million cells were preincubated with 2.4G2 in order to prevent nonspecific binding of mAb via FcR interactions, and were then incubated on ice for 90 min with 2.4G2 in order to prevent nonspecific binding of mAb via FcR interactions, and were then incubated on ice for 90 min with 2.4G2. Cells were stained with anti-Ly5.1 and Ly5.2 antibody, and were analyzed at a dose of 9.5 Gy. Peripheral blood cells of recipient mice were stained with anti-Ly5.1 and Ly5.2 antibody, and were analyzed for populations of Ly5.1⁻ cells and Ly5.2⁻ cells at 2, 4, 8, and 12 wk after transplantation. At 12 wk after transplantation, peripheral blood cells, thymocytes, splenocytes, and bone marrow cells from recipient mice were also analyzed. C57BL/6-Ly5.1 mice were kindly provided by Dr. Hiromitsu Nakauchi (Tokyo University, Tokyo, Japan).

Competitive repopulation assay

Competitive repopulation assay was performed using the Ly5 congenic mouse system. Fetal liver cells [2 × 10⁵, 6 × 10⁵, or 18 × 10⁵ cells] from test Ly5.2 mice were mixed with 2 × 10⁵ cells of fetal liver competitor cells [C57BL/6-Ly5.1] and were transplanted into C57BL/6-Ly5.1/Ly5.2 recipient mice irradiated at a dose of 9.5 Gy. Peripheral blood cells of recipient mice were stained with anti-Ly5.1 and Ly5.2 antibody, and were analyzed for populations of Ly5.1⁻ cells and Ly5.2⁻ cells at 2, 4, 8, and 12 wk after transplantation. At 12 wk after transplantation, peripheral blood cells, thymocytes, splenocytes, and bone marrow cells from recipient mice were also analyzed. C57BL/6-Ly5.1 mice were kindly provided by Dr. Hiromitsu Nakauchi (Tokyo University, Tokyo, Japan).

Microarray analysis and RT-PCR

For gene expression analysis, total RNA was isolated using Iso- gen reagent [Nippon Gene] from livers of two each of E12.5 MOZ⁻/−, MOZ⁺/−, and MOZ⁻/− embryos, and were purified with an RNeasy MinElute cleanup kit (Qiagen). The integrity of total RNA was confirmed using LabChip RNA 6000 Nano chips and a 2100 Bioanalyzer [Agilent Technologies]. For gene expression profiling, a GeneChip Mouse Genome 430 2.0 oligonucleotide microarray [Affymetrix], which contained 45,037 probe sets, was used according to the manufacturer’s instructions.

The expression value (Signal) of each gene was calculated and normalized using GeneChip Operating Software version 1.2 [Affymetrix]. The change value (Signal Log Ratio) and change call [Increase, Marginal Increase, No Change, Marginal Decrease, or Decrease] for each gene was calculated by Comparison Analysis of the software. To identify genes that were significantly affected by MOZ knockout, we selected genes that showed a change call of Increase and a Signal Log Ratio of more than 1 (more than twofold increase) or genes that showed a change call

Katsumoto et al.
of Decrease and a Signal Log Ratio of less than -1 (more than twofold decrease) in all four comparisons between MOZ+/− and MOZ−/− fetal livers.

Total RNA was isolated using Isogen LS reagent (Nippon Gene) from fetal liver Lin−/Sca-1− cells of two E14.5 C57BL/6 and MOZ−/− embryos. Reverse transcription of total RNA isolated from E12.5 fetal liver and E14.5 Lin−/Sca-1− cells was performed using SuperScript III [Invitrogen Life Technologies]. Threefold serial dilutions of template cDNA were obtained as described previously (Kimura et al. 2001). Primers and conditions used in the RT–PCR study were as follows: for HoxA9, 5′-ACAATGCCAGAATCGACGCC-3′ and 5′-CATTTCCTCTGCAGCCACAGG-5′, with cycles at 95°C for 30 sec, 57°C for 30 sec, and 72°C for 30 sec; for MOZ, 5′-TGATCTGCGTCTGGAAGGTGGAC-3′ and 5′-CCGGTTCCTGCTGCTTTTGTA-5′, with cycles at 95°C for 1 min, 72°C for 1 min; for c-Kit, 5′-ACAGGAGCAGAGGACGTGACTAGG-3′ and 5′-CGAGACCAAGTCGGAACAATG-5′, with cycles at 95°C for 1 min, 60°C for 1 min, 72°C for 1 min; for c-KIT, 5′-ACAGGAGCAGAGGACGTGACTAGG-3′ and 5′-CGAGACCAAGTCGGAACAATG-5′, with cycles at 95°C for 1 min, 60°C for 1 min, and 72°C for 1 min; and for β-actin, 5′-GAGAGGGAAATCGTGCCTGTGGAGAGCAGCTGAATG-3′ and 5′-ATACCTCTCTGGAGGAGCTGTGGAC-5′, with cycles at 95°C for 30 sec, 57°C for 30 sec, and 72°C for 1 min.

Immunoprecipitation, immunoblotting, and antibodies

For immunoprecipitation, cell lysates were prepared in lysis buffer (250 mM NaCl, 20 mM sodium phosphate at pH 7.0, 30 mM sodium pyrophosphate, 10 mM NaF, 0.1% NP-40, 5 mM DTT, 1 mM phenylmethyl sulfonyl fluoride [PMSF] supplemented with complete protease inhibitor (Roche). After removal of cell debris by ultracentrifugation at 4°C and 40,000 rpm for 30 min, the supernatant was incubated with anti-Flag antibody-conjugated agarose beads (Sigma) and slowly rotated at 4°C for 8 h. Beads were then extensively washed with lysis buffer. Precipitated proteins were eluted from the beads with 200 μL of lysis buffer containing Flag peptide at a final concentration of 2 mg/mL. The eluate was concentrated using centrifugation at 4°C for 8–10 h. Beads were then extensively washed with lysis buffer. Precipitated proteins were eluted from the beads with 200 μL of lysis buffer containing Flag peptide at a final concentration of 2 mg/mL. The eluate was concentrated using centrifugation at 4°C for 8–10 h. Beads were then extensively washed with lysis buffer. Precipitated proteins were eluted from the beads with 200 μL of lysis buffer containing Flag peptide at a final concentration of 2 mg/mL. The eluate was concentrated using centrifugation at 4°C for 8–10 h.

Luciferase assay

SaOS2 cells or 293T cells were transfected using the calcium phosphate precipitation method in 24-well plates, and luciferase activity was assayed after 24 h with a luminometer, Lumat LB9507 (Berthold), according to the manufacturer’s protocol [Promega]. Results of reporter assays represent the mean values for relative luciferase activity generated from three independent experiments normalized against the activity of the enzyme from pRL-CMV as an internal control.

Acknowledgments

We thank Dr. T. Okada [Kyoto Prefectural University], Dr. H. Yoshida, and Dr. M Ohki [National Cancer Center Research Institute] for discussion, and Ms. Kazumi Kimura, Ms. Noriko Aikawa, and Ms. Sachiyoh Mitani for technical assistance. This work was supported in part by Grants-in-Aid for Scientific Research from the Ministry of Health, Labour, and Welfare and from the Ministry of Education, Culture, Sports, Science, and Technology, and by the Program for Promotion of Fundamental Studies from the National Institute of Biomedical Innovation of Japan.
