The WIMP (weakly interacting massive particle) paradigm for dark matter is currently being probed via many different experiments. Direct detection, indirect detection and collider searches are all hoping to catch a glimpse of these elusive particles. Here, we examine the potential of the ILC (International Linear Collider) to shed light on the origin of dark matter. By using an effective field theory approach we are also able to compare the reach of the ILC with that of the other searches. We find that for low mass dark matter (< 10 GeV), the ILC offers a unique opportunity to search for WIMPs beyond any other experiment. In addition, if dark matter happens to only couple to leptons or via a spin dependent interaction, the ILC can give an unrivalled window to these models. We improve on previous ILC studies by constructing a comprehensive list of effective theories that allows us to move beyond the non-relativistic approximation.

I. INTRODUCTION

Weakly interacting massive particles (WIMPs) are one of the leading candidates to solve the dark matter puzzle [1]. Primarily this is due to the fact that a neutral particle that interacts with roughly the strength of the weak force, naturally gives the correct relic abundance. In addition many theoretical models predict that the masses of these states should exist around the scale of electroweak symmetry breaking, e.g. Supersymmetry (Susy) [2, 3], Universal Extra Dimensions (UED) [4], Little Higgs [5] etc.

Currently, this WIMP paradigm is being actively explored in a number of different ways. Perhaps the most well known are the direct detection searches that aim to observe interactions between the dark matter and an atomic nucleus [6]. As these are extremely low rate experiments, the detectors are typically placed deep underground to reduce background. The annihilation of dark matter into Standard Model particles in high density regions of our universe offers another potential method to see a signal e.g. [7].

In particle colliders here on Earth the same interactions may be probed in the production of dark matter. Unfortunately, the fact that WIMPs are neutral and only weakly interacting means that they cannot be detected directly in these experiments. Therefore collider based searches must rely on particles produced in combination with the dark matter candidates. If dark matter is produced directly, one possibility is to use initial state radiation (ISR), such as gluon jets, or photons, that will recoil against the WIMPs.

This idea was first explored in a model independent approach for the International Linear Collider (ILC) using mono-photons in a non-relativistic approximation [8, 9]. Later, detailed detector studies have been performed to understand the full capabilities of the ILC for such a signature [10–14]. Furthermore the same signature has been considered in the case of SUSY [15, 16]. At the LHC (Large Hadron Collider) and Tevatron similar signals have also been studied but with a mono-jet signal [17–25]. All of these papers used the idea of parameterising the dark matter interactions in the form of effective operators. This has the advantage that the bounds can be compared with those coming from direct detection and also that a non-relativistic approximation is not required to compare with the relic density measurement. These methods have now been used by the LHC experiments to set bounds on different effective operators that are competitive with other methods [26, 27]. In addition, LEP (Large Electron-Positron Collider) data has been reinterpreted to determine corresponding constraints [28].

In this paper we take the effective field theory approach to dark matter and apply this to an ILC search [29–31]. To apply the effective field theory in a consistent way we assume that the dark matter particles can only interact with the Standard Model fields via a heavy mediator. The mediator is always assumed to be too heavy to be produced directly at the ILC and thus can be integrated out. For our model choices we consider the possibility that the dark matter candidate could be a scalar, a Dirac (or Majorana) fermion or a vector particle. The same choices are taken for the heavy mediator and all combinations are considered. The collider phenomenology can

§ daschm@th.physik.uni-bonn.de
¶ jamie@th.physik.uni-bonn.de
vary significantly, depending on whether the mediator is exchanged in the s- or t-channel and consequently we examine both. In addition, we also study the different ways in which the mediator can couple to both the dark matter and Standard Model particles. We note that using the effective field theory approach allows us to move away from the non-relativistic approximation that had previously been used in ILC studies. This can be especially important if the dark matter candidate happens to be light.\footnote{The mass determination of a light neutralino dark matter candidate at the ILC has been discussed in Ref. \cite{32}.}

For all models we compare the reach of the ILC with the bounds derived from direct and indirect detection. We also calculate the couplings expected to lead to the correct relic density and see whether the ILC can probe these regions of parameter space. We also note that an ILC search is complementary to that at the LHC thanks to the different initial state.

The paper is laid out as follows. We begin in Sec. II by explaining how we derive the effective field theories for the dark matter interactions and we explicitly give the Lagrangian for both the full and effective theory. We also describe the benchmark models that we use throughout the study. In Sec. III we describe the various astrophysical constraints on our effective theories. We begin with the calculation of the relic density abundance before moving on to explain the bounds from direct and indirect detection.

Section IV describes in detail the potential search for dark matter at the ILC. Here we explain the calculation of the signal rate and the dominant backgrounds that were considered. In addition we detail how the ILC detectors are modeled to account for relevant experimental effects. We find that the polarisation of incoming beams is particularly important for many models of dark matter to discriminate the signal and background. We also investigate the advantage of a doubling of the ILC energy to $\sqrt{s} = 1$ TeV.

In Sec. V we present the results of the paper. We begin by examining the potential bounds of the ILC on the effective coupling of the dark matter model at the collider. Afterwards, we combine these results with those from direct and indirect detection to understand for which models and mass ranges the ILC presents a unique opportunity to discover dark matter. Finally in Sec. VI we conclude and summarise the main results of our work.

II. MODELS

A. General Motivation

The idea of parametrising the interaction of a dark matter particle with Standard Model particles by using effective operators is not new, see for example Refs. \cite{18, 28, 30, 31, 33, 34}. Many authors construct a list of effective 4-particle-interactions with Lorentz-invariant combinations of $\gamma^\mu$, $\partial_\mu$ and spinor-/vector-indices up to mass dimension 5 or 6. In many cases there is no explanation how those operators may arise in an underlying fundamental theory. That makes it difficult to judge how exhaustive the lists of operators are, whether interference between different operators should be taken into account and how the effective model is connected to realistic fundamental theories and their couplings.

We follow the effective approach introduced in \cite{31} by starting from different fundamental theories with given renormalisable interactions between Standard Model fermions and the hypothesized dark matter particles that are mediated by a very massive particle. From these theories we deduce effective 4-particle-vertices for energies significantly smaller than the mass of the mediator. Working with these effective operators, one can deduce information about the effective coupling and propagate this information to the parameters of the corresponding underlying fundamental theory. The effective approach allows us to reduce the dimensionality of the parameter space and more easily compare the different experimental searches.

