\(^1\)University of Pittsburgh Cancer Institute, W 1041 Biomedical Science Tower, 200 Lothrop Street, Pittsburgh, PA 15213-2582, USA; \(^2\)Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213, USA; \(^3\)Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213, USA; \(^4\)Department of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213, USA

A subset of circulating T cells (CD8\(^+\)CD45RO\(^-\)CD27\(^-\)) with a naive phenotype, but mediating effector function, is considered to play an important role in host antitumour defence. To investigate the attributes of these effector T cells in patients with squamous cell carcinoma (SCC) of the head and neck cancer, venous blood was obtained from 39 individuals with cancer and 45 normal controls (NC). Peripheral blood mononuclear cells were isolated, stained with labelled monoclonal antibodies specific for CD8, CD45RO, CD45RA, CD62L, CD27, TCR-\(\zeta\) as well as isotype controls and examined by multicolour flow cytometry. Annexin V binding to CD8\(^+\) T cells and PMA/ionomycin-induced IFN-\(\gamma\) expression were also evaluated in patients and NC. The proportions of CD45RA\(^-\)CD45RO\(^+\) (naïve) and CD45RA\(^+\)CD45RO\(^-\) (memory) cells were found to be comparable within the CD8\(^+\) T-cell subset. However, relative to NC, the frequency of effector CD8\(^+\)CD45RO\(^-\)CD27\(^-\) cells was strikingly increased in all SCC patients regardless of the disease status (P < 0.0003). The proportion of these cells was found to increase with age in both patients and NC. In NC, stimulated IFN-\(\gamma\) expression was largely restricted to CD8\(^+\)CD45RO\(^-\)CD27\(^-\) cells, while in patients CD8\(^+\)CD45RO\(^-\)CD27\(^-\) expressed IFN-\(\gamma\) after ex vivo stimulation. Expression of the TCR-associated \(\zeta\) chain was decreased or absent in freshly isolated CD8\(^+\)CD45RO\(^-\)CD27\(^-\) T cells in patients (P < 0.0001). Annexin V was found to bind to a higher proportion of circulating CD8\(^+\) T cells in patients than NC (P < 0.0006), and significantly more Annexin V\(^+\) T cells were present in the effector (P < 0.0059) than the naïve subset within the CD8\(^+\)CD45RO\(^-\) compartment. The data indicate that the expanded CD8\(^+\)CD45RO\(^-\)CD27\(^-\) T cells, which contain precursors of IFN-\(\gamma\)-producing T cells, are \(\zeta\)-negative and sensitive to apoptosis in the circulation of patients with HNC.

British Journal of Cancer (2003) 88, 223 – 230. doi:10.1038/sj.bjc.6600694 www.bjcancer.com © 2003 Cancer Research UK

Keywords: cancer; \(\zeta\) chain; apoptosis; naïve T cells; memory T cells

Recent data from our laboratory and other laboratories indicate that tumour-infiltrating and peripheral T cells of many patients with cancer are primed for apoptosis (Rabinovich et al., 1998; Reichert et al., 1998b; Lee et al., 1999; Reichert et al., 2002; Whiteside, 2002), and that the death of effector T cells could be responsible for inadequate antitumour functions. We previously reported that relative to healthy normal controls (NC), patients with cancer have increased proportions of circulating T cells that bind Annexin V (Dvoracki et al., 2001; Hoffmann et al., 2002). This observation suggests that a higher rate of lymphocyte turnover is associated with cancer. Furthermore, we recently observed that CD8\(^+\) T cells are preferentially primed for apoptosis, suggesting a more rapid turnover of CD3\(^+\)CD8\(^+\) than CD3\(^+\)CD4\(^+\) T cells (Hoffmann et al., 2002). CD8\(^+\) T cells are functionally heterogeneous, and several subsets of CD8\(^+\) T cells are known to contribute to antitumour immune responses. In addition to an effector T-cell subset, both naïve and memory CD8\(^+\) T cells exist within the peripheral CD8\(^+\) T-cell pool (Hamann et al., 1997; Young et al., 1997; Sallusto et al., 1999; Baares et al., 2000).

