Abstract. Sugar apple fruit are widely appreciated because of their flavor and functional qualities. However, the final value of the fruit varies according to its physical, physicochemical, and organoleptic qualities. The production and attributes that make up the quality of fruit can be influenced by climatic seasonality in both seasons (dry and wet). Therefore, this work aimed to evaluate whether the production and quality of fruit production of different size classes of A. squamosa L. in two seasons are affected by climatic seasonality. The experiment consisted of a randomized block design, with 4 blocks and 10 plants per block. The variables evaluated were number of fruit per hectare, production, and yield. The postharvest evaluation of the fruit consisted of a completely randomized experimental design, in a 3 × 2 factorial scheme, which referred to the three sizes and two seasons, and evaluated fruit length and diameter; firmness; fruit, bark, and seed weight; number of seeds; soluble solids; hydrogen ionic potential (pH); titratable acidity (TA); and ratio. The 2014 season had larger fruit in relation to those of the 2015 season; conversely, it showed a lower number of fruit per plant, production, and yield, besides inferior organoleptic quality. Fruit of size class 2 stood out in the 2014 season because of their physical characteristics. However, they had inferior organoleptic quality when compared with fruit of the same size collected during the 2015 season. Fruit of size class 3 (28.1 cm) had greater firmness, providing longer durability and shelf life.

Sugar apple (Annona squamosa L.) has been the subject of several studies in recent years as a result of its nutritional, medicinal, and pharmaceutical properties. The most important study fields are agriculture, botany, pharmacology, and chemicals (Cavalcante et al., 2011; Costa et al., 2015). The species is of great commercial relevance because of its medicinal and nutritional properties, such as vitamins A, B, C, E, and K1; antioxidants; polyunsaturated fatty acids; essential minerals; and its pleasant aroma and taste (Liu et al., 2013, 2015). The fruit is consumed mainly in natura; however, it can also be used in the production of juices, sweets, sorbets, liqueurs, and pharmaceutical products (Araújo et al., 2008).

The value of the sugar apple fruit depends on its quality and size. Thus, larger fruit with good visible aspects have a greater market value (Souza et al., 2012). According to Chitarra and Chitarra (2005), the attributes responsible for appearance, flavor, aroma, texture, nutritional value and safety, size, weight, color, firmness, sweetness, acidity, physical and physiologic defects, among others, are part of fruit quality. However, the quality of these attributes also depends on the genetic variability, cultural practices, climatic conditions of the cultivation site, and the incidence of pests and diseases (Araújo et al., 2008).

Depending on the seasonal variations of each biome, the crop may have an early or late cycle. The climate can also affect viability of flower set and the quantity and quality of fruit. George and Nissen (1988) observed that fruiting patterns in Nambour, Queensland, Australia, had significant seasonal variations between and within orchards in the same region. Therefore, this work aimed to evaluate whether the production and quality of fruit production of different size classes of A. squamosa L. in two seasons are affected by the climatic seasonality.

Material and Methods

Description of the area. The experiment was carried out in a commercial orchard belonging to Paricarana Farm, located in the municipality of Cantá, state of Roraima, Brazil (lat. 2°43 52.5°N, long. 60°38 12.1°W). The climate of the region is considered to be Am (tropical humid) according to the Koppen classification, with an average temperature of 27.4 °C and an altitude of 90 m (Alvares et al., 2013), a minimum annual rainfall of 944.7 mm, totaling 1678.6 mm/year, and relative air humidity of 70% (Araújo et al., 2001).

Plant material. The experiment was performed in an A. squamosa L. orchard and was based on seasonality of two different seasons: 2014 (rainy season) and 2015 (dry season). The experiment included 40 6-year-old plants produced from seedlings planted at a 4 × 4 m spacing, and was conducted in vase form.

Plants were pruned manually using pruning shears. Branches were cut to 40 cm in length and were pruned manually from the apex to the base to induce a new season. The first production pruning was carried out in Feb. 2014; the second production pruning was performed in Sept. 2014, shortly after the first cycle’s harvest.