B. Deriving Effective Lagrangians

We start with a list of fundamental Lagrangians taken from \cite{31}. However we do not perform a non-relativistic approximation, since we are interested in the phenomenology of this Lagrangian at a high energy experiment and therefore the results for our effective operators differ. We also use a different method to evaluate the effective vertices, motivated in Ref. \cite{35}, which uses the path integral formalism.

We give one explicit example for the derivation of the effective operators and only mention specific peculiarities for the other cases, which are apart from that calculated similarly. Let $\psi$ be a Standard Model fermion and $\chi$ a complex scalar field representing the dark matter candidate. For our example, we assume the mediator to be a real scalar field, $\phi$, with mass $M_\Omega$ (we will keep this notation for the mediator mass throughout). The relevant terms in the UV completed Lagrangian are then given by,

$$\mathcal{L}_{UV} = \frac{1}{2} \left[ \partial_\mu \phi(x) \right]^2 - \frac{1}{2} M_\phi^2 \phi^2(x) - g_\chi \chi^\dagger(x)\chi(x)\phi(x) - \bar{\psi}(x) \left( g_s + ig_\gamma \gamma^5 \right) \psi(x) \phi(x), \quad (1)$$

$$\equiv -\frac{1}{2} \phi(x) \square x \phi(x) - \frac{1}{2} M_\Omega^2 \phi^2(x) - F(x) \phi(x). \quad (2)$$

where the function $F(x)$ is given by,

$$F(x) \equiv g_\chi \chi^\dagger(x)\chi(x) + \bar{\psi}(x) \left( g_s + ig_\gamma \gamma^5 \right) \psi(x). \quad (3)$$

We have not included the kinetic terms for $\chi$, $\psi$, as they are not relevant for the computation of the effective La-
grangian. In this particular example, $g_s, g_p$ are dimensionless couplings and $g_h$ is a dimension one parameter but these definitions can change depending upon the precise model studied and we shall use this notation throughout. We have included the kinetic term for $\phi$, the heavy mediator field. After integrating out $\phi$, we obtain the effective Lagrangian,

$$\mathcal{L}_{\text{eff}} = \frac{1}{2M_{\Omega}^2} F^2 \supset g_h \chi \chi \bar{\psi} (g_s + i g_p \gamma^5) \psi. \quad (4)$$

Cases with different spin for the dark matter or the mediator particle are evaluated similarly. We only want to give some special remarks:

- For spin–1/2 mediators, the Dirac propagator has only one power of $M_{\Omega}$ in the denominator,

$$\frac{1}{\hat{p} - M_{\Omega}} \approx -\frac{1}{M_{\Omega}^2} - \frac{\hat{p}}{M_{\Omega}^3}. \quad (5)$$

We therefore get two effective vertices after expanding the Lagrangian up to order $1/M_{\Omega}^3$.

- Some effective operators give derivatives on the Standard Model fermion fields. These are not negligible, since they only vanish if the Dirac equation $i\gamma^\mu \psi = m \psi$ can be used and the fermion mass $m$ is small. This is not the case for e.g. heavy quark contributions in the annihilation sector and processes with off–shell fermions.

- We use the same list of effective operators for the cases of real scalar ($\chi = \chi^1$), real vector ($X_\mu = \chi_\mu^1$) or Majorana fermion [36] dark matter fields. However, we would like to mention that for consistency we do not introduce additional factors of $1/2$ in the couplings as is often done in the case of real fields.

The full list of models with their respective fundamental and effective Lagrangians is given in Table I. Note that all Lagrangians are hermitian by construction.

### C. Benchmark Models

The effective operators described above have multiple independent parameters to describe the effective coupling, for example $g_h, g_s, g_r$ and $M_{\Omega}$ in the scalar dark matter, vector mediator (SV) case or $g_s, g_p$ and $M_{\Omega}$ in the fermion dark matter, scalar mediator (FS) case in Table I. Considering the full range of parameters would lead to a plethora of scenarios, well beyond the scope of this paper. Thus we restrict our analysis to specific benchmark models (see Table II) with constraints on the individual couplings such that only one overall multiplicative factor remains. The effective coupling constant $G$ for each model is then defined as $G \equiv g_s g_j / M_{\Omega}^2$. For models with fermionic mediators, the leading term has only a $1/M_{\Omega}$ dependence, which is why we define $G \equiv g_s g_j / M_{\Omega}$ for these. We also choose two possible values for $M_{\Omega}$ to represent different suppression scales of the respective second order terms. Models with real fields that are trivially connected to the corresponding complex cases by multiplicative prefactors are not taken into account separately. We also omit models with left–handed couplings that are related to the respective right–coupled cases. Information on these can easily be extracted from the related models by rescaling the corresponding result accordingly.

### III. ASTROPHYSICAL CONSTRAINTS

Any model which aims to describe dark matter, for example through a WIMP, has to agree with present data. It has to give the correct relic abundance, and must be consistent with the bounds from direct and indirect detection searches [37–39].

#### A. The Relic Abundance

We first consider the best measurement of the relic abundance from WMAP-7 [37],

$$\Omega_{\text{DM}} h^2 = 0.1099 \pm 0.0056. \quad (6)$$

We employ the solution of the model dependent Boltzmann equation obtained in [30],

$$\Omega_{h}^\text{DM} h^2 \approx 1.04 \cdot 10^9 \text{GeV}^{-1} \frac{x_f}{\mu_{\text{Pl}} g_*(x_f) (a + 3b/x_f)}. \quad (7a)$$

Here $\mu_{\text{Pl}}$ is the Planck mass. $x_f = M_\chi / T_f$ is the inverse freeze–out temperature, $T_f$, rescaled by the WIMP mass, $M_\chi$. It is implicitly given by the equation,

$$x_f = \ln \left[ c(c + 2) \frac{45}{8} \frac{\mu_{\text{Pl}}}{2\pi^3} \frac{g_{*s}(x_f)}{\sqrt{x_f^*}} \sqrt{g_* (x_f)} \right]. \quad (7b)$$

g_*(x_f)$ denotes the relativistic degrees of freedom in equilibrium at freeze-out and is given in Ref. [40]. $a$ and $b$ are the first two coefficients of the non-relativistic expansion of the thermally averaged annihilation cross section,

$$\langle \sigma v \rangle \approx a + bv^2 + O(v^4), \quad (8)$$

where $v$ is the relative velocity of the colliding particles. Here the center-of-mass energy squared is approximated by [33, 34],

$$s \approx 4M_\chi^2 + M_\chi^2 v^2 + 3/4 M_\chi^2 v^4. \quad (9)$$

g are the internal degrees of freedom of the WIMP. $c$ is an order unity parameter which is determined numerically in the solution of the Boltzmann equation and we set this parameter to 0.5.
TABLE I. List of interaction vertices for Scalar, F(ermion) and V(ector) dark matter, \(\chi\), before and after integrating out the heavy mediator scalar field \(\phi\), spinor field \(\eta\) or vector field \(Z^\mu\) with mass \(M_\Omega\). \(\psi\) denotes the Standard Model fermion. \(\partial X^{\mu\nu} \equiv \partial^\mu X^\nu - \partial^\nu X^\mu\). tS and tV denote cases where the mediator is exchanged in the t-channel.