Human naïve and memory T cells can be identified by the reciprocal expression of the CD45RA or CD45RO isoforms (Young et al., 1997). More recent reports indicate that within the CD8\(^+\)CD45RA\(^-\)(CD45RO\(^+\)) compartment of naïve cells, a subset of effector T cells, which lack the CD27 receptor as well as the lymph node homing receptors CD62L and CCR7, can be identified (Hamann et al., 1997; Sallusto et al., 1999). These effector-type CD8\(^+\)CD45RO\(^-\)CD27\(^-\) T cells are thought to be derived from the CD27\(^+\) precursors in response to antigenic stimulation. They are characterised by a shorter telomeric restriction fragment (TRF) length compared with unprimed cells, express cytolytic activity and abundantly produce IFN-\(\gamma\) and TNF-\(\alpha\) (Baares et al., 2000). It has been suggested that this subset of CD8\(^+\) T cells plays an important role in host antitumour defence.

To further evaluate the role of this effector CD8\(^+\) T-cell subset subpopulation in the control of cancer progression, we investigated the frequency and functional characteristics of effector CD8\(^+\) T cells in a cohort of patients with squamous cell carcinoma (SCC) of the head and neck. We find that, in contrast to normal controls, the frequency of CD8\(^+\)CD45RO\(^-\)CD27\(^-\) T cells is significantly increased in the circulation of HNC patients. However, these CD8\(^+\) effector cells have no or low \(\zeta\) expression and are thus unable to signal. They also contain increased proportions of Annexin V-binding cells. The data indicate that the CD8\(^+\)CD45RO\(^-\)CD27\(^-\) effector T-cell subset appears to be dysfunctional and destined for apoptosis in patients with cancer.
MATERIALS AND METHODS

Patients and controls

Venous blood samples (10 – 30 ml) were obtained from patients with SCC of the head and neck, who were seen between April 2001 and March 2002 at the Outpatient Otalaryngology Clinic at the University of Pittsburgh Cancer Institute (UPCI). The Institutional Review Board has approved the protocol for collection of patient blood samples. Normal healthy donors (NC) were recruited among the laboratory personnel and other volunteers. A written informed consent was obtained from all individuals participating in this study. Two groups of patients and NC were studied. In total, 28 patients and 38 NC were included in studies of CD8+ T-cell subset and analysis of CD3 z-chain expression. An additional 11 patients and seven NC were included in the evaluation of Annexin V binding to the CD8+ effector T cells.

The characteristics of all the patients included in this study are shown in Table 1. The cohort of 39 patients included 33 men and six women with a mean age of 61 years (range 36 – 82). The group of normal volunteers comprised 11 males and 34 females with a mean age of 51 years (24 – 88). All patients had histologically proven SCC of the head and neck, with 11 tumours originating in the larynx, 12 in the oral cavity, 10 in the pharynx, two in the hypopharynx and three at miscellaneous sites. One tumour was of unknown origin. The histological grades of the tumours were well-differentiated (n = 29), poorly differentiated (n = 7) and undifferentiated (n = 1). At the time of blood draw, 25 patients showed no evidence of disease, whereas 14 patients were studied either before surgery (n = 12) or had newly diagnosed lymph node metastases (n = 2) and were classified as having active disease.

Cell isolation

Peripheral blood mononuclear cells (PBMC) were isolated by Ficoll–Hypaque density gradient centrifugation, recovered from the gradient interface, washed in Dulbecco’s phosphate-buffered saline (D-PBS; Life Technologies, Inc., Grand Island, NY, USA), counted in a trypan blue dye, and either stained for flow cytometry or used for ex vivo experiments. In each experiment, PBMC obtained from patients were evaluated together with the cells obtained from at least one normal control.

Cell activation

PBMC obtained from patients or NC were suspended in AIMV medium containing 10% (v/v) foetal bovine serum (FBS) (Life Technologies, Rockville, MD, USA) at a concentration of 2 × 10^6 cells ml⁻¹. Cells were stimulated with phorbol myristate acetate (PMA, Sigma Chemical Co., St Louis, MO, USA) at 0.5 ng ml⁻¹ and 0.5 μM ionomycin (Sigma) for 4, 12 or 18 h followed by 4 h incubation with 2 μM monensin (Sigma). Cells were then harvested for the determination of intracellular IFN-γ expression by flow cytometry. In other experiments, cells were stimulated with anti-CD3 mAb (10 μg ml⁻¹ Ortho Biotech, Bridgewater, NJ, USA), and incubated for 24 or 48 h in preparation for determinations of z-chain expression as described below.