Weather and soil conditions. The maximum, average, and minimum temperatures, rainfall, and relative humidity were measured throughout the experiment (Fig. 1). The vapor pressure deficit (VPD) was calculated using climatic data (Fig. 2).
The soil of the experimental area was classified as Dystrocohesive Yellow Latosol (Santos et al., 2018). The soil chemical attributes are shown in Table 1.

The irrigation system was composed of a conventional sprinkler with a flow rate of 2450 L·h⁻¹, twice a day, for 30 min. However, irrigation was not performed on rainy days.

Experimental design. The experiment consisted of a completely randomized block design with 4 blocks and 10 plants per block. Conversely, the experimental design adopted to evaluate the quality of fruit production was completely randomized, in a 2 × 3 factorial scheme, with three replications and four fruit per replication. The factors consisted of the two seasons (2014 and 2015) and three different size classes, which were based on the equatorial diameter of the fruit (1 = small ≤ 6 cm; 2 = medium, 6.1 to 8.0 cm; and 3 = large, ≥ 8.1 cm) (Fig. 3).

The following variables were evaluated: number of fruit per hectare; production (measured in kilograms per plant); yield (measured in megagrams per hectare); fruit diameter and length (measured in millimeters); fruit, bark, pulp, and seed weight (measured in grams); firmness (measured in Newtons); soluble solids (measured in degrees Brix), total acidity (measured in grams of citric acid/100 g pulp); pulp yield; and ratio.

Statistical analysis. All data collected were subject to analysis of variance. The differences between treatments were compared using Tukey’s test, and the probability level for the determination of significance was $P < 0.05$. Also, the fruit quality of the different fruit sizes was evaluated by principal component analysis to determine the fruit size with the best qualitative traits in the different seasons. Analyses were performed using the statistical software Sisvar and InfoStat (di Rienzo et al., 2016; Ferreira, 2014).

Results

Response to seasonal variation in productive performance. The variables number of fruit per hectare, production, and yield showed significant differences by the F test ($P < 0.01$) in function of seasonality. The 2015 season was superior in relation to the 2014 season, showing the best means for all variables (Table 2).

When comparing the results for all the variables in both seasons, values recorded in the 2015 season were more than twice as much as those recorded for the 2014 season as a result of protogynous dichogamy and the action of pollinating beetles. These factors influence crop production, either individually or combined with climatic factors.

The 2015 season had better climatic conditions, with constant rainfall and higher temperatures, leading to greater production, yield, and number of fruit per plant (Fig. 1). When comparing the first three consecutive months after the production pruning—a crucial moment in which floral development and the action of VPD is one of the climatic factors that most influence A. squamosa L. flowers (George and Nissen, 1988). When comparing the first three consecutive months after the production pruning—a crucial moment in which floral development and the action of...
pollinating beetles occur—between the 2014 and 2015 seasons, the VPD of the former had greater values than the latter (Fig. 2), especially during the second month after production pruning. This period is characterized by intense flower development followed by anthesis.

Thus, the greater the VDP values, the greater is the probability of occurring stigma desiccation before floral dehiscence, given that the flower exhibits protogynous dichogamy. Thus, flower abscission occurs with an increase in VDP.

In our experiment, flowers were pollinated naturally by insects of the family Nitidulidae. Therefore, the population of pollinators in the 2014 season might have been reduced as a result of low rainfall and constant high temperatures in February, March, and April, resulting in an unsuitable environment for both the normal development of the flowers and the activity of the beetles.

Despite the low yield obtained during the 2014 season, the observed mean yield in our experiment was greater than those reported in the literature: 3.2 Mg·ha⁻¹ (Kavati, 1997), 6.05 Mg·ha⁻¹ (Kavati and Piza, 1997), 5.3 Mg·ha⁻¹ (Costa et al., 2002), and 6.98 Mg·ha⁻¹ (Patel et al., 2010) without humic substances; and 7.61 Mg·ha⁻¹ with humic substances (Cunha et al., 2015).