| Operators | Definition | Name |
|-----------|------------|------|
| SS, VS, FS, FtS, FtSr: | \(g_\rho = 0\) | scalar |
| | \(g_\rho = 0\) | pseudoscalar |
| SF, SFr: | \(g_\rho = 0, M_\Omega = 1\) TeV | scalar_low |
| | \(g_\rho = 0, M_\Omega = 10\) TeV | scalar_high |
| | \(g_\rho = 0, M_\Omega = 1\) TeV | pseudoscalar_low |
| | \(g_\rho = 0, M_\Omega = 10\) TeV | pseudoscalar_high |
| SV, FV, FtV, FtVr, VV: | \(g_l = g_r\) | vector |
| | \(g_l = -g_r\) | axialvector |
| | \(g_l = 0\) | right-handed |
| VF, VFr: | \(g_l = g_r, M_\Omega = 1\) TeV | vector_low |
| | \(g_l = -g_r, M_\Omega = 10\) TeV | vector_high |
| | \(g_l = g_r, M_\Omega = 1\) TeV | axialvector_low |
| | \(g_l = -g_r, M_\Omega = 10\) TeV | axialvector_high |
| FVr: | \(g_l = 0\) | right-handed |

TABLE II. Benchmark models with specific values for the coupling constants shown in Table I.

Instead of testing all the models presented in Table I, we shall focus on a few exemplary cases. First, the relic density depends on the possible Standard Model particles, \(f\), the WIMPs can annihilate into \(\chi_\Omega \rightarrow f\bar{f}\). We shall consider two cases for the set of particles \(f\): (i) all leptons, (ii) all SM fermions. Second, two variants of couplings are tested. In one scenario all SM particles couple via the mediator to the WIMP with the same strength; this is called *universal coupling*. In the other they have a coupling proportional to their mass, which we call *Yukawa-like coupling*. In the cases where we have the same effective operator our results agree with Refs. [33, 34], up to the normalisation (see Appendix A).

In order to set constraints, we must determine the total relic density, which is the sum of the relic density of the particle and the anti-particle (if the latter exists). This means the relic density for a complex particle-pair is two
times the density of a real particle. If we consider the WMAP result as an upper bound on the relic density, i.e. allowing for other dark matter, then this corresponds to a lower bound on the effective coupling of the WIMP to the SM particles. If we require our WIMP to be the only dark matter, we shall also obtain an upper bound on the effective coupling.

The strict interpretation that our model only contains a heavy mediator and a single WIMP ensures that there are no resonances or co-annihilations. However we also note that in many full theories that contain dark matter, a ‘co-annihilation’ regime can exist that can significantly alter the relic density in the universe. Whilst the co-annihilation mechanism cannot be incorporated into the strict definition of our model, it may actually have no observable effect on the collider based phenomenology. An example of such a feature could be stau co-annihilation in SUSY that would not change the ILC production process of the lightest supersymmetric particle. Another example is that a more complicated model may contain resonant annihilations. Both of these examples can significantly weaken the relic abundance bounds.

B. Direct Detection

We shall also impose bounds on our operators from the direct detection searches for WIMP dark matter. The experiments are designed to measure the recoil energy from the scattering between a (dark matter halo) WIMP and the target nucleus. The interactions are difficult to detect since the energy deposited is quite small, 1 to 100 keV, [1]. These experiments give an upper limit for the cross section between the dark matter and the nucleus of the target. One drawback is that in the cases where the WIMP does not couple to quarks, the coupling can only occur through loop diagrams.

The direct detection experiments give a much stronger bound on spin independent (SI) interactions than on spin dependent (SD). The reason is that in the SI case the interaction with all nucleons adds coherently which enhances the corresponding cross section by the atomic number squared. However, the spins of the nucleons cancel if they are paired. Thus SD interactions are only enhanced for very special nuclei.

The SI interactions are scalar or vector interactions in the s-channel, the axialvector and tensor interactions in the s-channel give a SD interaction. Note that due to the low kinetic energy of the WIMPs the cross section should be computed in the non-relativistic limit. In that case the pseudoscalar interaction, \( \bar{\psi} \gamma^\mu \psi \), vanishes.

The t/u–channel diagrams are cast into a sum of s–channel diagrams via the Fierz identities. From this only the SI parts are employed, since any SD contribution is negligibly small. Tensor interactions occur only via the Fierz identities, since we do not consider fundamental tensor interactions. However, since Fierz identities will always give at least one SI contribution, tensor terms can be dropped.

For the SI interactions we shall consider the limits set by the Xenon100 experiment [38]. These are the most recent and set the strictest limits over a broad parameter range. For the SD interactions we consider the Xenon10 data [41] since Xenon100 gives no statement on SD interactions. The smaller data set along with the physical reasons mentioned above lead to a bound that is \( \sim 10^6 \) times weaker than for the SI interactions. The calculations for the WIMP–nucleus cross sections follow Ref. [31] and for identical models we find the same results. See Appendix B for the complete list of cross sections.

C. Indirect Detection

We also consider the indirect detection searches for dark matter. These are much more model dependent, as the dark matter is seen via an agent, for example neutrinos, which could also be produced via other means. Specifically we shall consider the PAMELA experiment [39] which measured an excess of positrons. These could potentially originate from dark matter annihilation. To implement this we need to compute the propagation of the produced positrons and electrons from the source to the earth. This is described by the diffusion–loss equation [42],

\[
\frac{\partial \psi}{\partial t} - \nabla [K(x,E)\nabla \psi] - \frac{\partial}{\partial E} [b(E)\psi] = q(x,E). \tag{10}
\]

Here \( \psi(x,E) = d\alpha_{e+}/dE \) is the positron density per energy. \( K(x,E) \) is the diffusion coefficient which describes the interaction with the galactic magnetic field. \( b(E) \) denotes the energy loss due to synchrotron emission and inverse Compton scattering. \( q(x,E) \) is the source term due to dark matter annihilation. We note that convection and re-acceleration terms are ignored as these do not apply to positrons [43].