Staining for flow cytometry

Aliquots of PBMC were stained for flow cytometry, using a panel of labelled monoclonal antibodies (mAbs) specific for cell surface-associated lymphocyte antigens as follows: anti-CD8-PE-Cy5, anti-CD45RO-EC0, anti-CD45RA-PE, anti-CD27-PE, anti-TCRζ-PE, anti-CD62L-FITC (all from Beckman Coulter, Miami, FL, USA) and anti-CD27-FITC (Caltag Laboratories, Burlingame, CA, USA). Isotype control Abs IgGl-FITC or IgGl-PE were purchased from Becton Dickinson (San Jose, CA, USA). FITC-conjugated Annexin V was purchased from PharMingen (San Diego, CA, USA) and anti-IFN-γ-FITC mAbs from Beckman Coulter (Miami, FL, USA). All antibodies were pretitrred on normal PBMC to determine optimal working concentrations. Freshly isolated PBMC were incubated with antibodies for 25 min on ice and washed twice in PBS, containing 4% (v/v) FBS and 0.1% (v/v) NaN₃. After staining, the cells were fixed with 0.5% paraformaldehyde in PBS prior to flow cytometry analysis. Staining for the TCR z-chain or IFN-γ in CD8+ T-cell subsets was performed as follows: first, the cells were surface stained, then fixed with 0.5% paraformaldehyde in PBS for 10 min at room temperature and washed once with PBS/FBS/NaNaN₃ and once with 0.1% saponin (Sigma, St Louis, MO, USA) in PBS containing 0.1% bovine serum albumin (BSA). The cells were then stained either with anti-TCRζ-PE, IFN-γ-PE or respective isotype control Abs for 30 min on ice in the dark. After the incubation period, the cells were washed once in saponin

solution and once in PBS/FBS/Na₂₃ before fixation with 0.5% paraformaldehyde in PBS.

To measure apoptosis, cells were surface stained and then washed once with PBS/FBS/Na₂₃ and once with Annexin-binding buffer (PharMingen), followed by incubation with FITC-conjugated Annexin V for 15 min at room temperature. Flow cytometry analysis was performed within 60 min on a Coulter Epics XL flow cytometer.

Statistical analysis

Linear regression analysis was conducted to assess the association between the phenotypically defined T-cell subsets and age. Estimated regression parameters were tested for homogeneity between patients and controls. If changes in the subsets were associated with age, differences between patients and controls were adjusted to reflect the imbalance in age between the two groups. If changes in subsets were independent of age, group differences were examined using the Wilcoxon test for two group differences (patients vs controls) or the Kruskal–Wallis test for three groups (patients with active disease vs controls). Differences with P-values of less than 0.05 were considered to be significant.

RESULTS

Distribution of CD8⁺ T-cell subsets in patients and NC

To study the heterogeneity of the peripheral CD8⁺ T-cell pool, we first evaluated the distribution of memory and naïve CD8⁺ T cells based on the surface expression of the CD45RA ('naïve') or CD45RO ('memory') isoforms in patients and NC. There was no significant difference in the proportion of CD45RA⁻ naïve CD8⁺ T cells between patients and controls (Figure 1). In NC, the median (range) for CD8⁺ CD45RA⁻ cells was 67% (24 – 80%) compared to 58% (24 – 83%) in patients. The CD8⁺ CD45RO⁺ memory cells represented 37% (20 – 75%) of circulating CD8⁺ cells in NC compared to 43% (17 – 75%) in patients (Figure 1). Although patients generally had fewer naïve CD8⁺ T cells and a higher proportion of memory CD8⁺ T cells than NC, these differences were not statistically significant (P = 0.1641 and 0.1550, respectively; Table 2).

We next examined the expression of CD27 molecules on the surface of peripheral blood CD8⁺ T cells. The proportion of CD8⁺CD45RO⁻ CD27⁺ cells was found to be significantly greater in patients than in NC (P = 0.0003; Table 2). The observed enrichment of CD27-negative cells within the CD8⁺CD45RO⁻ T-cell compartment in patients with HNC was of special interest, because the loss of CD27 expression has been reported to identify the effector phenotype (Hamann et al, 1997). As illustrated in Figure 2, CD27-negative T cells within the CD8⁺CD45RO⁻ population were expanded in the peripheral circulation of a patient, whereas considerably fewer of these cells were present in the circulation of an NC.