Physical, chemical, and physical-chemical characteristics of fruit. Regarding the quality of fruit production, a significant effect was reported at the 1% probability level ($P < 0.01$) in the seasons × fruit size interaction for all variables, except for fruit firmness, which exhibited a significant effect only for the factor fruit size at the 5% probability level by the F test.

The length and diameter of the fruit showed no differences between the size classes for the 2014 season. Moreover, the means of the 2014 season were greater than those of the 2015 season. For bark firmness, fruit of 8 cm or larger had the highest mean values; however, fruit 6.1 to 8.0 cm in size did not differ statistically for this variable. Fruit fresh weight in the 2014 season had greater means in the different sizes, diverging statistically from the 2015 season. During the 2014 season, fruit of size class 6.1 to 8.0 cm differed statistically only from those of size class 6 cm or smaller. For the 2015 season, the size class ≥8 cm was superior to the others, showing a statistical difference in fruit weight (Table 3).

Fruit production per plant had a significant difference between seasons, resulting in 42.75 and 104.25 fruit/plant in the 2014 and 2015 seasons, respectively. Moreover, the production of the 2015 season had no fruit of class 1 (small), even though the result of production per plant was much greater than that of the previous season.

Fruits of size class ≥8 cm had greater bark firmness (3.55 N) than the other fruit. These results show that fruit of size class 3 may have a longer shelf life in relation to fruit of sizes classes ≤6 cm and 6.1 to 8 cm (1.21 and 1.88 N, respectively) (Table 3). Sugar apple fruit have a short postharvest life and are highly perishable.

The lower fruit rate of plants of the 2014 season resulted in better fruit development resulting from less competition for photo-assimilates, leading to fruit with greater values for length, diameter, and fruit weight (Table 3). This result proves the need for thinning to obtain fruit with a greater final weight.

The variables bark weight, seed weight, and number of seeds were greater for fruit of size class ≤6 cm in the 2014 season when compared with those of the 2015 season. The mean seed weight and the number of seeds in fruit of size class ≥8 cm were greater—15.98 and 46.25 g, respectively—differing statistically from fruit of size classes ≤6 cm and 6.1 to 8 cm. No differences were observed in fruit pulp yield between the 2014 and 2015 seasons and size classes (Table 4).

TA, pH, and ratio did not differ among fruit size classes in either season. The variable soluble solids did not differ among fruit sizes; however, it exhibited statistical differences within the 2015 season. In this same season, fruit of size class ≥8.1 cm had greater degrees Brix than those of the class 6.1 to 8.0 cm. When comparing the TA of the two seasons, only the variable ratio had no significant differences for the size class ≥8.1 cm. The other variables were greater in the 2015 season (Table 5).

$pH$ measures the degree of acidity of the fruit pulp and can be an indicator of organoleptic quality when associated with other traits, such as soluble solids content. Results showed mean $pH$ values ranging from 5.03 to 5.7, indicating the low acidity of sugar apple fruit. Similarly, Silva et al. (2007) reported $pH$ values ranging from 5.4 to 5.8, and Hernández et al. (2011) observed $pH$ values from 5.8 to 6.0, at different harvest times.

Results of TA were within those established as a standard for the species. Gouveia et al., (2007) verified values close to those observed in our experiment, with 0.42 g citric acid/100 g pulp. Moreover, Dantas (2007) detected values of TA ranging from 0.35 to 0.37 g citric acid/100 g pulp. TA acidity is a crucial trait because it is related to appreciation of the fruit in terms of taste and aroma, and its value is used in the norms that establish the quality of the product (Araújo et al., 2008; Chitarra and Chitarra, 2005).

The variable ratio is known as one of the forms for obtaining fruit flavor because it expresses more representative values in the individual evaluation of sugars or acidity (Dantas, 2007). Greater ratio values indicate a more significant presence of the sugar contents than the acid content of the fruit, indicating the sweet predominance of the fruit. Souza (2006) found values ranging from 86.95 to 97.83 in mature fruit.