We use the conventional formalism [44, 45] to derive a solution of Eq. (10). It is also possible to use the so-called extended formalism that takes the corrections from sources in the free propagation zone into account as well as those from the diffusion zone. However, this increases the runtime of the calculation considerably while only giving a small correction that is less than the measurement error. To perform the numerical comparison we use the cored isothermal dark matter density profile [46] and the galactic propagation model M2 [44].

The above choices result in the following positron flux,

\[
\Phi_{e+}(E) = \frac{\beta_{e+}}{4\pi} \psi(r_\odot, z_\odot, E), \tag{11}
\]

\[
\psi(r, z, E) = \frac{\tau_E}{e^2} \int_\epsilon^{\epsilon_{max}} d\epsilon_S f(\epsilon_S) I(r, z, \epsilon, \epsilon_S), \tag{12}
\]

\[
I(r, z, \epsilon, \epsilon_S) = \sum_i \sum_n J_0(\alpha_{i,n} R) \sin \frac{n\pi(z + L)}{2L} \times \exp (-\omega_{i,n}(t - t_S)) R_{i,n}. \tag{13}
\]
\[ \omega_{i,n} = K_0 \left( \frac{\alpha_i}{R} \right)^2 + \left( \frac{n \pi}{2L} \right)^2. \] (14)

Here \( \tau_E \), \( R \), \( K_0 \), \( L \) are parameters which describe the M2 propagation model. They are set to the standard choices \cite{44, 45} \( \tau_E = 10^{16} \) s, \( R = 20 \) kpc as well as to the M2 propagation model \( L = 1 \) kpc, \( K_0 = 0.00595 \) kpc\(^2\)/Myr, \( \delta = 0.55 \). \( f(\epsilon) \) is the energy distribution of the positrons from the annihilation and is generated with PYTHIA8 \cite{47}. \( R_{i,n} \) are the coefficients of the Bessel-Fourier expansion of \( R(r,z) \),

\[ R(r,z) \equiv \eta(\sigma v) \left( \frac{\rho(r,z)}{M_\chi} \right)^2, \] (15)
\[ \rho(r,z) \equiv \rho(\frac{r_\odot}{r}) \left( \frac{1}{1 + (r_\odot/r)^\alpha} \right)^{(\beta-\gamma)/\alpha}. \] (16)

Here \( \langle \sigma v \rangle \) is the thermally averaged annihilation cross section. We include all possible final states, not just those resulting in positrons. Furthermore \( \eta = 1/2 \) for real particles and 1/4 for complex particles. \( r_\odot = 8.5 \) kpc is the distance of the solar system from the galactic center. \( \rho_\odot = 0.3 \) GeV/cm\(^3\) is the local dark matter density and \( \alpha = 2, \beta = 0 \), \( r_S = 5 \) kpc are chosen according to the cored isothermal dark matter density distribution \cite{44, 45}.

PAMELA measures the ratio \( \Phi_{e^+}/(\Phi_{e^-} + \Phi_{e^+}) \), where the fluxes, \( \Phi_{e^\pm} \), contain the flux from dark matter annihilation and from any astrophysical background. The background we take is \cite{42},

\[ \frac{d\Phi_{e^-}}{dE} = \left( 0.16 \epsilon^{-1.1} + \frac{0.7 \epsilon^{0.7}}{1 + 650 \epsilon^{2.3} + 1500 \epsilon^{4.2}} \right) \text{GeV}^{-1} \text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1}, \] (17a)
\[ \frac{d\Phi_{e^+}}{dE} = \frac{4.5 \epsilon^{0.7}}{1 + 650 \epsilon^{2.3} + 1500 \epsilon^{4.2}} \text{GeV}^{-1} \text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1}, \] (17b)
\[ \epsilon \equiv E/\text{GeV}. \]

The quantity we compare to PAMELA is,

\[ \frac{\Phi_{e^+}}{\Phi_{e^+} + \Phi_{e^-}} = \frac{\Phi_{e^+} + \Phi_{e^+}}{\Phi_{e^+} + \Phi_{e^-} + \Phi_{e^-}}, \] (18)

and we note that \( \Phi_{e^+} + \Phi_{e^-} \).

We find an upper bound on the annihilation cross section by assuming that all of the excess comes from dark matter. However, it is possible that other background sources contribute and thus we also allow models that produce a flux smaller than the one seen.

We also note that for dark matter masses above \( \sim 1 \) TeV, the FERMI-LAT \cite{48} experiment may provide competitive bounds from inverse Compton scattering \cite{49, 50}. However, since we are only interested in models that can be probed at the ILC we ignore them here.

The ICECUBE collaboration also sets limits on heavier dark matter masses via annihilations into neutrino final states \cite{51, 52}. In addition these bounds may be competitive for spin dependent interactions but we do not consider the limits in this study.

\end{figure}

\section{IV. DARK MATTER SEARCH AT THE ILC}

\subsection{A. Radiative Production of Dark Matter}

For the ILC search, we look at the process \( e^+e^- \rightarrow \chi\chi^\gamma \) with a hard photon being the only detected particle in the final state, Fig. 1. We determine the polarized differential cross section for this process with respect to the relative photon energy \( x = E_\gamma/\sqrt{s} \) and its polar angle \( \theta \) by integrating over the full phase space of the final state dark matter particles. The results for this calculation are given in Table III, with further explanation of the abbreviations used given in Appendix C 1. Previous ILC studies, e.g. \cite{8, 13, 14}, have used the Weizsäcker–Williams approximation for soft photons. This formula relates the differential photon cross section to the total pair production cross section \( e^+e^- \rightarrow \chi\chi^\gamma \) with a reduced center of mass energy \( s \rightarrow \hat{s} \equiv s(1-x) \) and multiplied by the kinematical function \( F_{\gamma \theta} \),

\[ \frac{d\sigma [e^+e^- \rightarrow \chi\chi^\gamma]}{dx \, d\cos \theta} \approx F_{\gamma \theta} \, \hat{\sigma} \left[ e^+e^- \rightarrow \chi\chi^\gamma \right]. \] (19)

Due to the soft collinear approximation used, we expect that the above equation will perform poorly for large angle and high \( p_T \) photons. We compare the analytical result to this approximation to test the reliability. In Table III we put terms in bold, which are purely caused by our analytical treatment. The corrections are either of the form of an additional kinematical factor \( V_{\theta \phi} \), mostly appearing in models with vector mediators, or completely new terms that typically appear in t-channel interactions. Since \( \lim_{x \rightarrow 0} V_{\theta \phi} = 1 \) and \( \lim_{x \rightarrow 0} (A_i) = 0 \), the WW–approximation is in agreement with our full result for small energies. In Fig. 2 we show the respective photon energy distributions for different models in both the WW–approximation and the full analytical treatment.
TABLE III. Analytical differential cross sections for the process $e^+ e^- \rightarrow \chi \chi \gamma$ in the various effective models. Terms in bold do not appear in the Weizsäcker–Williams approach and are given in Appendix C1 where we also define all used abbreviations. Models with a suffix ‘r’ correspond to the case of real particles. Cross sections for SSr, FSr and VSr are twice as large as in the complex case while SV and VV vanish completely for real particles.