The cohorts of patients and NC were not age matched in our study, and it was possible that the observed difference in the proportion of CD8⁺CD45RO⁻ CD27⁺ cells between these cohorts was related to age. We therefore compared the patients and NC for changes in this subset of cells relative to age. As Figure 3 shows, the frequency of CD8⁺CD45RO⁻ CD27⁺ T cells increased with age in both patients and NC, but the percentage of these cells was significantly higher in patients compared to healthy normal individuals at all ages (P = 0.0003). We also examined the proportion of the reciprocal subset of naïve CD8⁺CD45RO⁺ CD27⁺ T cells in the same patients as well as NC, and found that it decreased with age and was significantly lower in patients than in controls (data not shown).

In addition to lacking CD27, the effector CD8⁺ T-cell subset was also reported to lack the lymph node homing receptor CD62L (Sallusto et al, 1998). In our cohort of NC, the expression of CD62L within the CD8⁺CD45RO⁻ CD27⁻ population was found to be very low with a mean ± s.d. of 4% ± 4 (Table 2). In agreement with the data reported in the literature, the CD27⁻ negative effector CD8⁺ T cells were also CD62L⁻ negative, and the proportion of these cells was elevated in the peripheral circulation of patients (50% ± 23) relative to NC, (25% ± 23). Representative data for one patient and an age-matched control are shown in Figure 4.

Within the memory CD8⁺CD45RO⁺ lymphocyte subset, the proportions of CD27-negative and CD27⁺ cells were found to be comparable in patients and NC (P = 0.38 and 0.39, respectively). The subset of CD8⁺CD45RO⁻CD27⁻ cells decreased with age in both patients and NC, while the reciprocal subset of CD8⁺CD45RO⁺CD27⁺ cells showed an increase with age in both groups (data not shown).
Molecular and Cellular Pathology

Signalling defects in CD8⁺ T cells in cancer
I Kuss et al

The percentage of effector CD8⁺CD45RO⁻CD27⁻ T cells was not found to be significantly different among patients with active disease or those who had no evidence of disease (NED). Likewise, patients with tumours at different sites or with tumours at distinct stages of differentiation had similar percentages of effector CD8⁺ T cells (data not shown).

Stimulated IFN-γ expression in CD8⁺ T-cell subsets

PBMC of patients and controls were cultured in the presence of PMA/ionomycin, stained for IFN-γ expression and examined by flow cytometry to determine the distribution of precursors of IFN-γ-producing cells among CD8⁺ T-cell subsets. Stimulated IFN-γ expression was found to be largely confined to CD27⁺ T cells in NC. However, in cancer patients, most of IFN-γ⁺ cells were CD27-negative following stimulation with PMA and ionomycin (Figure S5). While the proportions of IFN-γ⁺CD27⁺ T cells observed after ex vivo stimulation varied broadly in different patients, the precursors of IFN-γ⁺-producing cells were consistently found within the CD8⁺CD45RO⁻CD27⁺ compartment in patients and within the CD8⁺CD45RO⁺CD27⁺ subset in NC. Freshly isolated, noncultured subsets of CD8⁺CD45RO⁺ cells expressed no IFN-γ in patients or NC. Thus, the CD27-negative subset, which is expanded in patients, contains precursors of IFN-γ⁺-producing effector CD8⁺ T cells.

Expression of TCR ζ in CD8⁺ T-cell subsets

In order to verify the functional integrity of the TcR signalling pathway in CD8⁺ effector T cells in the peripheral circulation, we next determined the expression of TCR-associated ζ chain in CD8⁺CD45RO⁺CD27⁺ effector T cells in an additional 13 patients with SCC of the head and neck and 16 NC. We observed a significantly decreased mean fluorescence intensity (MFI) for ζ in patients relative to NC (Figures 6 and 7), with an MFI of 194 (range 15 – 782) compared to 760 (range 19 – 1385) in NC (P<0.0001). Thus, although this subset of effector cells was expanded in patients relative to NC, the near absence of ζ expression in effector T cells suggested that their signalling via TcR was compromised. Expression of the ζ chain was also found to be depressed in the naive and memory subsets of CD8⁺ T cells in these patients (data not shown). When PBMC of patients and controls were stimulated with anti-CD3 mAb, expression of ζ in CD8⁺ T cells was lower in patients than in NC at 24 and 48 h of culture (data not shown).