Principal component analysis of the different seasons (Fig. 4) demonstrated that fruit size presented the best attributes together. Principal component 1 accounted for 60% of the data, whereas principal component 2 accounted for 17.5%. Therefore, the ranking explained 77.5% of the size variance in the variables, in the different seasons. A greater correlation was detected for firmness, degrees Brix, and $pH$ for fruit of size class ≥8.1 cm, as in the univariate analysis. Conversely, fruit of size class 6.1 to 8 cm had a greater relation with fresh weight, yield, and TA. The 2015 season had no fruit of the smaller size and, once again, larger fruit had greater correlations with most variables. The analysis of the ranking allowed separating the groups to predict possible future results consistent with the correlations shown in this study.

Discussion

Factors that influence productive performance. The occurrence of low rainfall during the first 3 months after production pruning in the 2014 season interfered with plant development. A suitable water blade
for the plant to complete the vegetative and reproductive stages is crucial during this period. Adequate water supply to the plant is related to maintenance of tissue turgor, which is essential for photosynthesis, flowering, and fruiting (Floss, 2008).

Table 2. Number of fruit per hectare, production, and yield for the 2014 and 2015 seasons of sugar apple, under the savanna conditions, in Roraima.

| Season | No. of fruit/ha | Production (kg/plant) | Yield (Mg·ha⁻¹) |
|--------|----------------|-----------------------|-----------------|
| 2014   | 26.72 b        | 8.69 b                | 5.43 b          |
| 2015   | 65.16 a        | 18.92 a               | 11.82 a         |
| CV     | 16.71          | 15.79                 | 15.79           |

Means followed by the same lowercase letter in the column do not differ from each other by Tukey’s test at P < 0.05.

Table 3. Length, diameter, firmness, and weight of fruit in the different size classes.

| Season | Length (mm) | Diam (mm) | Firmness (N) | Fruit weight (g) |
|--------|-------------|-----------|--------------|------------------|
|        | Size (cm)   | Size (cm) |              |                  |
|        | ≤6       | 6.1–8.0   | ≥8.1       | ≤6       | 6.1–8.0   | ≥8.1       | Mean |
|        |          |           |            |          |           |            |      |
| 2014   | 75.79 A   | 79.63 aA  | 76.3 aA    | 77.24    | 82.45 A   | 85.61 aA  | 86.36 aA |
| 2015   | —         | 65.42 bA  | 68.83 aA   | —        | —         | 65.53 bA  | 71.36 bA |
| Mean   | 75.79     | 72.54     | 72.56      | —        | 82.45     | 75.57     | 78.86   |
| CV (%) | 7.56      | 6.79      |            |          | 10.17     |            |         |

Means followed by the same lowercase letters in the columns and uppercase letters in the rows do not differ from each other by Tukey’s test at the 5% probability level.

Table 4. Bark weight, seed weight, seed number, and pulp yield of fruit of different size classes.

| Season | Bark weight (g) | Seed weight (g) | Yield (%) |
|--------|-----------------|-----------------|-----------|
|        | Size (cm)       | Size (cm)       |           |
|        | ≤6       | 6.1–8.0   | ≥8.1       | ≤6       | 6.1–8.0   | ≥8.1       | Mean |
|        |          |           |            |          |           |            |      |
| 2014   | 115.85 A   | 137.27 aA  | 127.40 aA  | 126.84   | 17.82 A   | 15.26 aA  | 15.71 aA |
| 2015   | —         | 78.45 bA  | 99.72 aA   | —        | —         | 11.59 bB  | 13.78   |
| Mean   | 57.92     | 107.86    | 113.57     | —        | 233.88    | 212.61    | 232.58   |
| CV (%) | 26.77     | 12.49     |            |          | 8.91      | 13.43     | 15.84    |

Means followed by the same lowercase letters in the columns and uppercase letters in the rows do not differ from each other by Tukey’s test at the 5% probability level.