The curves behave quite congruently with differences visible in the high energy sector. Since most of the signal events lie in the low energy part, the approximation gives accurate results for counting experiments. A shape dependent analysis would need to use the analytical result to estimate the correct threshold behaviour for high energies. Our subsequent analysis is performed with the full analytical cross section.

When we restrict the various couplings in our model according to the benchmark scenarios, Table II, most of the cross sections simplify and have only one polarisation dependent term $C_i$. To determine the polarisation leading to the best signal to background ratio, we only need to consider cases with different $C_i$. We therefore classify our models as follows:

| Model | $\frac{d\sigma}{dx \, d\cos \theta}$ |
|-------|-------------------------------------|
| SS $\beta F_{\theta \bar{\theta}} \frac{32\pi M_i^2}{32\pi M_i^2}$ | $G_{s+p}g_s^2 C_s \left[(g_s + g_p)^2 C_R + (g_s - g_p)^2 C_L\right] + A_{SF}$ |
| SF $\beta F_{\theta \bar{\theta}} \frac{32\pi M_i^2}{32\pi M_i^2}$ | $\left[G_{s-p}C_s + \frac{\beta^2 \hat{s}}{12M_i^2} V_{\theta \bar{\theta}} \left[(g_s + g_p)^2 C_R + (g_s - g_p)^2 C_L\right] + A_{SFr}\right]$ |

The right–like : $\sigma_{pol} = C_R \sigma_{unpol}$.

The left–like : $\sigma_{pol} = C_L \sigma_{unpol}$.

Models with t–channel mediators usually have multiple terms with different polarisation behaviour and do not fall into one of the basic polarisation classes given in Eq. (20). We choose the following polarisation settings for those:

- Models with fermionic mediators are classified according to their leading term, which is always scalar–like.
- All other models have both scalar–like and vector–like parts of about the same size. We analyse them in a vector–like scenario that naturally leads to a better background suppression.
B. Standard Model Background for Monophotons

We consider the two leading dominant Standard Model background contributions after selection, determined with a full ILD (International Linear Detector concept) detector simulation [13, 53]. All numbers here and in the following paragraphs refer to the nominal ILC center of mass energy of 500 GeV [54]. We also consider the case of an increased energy of 1 TeV and mention the differences later.

- Neutrinos from $e^+e^- \rightarrow \nu\bar{\nu}\gamma(\gamma)$ form a polarisation dependent background. The leading contribution comes from $t$-channel $W$-exchange, which only couples to left-chiral leptons. Additional smaller contributions come from $s$-channel $Z$-diagrams with both left- and right-chiral couplings. We also consider the case of one additional undetected photon, which contributes with a size of roughly 10%.

- Bhabha scattering of leptons with an additional hard photon, $e^+e^- \rightarrow e^+e^-\gamma$ has a large cross section but a very small selection efficiency, since both final state leptons must be undetected. It has been determined to give a contribution of the same order of magnitude as the neutrino background, after application of all selection criteria. It is mostly polarisation independent [13, 53].

Other background sources contribute with less than 1% compared to the neutrino background and are therefore omitted.

C. Data Modeling

To evade the use of a full detector simulation, we build on the results of Refs. [13, 53]. For the signal and monophoton neutrino background, we generate the events by ourselves with the given phase space criteria. We then apply the ILD estimates for the energy resolution as well as the reconstruction and selection efficiencies and compare the final energy distributions. For the diphoton neutrino and Bhabha background, we model the final distributions directly from the given results performed with a full detector simulation [13, 53].

For the generation of signal and monophoton neutrino events we use CalcHEP [55]. We produce signal events for all benchmark scenarios with dark matter masses ranging from 1 GeV to 240 GeV. To avoid collinear and infrared divergences, we limit phase space in the event generation to $E_\gamma \in [8 \text{ GeV} , 250 \text{ GeV}]$ and $\cos \theta_\gamma \in [-0.995, 0.995]$. Initial State Radiation (ISR) and beamstrahlung significantly change the width and position of the neutrino $Z^0$-resonance, Fig. 3a), and are taken into account. We set the accessible parameters in CalcHEP according to the ILC Letter of Intent [56] to 645.7 nm for the bunch size, 0.3 mm for the bunch length and a total number of particles per bunch of $2 \cdot 10^{10}$.

The finite resolution of the detector components and the use of selection criteria to reduce beam-induced background are taken into account by applying the following steps to both signal and background data. First we shift
FIG. 3. Photon energy distribution before and after application of beam effects (Isr + beamstrahlung) and detector effects (resolution + efficiency) for a) unpolarised neutrino background and b) unpolarised FS scalar signal with $M_\chi = 150$ GeV. Distributions are normalised to $10^6$ tree level events.

FIG. 4. Photon energy distributions of the most dominant background contributions (stacked) compared to an example signal (FS Scalar, $M_\chi = 150$ GeV) with a total cross section of 100 fb. All spectra are taken after selection for an unpolarised initial state.

$$\Delta E_\gamma = \frac{16.6 \%}{\sqrt{E_\gamma \text{ in GeV}}} \oplus 1.1 \%.$$  \hspace{1cm} (21)

Afterwards we further limit the phase space to reduce background processes in the $Z^0$ resonance peak at 242 GeV and additional collinear photons from Isr,

$$E_\gamma \in [10 \text{ GeV}, 220 \text{ GeV}],$$

$$\cos \theta_\gamma \in [-0.98, 0.98].$$  \hspace{1cm} (22)

The additional angular cut ensures a good photon reconstruction within the detector. Finally a random elimination of events is used to simulate the efficiency factor for reconstruction and selection determined in Ref. [53]. The efficiency consists of an energy dependent part $\epsilon_1$ and a constant part $\epsilon_2$ that are applied successively,

$$\epsilon_1 = 97.22 \% - (E_\gamma \text{ in GeV} \cdot 0.1336 \%),$$

$$\epsilon_2 = 96.8 \%.$$  \hspace{1cm} (23)

The numbers in brackets are taken from Ref. [53] which employed a proper detector simulation.