Annexin V binding to CD8⁺ effector T cells

We have previously reported that decreased ζ-chain expression could be related to programmed cell death of circulating CD3⁺ T cells in patients with cancer (Gastman et al, 1999; Dworacki et al, 2001; Hoffmann et al, 2002). To investigate whether apoptosis...
could account for the observed decreased \( z \) expression in CD8\(^+\)CD45RO\(^-\)CD27\(^-\) effector T cells, we studied Annexin V binding to subpopulations of naïve, effector and memory CD8\(^+\) T cells in a subset of our patients. In agreement with our previously reported data (Hoffmann et al., 2002), we observed that a greater proportion of CD8\(^+\) T cells bound Annexin V in patients than in NC \((P = 0.006)\). Furthermore, when Annexin V binding to the cells within the CD8\(^+\)CD45RO\(^-\) compartment was evaluated in patients, significantly more CD27-negative-Annexin-binding T cells were observed relative to NC \((P = 0.0059)\), as shown in Figure 8. Thus, while this subset of effector cells was expanded in patients with cancer, a higher proportion of the cells were in early apoptosis in patients than in NC. There was almost no binding of Annexin detected among the remaining naïve subset of CD8\(^+\) T cells, while in the memory compartment (CD8\(^+\)CD45RO\(^+\)), the proportion of Annexin-binding cells was increased in patients relative to NC (Figure 8).

**DISCUSSION**

Our earlier observations indicated that CD8\(^+\) lymphocytes are preferentially targeted for apoptosis in patients with advanced cancer (Hoffmann et al., 2002). This finding has focused our attention on the subsets of CD8\(^+\) T cells and their susceptibility to apoptosis. Among the subsets of CD8\(^+\) T cells, CD8\(^+\)CD45RO\(^-\)CD27\(^-\) cells are considered to be responsible for effector functions (Hamann et al., 1997; Sallusto et al., 1999; Baares et al., 2000). The phenotypic and functional characteristics of these cells have been extensively investigated and are consistent with their status of antigen-primed effector cells (Baares et al., 2000; Hendricks et al., 2000). In tumour-bearing hosts, these cells are likely to play an important role in the control of tumour growth. Thus, we were especially interested in the fate of CD8\(^+\)CD45RO\(^-\)CD27\(^-\) in patients with cancer.