A. squamosa L. has hermaphrodite flowers with protogynous dichogamy (Thakur and Singh, 1965). Flowers are pollinated by...
insects of the family Nitidulidae, which are pollinator agents of the species. However, these beetles require favorable environmental conditions for efficient pollination. Artificial pollination is also possible, and this technique is widely used in commercial orchards for providing regular fruit with uniform diameter resulting from the complete pollination of all ovaries. Nevertheless, for good production in both pollination forms, a suitable environment is required for the development of the flower. This process is strongly influenced by climatic factors.

George and Nissen (1989) observed that soil water stress reduced the fruit yield of the hybrid cultivar African Pride (Annona cherimolía × Annona squamosa) significantly under high-temperature conditions. They also reported that the greater the VPD, the greater the reduction in the number of fruit of both naturally and artificially pollinated plants. In addition, they reported a significant reduction in the number of flowers that reached anthesis as a result of floral abscission and stigma desiccation caused by high VPD (3.0 kPa) at the flowering stage.

Kishore et al. (2012) analyzed the visitation frequency of the pollinating agents Carpophilus domidiatus and Carpophilus hemipterus of the family Nitidulidae in A. squamosa L. flowers and detected seasonal and climatic variations. According to the authors, the visitation frequency of both species in September was significantly greater in relation to April. Although our study did not count the beetle population, the periods when the flowers were ready for anthesis were similar.

Effect of quality of fruit. The higher value of fruit weight obtained in the 2014 season was a result of low fruit production. This phenomenon is related to the redistribution of photoassimilates in the plant. Souza (2006) studied the number of fruit per plant in sugar apple and verified that, based on economic analysis, the best yield is obtained when the fruit load occurs in ≈30% of the branches.

Although the 2015 season had a lower mean of fruit per plant than the 2014 season, the mean values for this variable were within those observed by Costa et al. (2002), Junqueira et al. (2003), Nietsche et al. (2008), and da Silva et al. (2002).

According to Goiti et al. (2010), the loss of firmness is one of the most relevant factors in fruit quality depreciation postharvest. Chittara and Chittara (2005) state that a steady reduction in firmness begins with normal fruit maturation, which leads to loss of cell turgor and reduction in fruit size by the action of hydrolytic enzymes and nonenzymatic mechanisms. Therefore, fruit of size class ≥8 cm have better market characteristics, which allow better fruit transportation and a longer commercialization period than the other size classes. This result is a result of the greater firmness of the fruit, which provides a longer postharvest life.

The values found in our study demonstrate the relationship between fruit weight, bark weight, seed weight, and fruit size. Silva et al. (2007) reported a much greater variation in bark weight and seed weight, which ranged from 167.64 to 193.76 g and from 25.82 to 27.79 g, respectively. These results are related closely to pulp yield, with expressive results for the different seasons in the three size classes, and the means were similar to those found by Silva et al. (2007) (40.08 g).

The values for soluble solids content were consistent with those reported in the literature. Pereira et al. (2010) obtained soluble solids content between 19.32 and 29 °Brix; Silva et al. (2007) detected soluble solids content between 25.10 and 27.71 °Brix; and Pereira et al. (2003) reported soluble solids content between 25.48 and 27.52 °Brix.

Soluble solids content can be influenced by several factors, such as plant genetics, chemical and organic fertilization, irrigation, and temperature (Junqueira and Junqueira, 2014). In general, soluble solids content of the fruit produced during the two seasons (2014 and 2015) had high means, showing the quality of fruit produced in the savanna environment, in the state of Roraima. These
results are confirmed by comparing the contents of soluble solids with the low TA, expressing the sweetness of the fruit.

**Conclusion**

Seasonality affects yield and fruit quality of *A. squamosa* L. The dry season is more detrimental to production. Fruit of size class ≥8 cm are more desirable in both seasons because of their greater firmness, which provides longer durability and longer postharvest shelf life.