FIG. 5. Total number of events in the different background sources after application of all selection criteria. The numbers are given for an integrated luminosity of 1 fb$^{-1}$ in different polarisation settings. Numbers in brackets are employed in Ref. [53] which employed a proper detector simulation.

**D. Analysis**

We are interested in determining the lower bound on the effective coupling constants that the ILC can find for
one will get ten times as many events in all channels; to better compare to the error of the low luminosity case, we give

\[ \Delta \epsilon \]

de the dark matter particle and the underlying interaction. The final energy distribution depends on the unknown mass of

effects however. This is due to the fact that the signal will be different from the used neutrino background

edetermined at the real experiment by measuring the Z

describes the number of polarised signal events with \( \Delta N_p \) and \( \Delta N_{500} \). We mark the numbers which lead to

for the different classes described in Sec. II with a common reference value of 500 unpolarised events for an integrated

For the polarisation dependence for \(\nu\nu\gamma\) and \(\nu\nu\gamma\gamma\) events and no dependence for the Bhabha background.

\[
N_{\text{pol}} = (1 + P^+)(1 - P^-)N_{\text{unpol}}.
\]

\[
\Delta N_{\text{pol}} = \sqrt{[P^-(1 + P^+)]^2 + [P^+(1 - P^-)]^2} \Delta P / P \cdot N_{\text{unpol}}.
\]

From the numbers in Table 5, we assume an identical polarisation dependence for \(\nu\nu\gamma\) and \(\nu\nu\gamma\gamma\) events and no dependence for the Bhabha background.

Since the neutrino spectrum depends on the incoming lepton’s polarisation \( P^\pm \), any fluctuation within those parameters will give additional systematic uncertainties on the number of expected background events. One can not use the information from measuring the \(Z^0\)–resonance in this case to infer information in the low energy signal range because of the polarisation dependence of the shape itself. Given the assumed accuracy of at least \( \Delta P / P = 0.25 \% \) [56] with a possible improvement to 0.1 % at the ILC, we can derive the corresponding error on the polarised number of background events. As an example we show the left handed background,

| \( P^- / P^+ \) | \( N_p \) | \( \Delta_{50} \) | \( \Delta_{500} \) | \( \Delta_r \) | \( \Delta_{50} \) | \( \Delta_{500} \) |

TABLE VIII. Determination of the best ratio $r \equiv N_S / \Delta N_B$ (see Table V) for $\sqrt{s} = 1$ TeV.
error sources and the determination of the best polarisation setting for the increased center of mass energy. In contrast to the Bhabha cross section that falls mainly according to $\sigma \propto 1/s$, the neutrino background gets significant contributions from t-channel $W^\pm s$, which give $s/m^0_N$ -- terms in the evaluation of the total cross section. The left-handed neutrino contribution therefore gets enhanced whereas the Bhabha background becomes less dominant in some polarisation channels. This leads to a larger relative polarisation error and therefore a larger impact on the size of the background fluctuation. In the end, vector-- and right–coupling models receive stronger enhancement for polarised input than in the $\sqrt{s} = 500$ GeV case, whereas the other models suffer from the larger impact of polarisation on the total error and prefer smaller polarisation.

V. RESULTS

We begin by presenting the reach at the ILC in terms of the effective coupling constant in Sec. VA. We then compare these potential bounds with the couplings predicted by the cosmological relic density and the bounds coming from direct and indirect detection experiments. Of course we would also like to discover a dark matter at the ILC and the bounds provide an estimate of the potential sensitivity of the collider.

A. ILC Bounds

We determine the 90% exclusion bound for the effective coupling constant in each benchmark model for the best case scenario. The integrated luminosity is set to 500 fb$^{-1}$ and the systematic polarisation error to $\Delta P/P = 0.1\%$. For each benchmark model we choose the polarisation setting that leads to the best signal to background ratio for the corresponding polarisation behaviour according to Tables V and VIII. Results for different polarisation settings can be found by rescaling the bound on the coupling according to $G' = G\sqrt{r}/r$ with $r$ denoting the ratio $N_S/\Delta N_B$ given in Table VIII. We choose to present all of the results for an ILC with a center of mass energy of 1 TeV due to the increased range of dark matter masses that this option can probe. In addition, smaller effective couplings can be probed, mainly due to the falling Bhabha background.

In Fig. 6 we show the derived bounds on the coupling constants for an ILC center of mass energy of 1 TeV. The hashed area denotes the region that either violates the tree level approach with a too large dimensionless coupling constant $g^2 > 4\pi$, or by having a too small mediator mass $M_\Omega < 1$ TeV, for the effective approach to be valid. Note that the leading order in models with fermionic mediators has a different mass dimension and therefore gives a different definition for the effective coupling constant $G_{\text{eff}}$. If a model has no separate ‘pseudoscalar’ or ‘axialvector’ results, it is identical to the corresponding ‘scalar’/ ‘vector’ line due to identical cross section formulas. For masses away from the threshold, the ILC is able to exclude coupling constants down to the order of $10^{-7}$ GeV$^{-2}$ or $10^{-4}$ GeV$^{-1}$, depending on the mass dimension. This corresponds to a total cross section (for the given phase space criteria) of about 0.3 fb. Exceptions however arise for models with vector dark matter that tend to have very strong exclusion limits for small masses. This is caused by the $1/M_\Omega^4$ dependence in the photon cross section, which leads to divergences for very small vector boson masses. It has been shown [59] that only spontaneously broken gauge theories can lead to models with massive vector particles that are not divergent. Therefore, our initial fundamental model cannot be the full theory for all energies. In our effective approach, we restrict the energy to a maximum and in that case one can still receive perturbative valid results for mass ranges that do not violate unitary bounds. However, the perturbatively allowed mass range cannot be given in this model independent approach, since such an analysis needs more information about the size of the individual couplings and the relation between the mass of the mediator and the dark matter mass itself. In summary, a more detailed fundamental theory is needed to evaluate the breakdown of perturbation theory in this scenario.