By multicolour flow cytometry, it was possible to differentiate between the naïve, memory and effector subsets of CD8\(^+\) T lymphocytes, using antibodies to well-recognised surface markers CD45RA and CD45RO in combination with CD27 or CD62L (Hamann et al., 1997; Young et al., 1997). Strikingly, we observed that the population of CD8\(^+\)CD45RA\(^-\)CD27\(^-\) T cells was greatly expanded in the circulation of patients with SCC of the head and neck. This finding was readily explainable by the accelerated recruitment of naïve T cells into the effector and memory cell pools. Indeed, the overall proportion of naïve CD8\(^+\)CD45RA\(^-\) T
Furthermore, potentially important manifestation of host antitumour defence. Not found to be an age-dependent process (Figure 3), as it was significance. The expansion of the effector cell pool in patients was (Figure 1) although these differences did not reach statistical ionomycin showed that the expanded CD8+CD45RO+ cells higher in patients than in controls (Figure 1); however, the loss of CD27 expression, including production of reactive oxygen species (ROM) by tumour or tumour-associated monocytes (Kono et al, 1996; Otsuji et al, 1998). A transient loss of ζ chain expression appears to be a normal consequence of signalling via TcR (Valiuzzi et al, 1997). However, in patients with cancer or chronic infections such as leprosy or HIV, ζ chain expression may never recover to equal that in normal T cells (Stefanova et al, 1996; Zea et al, 1998), and its absence or partial loss in cancer patients appears to be substantially more common in tumour-infiltrating than in circulating T lymphocytes (Otsuji et al, 1996). Several different mechanisms have been proposed to explain the loss of ζ chain expression, including production of reactive oxygen species (Rom) by tumour or tumour-associated monocytes (Kono et al, 1996; Otsuji et al, 1996), or by circulating activated granulocytes (Schmielau and Finn, 2001); apoptosis in the tumour microenvironment (Gastman et al, 1999; Hoffmann et al, 2002); production and release by the tumour of ζ inhibitory proteins (Taylor et al, 2001); the availability of ζ-arginine in the microenvironment (Taheri et al, 2001) or increased degradation of ζ in chronically activated T cells (Penna et al, 1999). It is interesting to note that the loss of ζ was observed not only in the CD8+CD45RA−CD27− subset of effector cells, but also in other CD8+ T-cell subsets of patients with SCC of the head and neck. Therefore, in agreement with our previously reported data, ζ downregulation appears to be a generalised phenomenon in cancer patients, which might be mediated by several distinct mechanisms (Kießling et al, 1999; Whiteside, 2002); production and release by the tumour of ζ inhibitory proteins (Taylor et al, 2001); the availability of ζ-arginine in the microenvironment (Taheri et al, 2001) or increased degradation of ζ in chronically activated T cells (Penna et al, 1999). It is possible that the observed low or absent ζ expression in CD8+ T cells of patients with cancer is a consequence of normal antigen engagement in this effector cell population, consistent with their tumour activity. The cells were able to recover responsiveness after ex vivo stimulation with PMA/ionomycin, as evidenced by IFN-γ expression. However, not all cells responded by IFN-γ expression, and in some patients we studied, none responded. It appears that the expanded precursors of IFN-γ producing effector cells in patients with SCC of the head and neck are functionally crippled, and that the mechanism responsible for their dysfunction may be low or absent ζ expression. In this respect, it is interesting to note that ζ is slowly emerging as a biomarker of survival and prognosis as well as responsiveness to immune therapy in patients with cancer (Zea et al., 1995; Reichert et al, 1998a, b; Meidenbauer et al, 2002).

The finding of increased Annexin binding to the CD8+CD45RO−CD27− cell subset in patients relative to NC indicated that low ζ expression might be related to apoptosis, as previously suggested (Gastman et al., 1999; Dworacki et al., 2001; Hoffmann et al., 2002). As indicated above, the subset of CD8+CD45RA−CD27− effector cells was not the only subset with a higher rate of apoptosis and low ζ expression in CD8+ T cells of patients with cancer. In these patients, the memory CD8+ compartment was similarly affected. Only the naïve CD8+CD45RO−CD27− subset of T cells showed a relatively low rate of apoptosis, which was comparable to that of normal naïve cells. Although the CD8+CD45RA−CD27− effector cell subset was not selectively targeted for apoptosis, ζ downregulation, greater sensitivity to apoptosis and the concomitant decreased functional expression in other memory T cell subsets.
potential of the effector cells, which are normally responsible for antitumour activity, is likely to have a negative impact on the host response to the tumour.

The seemingly contradictory observations of the expanded effector cell pool and increased apoptosis as well as \( \zeta \) degradation within this CD8 subset could be reconciled by considering lymphocyte turnover in a tumour-bearing host. Under conditions of chronic antigenic stimulation, lymphocyte turnover is likely to be increased owing to an increased rate of antigen-driven expansion and activation-induced cell death (AICD), as previously suggested (Van Parijs and Abbas, 1998). Hence, the expansion of the effector cell subset in patients with cancer could be viewed as a natural consequence of response to tumour-associated antigens. The concomitant loss of function and death of activated T lymphocytes are compensated for by the sequestration and release of new T cells from the bone marrow stores (Tough and Sprent, 1994; Mackall et al., 1997). However, the pool of naïve CD8 \( ^+ \) T cells is not increased because of their rapid maturation and transfer to the antigen-experienced compartment. This series of events is consistent with a high rate of lymphocyte turnover in patients with cancer, not unlike that seen in patients with HIV (Mohri et al., 1998; Hellerstein et al., 1999). The obvious downside of such rapid turnover in T cells is that the normal processes of maturation and differentiation of effector cells are disturbed, possibly leading to ineffective immune responses. Further studies will be necessary to confirm directly the hypothesis linking signalling defects we observed with apoptosis and rapid lymphocyte turnover in patients with cancer.