We note that in models with fermionic operators, the sub-leading order has a negligible effect, as can be seen from the nearly identical lines for fermionic mediators with different masses.

B. Combined Results

The combined maximum exclusion limits for spin independent DM–proton interaction at Pamela, WMAP and the ILC are shown in Figs. 7-9. We choose a subset of models that couple to all Standard Model fermions and give an overview of the bounds that we can expect. Other models behave similarly and are therefore not shown again separately. We can give the following statements about the comparison of the ILC exclusion bound with the current Xenon limits:

- We have sensitivity to spin independent proton cross sections for, as an example, the FV Vector model down to $10^{-12}$ cm$^{-2}$ or equivalently $10^{-4}$ fb, which is an improvement of about four orders of magnitude compared to current LEP [28] and two orders of magnitude compared to current Tevatron [18] and CMS [26] results.

- An increased center of mass energy can lead to stronger bounds by up to one order of magnitude. It also allows a larger dark matter mass range to be probed.

- ILC bounds get significantly weakened if the interaction is Yukawa–like. At the ILC the mediator
FIG. 6. 90% exclusion limits on the effective couplings accessible at the ILC with $\sqrt{s} = 1$ TeV. We only give effectively allowed regions for models with dimensionless fundamental couplings $g$.

must couple to electrons, which have a suppressed Yukawa coupling. The production cross section is thus small, leading to weaker bounds.

- Models with scalar mediators give weaker bounds than models with vector interactions. For fermionic dark matter we observe a difference of about two orders of magnitude, which is in agreement with previously mentioned results from e.g. LEP. For scalar and vector dark matter the difference is mass-dependent and can increase to up to six orders of magnitude, which is due to the different mass dimension of the couplings.

- The WMAP bounds are for many effective models very constraining, Figs.7–10. However, we would like to point out that these can be highly dependent on the full theory whilst not affecting the ILC or direct detection phenomenology. For example, annihilation can occur via some resonance or as in some SUSY models, co-annihilation with staus or stops.

In Fig. 10 we show some models which allow for lepton couplings only. In that case, dark matter can only interact with protons via photons through a fermion loop, cf. Appendix. B 4. The loop factor significantly lowers the cross section and therefore increases the bound in the case of vector coupled models. Other models allow quark couplings only at the two-loop level or theoretically completely forbid them [28]. In all cases, the ILC would give the strongest exclusion bounds for dark matter lepton couplings. For models with fermionic mediators there is an extra subtlety when comparing the bounds. In particular the exclusion limit at the ILC is mainly given by the leading term in the operator expansion, which is scalar like. Loop couplings can only happen for vector currents, which in the case of a fermionic mediator is only given by the sub-leading order and has an additional factor of $1/M_\Omega^2$. In that case, when translating any exclusion limits into bounds on the WIMP–proton cross section, we need to know the exact mass of the mediator. We show this in Fig. 10 for the two different chosen suppression scales ‘Low’ ($M_\Omega = 1 \text{ TeV}$) and ‘High’ ($M_\Omega = 10 \text{ TeV}$), Table II.

In Fig. 11 we show the exclusion limits for the spin-dependent interaction. In our case, only the model with fermionic dark matter, a vector mediator and an axial–vector coupling leads to such an interaction. In that case, we compare with data from the previous XENON experiment (XENON10), since no results for the XENON100 phase were available when this study was completed. Since in this scenario dark matter only couples to a single nucleon on average because of the natural spin anti-alignment in nuclei, the XENON bounds are not coherently enhanced by the atomic number and therefore strongly lose sensitivity. The ILC would also give strongest exclusion bounds over the whole accessible mass range here.

VI. CONCLUSIONS

In this paper we considered a broad range of effective models for dark matter and investigated the possibility that these models could be explored at the ILC. The models considered the possibility that dark matter was a new scalar, fermion or vector particle and would be produced at the ILC via a new, heavy intermediate state, the mediator particle. For the mediator we also considered spins 0, 1/2 and 1. We obtained the corresponding effective theories by integrating out the mediator field.

To be able to compare the reach of the ILC with the other experimental searches, certain assumptions have to be made on how the mediator and dark matter couples to the Standard Model particles. We assume in all models that interactions only occur with the Standard Model fermions but the relative strength to different particles is varied. In the simplest variant we choose that the coupling is equal between all the Standard Model states. Another choice is that the interaction scales with the mass of the interacting Standard Model fermion, a ‘Yukawa-like’ interaction. The last choice we make is the most optimistic for ILC phenomenology with only the Standard Model leptons interacting with the heavy mediator. Since the produced dark matter particles will be invisible to the ILC detectors, we require a radiated photon to be emitted from the initial state that will recoil against missing momentum. This topology provides a distinctive signal with which to discover dark matter. For the ILC study, we included the dominant backgrounds and most important detector effects. In addition we considered the possibility of using polarised initial states to reduce backgrounds and improve the signal strength.

The effective theories that we consider provide an efficient way to compare the reach of the ILC with other methods to discover dark matter. Firstly, we consider the dark matter annihilation cross section required for the relic density observed by WMAP. We also look at the direct detection bounds at XENON by calculating the dark matter-nucleon scattering cross section. In addition, we include bounds from dark matter annihilation to positrons from the PAMELA experiment.

In terms of the effective dark matter model, we found that the ILC should be able to probe couplings \(10^{-7}\) GeV\(^{-2}\) or \(10^{-4}\) GeV\(^{-1}\) depending on the mass dimension of the theory. In models that contain vector dark matter, the ILC may be able to probe even weaker couplings in the case of low dark matter mass.

To compare with astrophysical bounds, we found that the ILC reach is strongly dependent on the exact dark matter model. If we assume that dark matter is relatively heavy (> 100 GeV) and interacts with a Standard Model particle in proportion to its mass, then the ILC is uncompetitive. However, in the case that dark matter is relatively light (< 10 GeV) then the bounds from the ILC are competitive with astrophysical bounds in many models. In addition, if dark matter happens to only interact with the Standard Model leptons then the ILC offers a unique possibility to discover dark matter. For this reason, an ILC search is complementary to those done at the LHC thanks to the different initial state.

ACKNOWLEDGMENTS

We would especially like to thank Jenny List for many detailed discussions regarding the ILC analysis. The work has been supported by the Helmholtz Alliance “Physics at the Terascale”, the DFG SFB/Tr9 “Computational Particle Physics”, and the DFG SFB/Tr33 (‘The Dark Universe’). H.K.D. would like to thank the Aspen Center for Physics where part of this work was completed.
Appendix A: Cross Sections for Annihilation

We give the full cross sections for annihilation of a pair of dark matter particles with mass $M_\chi$ into a pair of Standard Model fermions with mass $m_f$. To find the expansion coefficients in $\sigma v \approx a + b v^2$, we perform the non-relativistic approximation $s \approx 4M_\chi^2 + M_\chi^2 v^2 + \frac{1}{3}M_\chi^2 v^4$ [30]. Note that in order to find the correct result for the $v^2$ term in $\sigma v$, it is necessary to expand up to order $v^4$ because of the appearance of $\sqrt{s}$ in the cross section formulæ.

The total cross section is then given as the sum of the cross sections over all allowed final state fermions. This set is restricted both by kinematics ($m_f \leq M_\chi$) and by the assumed model. The latter also determines whether the coupling $G_f$ is universal or particle–dependent.

We define the mass ratio $\xi \equiv m_f/M_\chi$ and the velocities of both particles $\beta_\chi \equiv \sqrt{1 - 4m_\chi^2/s}$ to compactify the following expressions.

Some of our effective operators have been analysed before, for example [33, 34], and we agree with the respective results for the annihilation cross sections.

1. Scalar Wimp

\begin{equation}
\sigma_{\text{Sc}} = \frac{G_f^2}{8\pi s} \frac{\beta_f}{\beta_\chi} (s - 4m_f^2),
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{4\pi} \sqrt{1 - \xi^2} \left[(1 - \xi^2) + \frac{v^2}{8} (5\xi^2 - 2)\right],
\end{equation}
\begin{equation}
\sigma_{\text{Ps}} = \frac{G_f^2}{8\pi} \frac{\beta_f}{\beta_\chi},
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{8\pi} \left[\sqrt{1 - \xi^2} + \frac{v^2}{8} (3\xi^2 - 2)\right].
\end{equation}
\begin{equation}
\sigma_{\text{Vvec}} = \frac{G_f^2}{12\pi} \frac{\beta_f}{\beta_\chi} (s + 2m_f^2),
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{12\pi} \left[M_\chi^2 v^2 \sqrt{1 - \xi^2} (\xi^2 + 2)\right].
\end{equation}
\begin{equation}
\sigma_{\text{Ax}} = \frac{G_f^2}{6\pi} \frac{\beta_f}{\beta_\chi} (s - 4m_f^2),
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{6\pi} \left[M_\chi^2 v^2 (1 - \xi^2)^{3/2}\right].
\end{equation}
\begin{equation}
\sigma_{\text{Ch}} = \frac{G_f^2}{24\pi} \frac{\beta_f}{\beta_\chi} (s - m_f^2),
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{24\pi} M_\chi^2 v^2 \sqrt{1 - \xi^2} (4 - \xi^2).
\end{equation}
\begin{equation}
\sigma_{\text{SF}} = \frac{G_f^2}{48\pi s} \frac{\beta_f}{\beta_\chi} \left[2s(4m_f^2 - 2M_\chi^2 + 3M_\Omega^2 + 6m_f M_\Omega) - 8m_f^2 (3(M_\Omega + m_f)^2 + M_\chi^2) + s^2\right],
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{4\pi} \sqrt{1 - \xi^2} \left[(1 - \xi^2) (\xi M_\chi \mp M_\Omega)^2\right] + \frac{v^2}{24} \left[(15\xi^2 - 6)M_\Omega^2 \mp 6\xi (5\xi^2 - 2) M_\Omega^2\right].
\end{equation}
\begin{equation}
\sigma_{\text{SFv}} = \frac{G_f^2}{2\pi s} \frac{\beta_f}{\beta_\chi} (m_f \mp M_\Omega)^2
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{\pi} \sqrt{1 - \xi^2} \left[(\xi M_\chi \mp M_\Omega)^2\right] \times \left[1 + \frac{v^2}{8} (5\xi^2 - 2)\right].
\end{equation}

2. Fermion Wimp

\begin{equation}
\sigma_{\text{Sc}} = \frac{G_f^2}{16\pi} \frac{\beta_f}{\beta_\chi} (s - 4m_f^2),
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{8\pi} \sqrt{v^2 M_\chi^2 (1 - \xi^2)^{3/2}}.
\end{equation}
\begin{equation}
\sigma_{\text{Ps}} = \frac{G_f^2}{16\pi} \frac{\beta_f}{\beta_\chi},
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{8\pi} \sqrt{1 - \xi^2} \left[v^2 \frac{\xi^2}{8} \sqrt{1 - \xi^2}\right].
\end{equation}
\begin{equation}
\sigma_{\text{Vvec}} = \frac{G_f^2}{12\pi} \frac{\beta_f}{\beta_\chi} (s + 2M_\chi^2),
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{2\pi} \left[M_\chi^2 \left(1 - \xi^2 (2 + \xi^2)\right) + v^2 \frac{8 - 28\xi^2 + 23\xi^4}{24\sqrt{1 - \xi^2}}\right].
\end{equation}
\begin{equation}
\sigma_{\text{Ax}} = \frac{G_f^2}{48\pi s} \frac{\beta_f}{\beta_\chi} (s - 4m_f^2 + M_\chi^2),
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{8\pi} \left[M_\chi^2 \left(1 - \xi^2 \frac{8 - 28\xi^2 + 23\xi^4}{24\sqrt{1 - \xi^2}}\right)\right].
\end{equation}
\begin{equation}
\sigma_{\text{Ch}} = \frac{G_f^2}{24\pi} \frac{\beta_f}{\beta_\chi} (s - m_f^2 + M_\chi^2),
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{8\pi} \left[M_\chi^2 \left(1 - \xi^2 \frac{8 - 28\xi^2 + 23\xi^4}{24\sqrt{1 - \xi^2}}\right)\right].
\end{equation}
\begin{equation}
\sigma_{\text{SF}} = \frac{G_f^2}{24\pi s} \frac{\beta_f}{\beta_\chi} \left[(s - 4M_\chi^2)(s - m_f^2) + 6m_f^2 M_\chi^2\right],
\end{equation}
\begin{equation}
\sigma v \approx \frac{G_f^2}{4\pi} \left[M_\chi^2 \left(1 - \xi^2 \frac{8 - 28\xi^2 + 23\xi^4}{24\sqrt{1 - \xi^2}}\right)\right].
\end{equation}
\[ \sigma_{\text{FSS}}^{\text{sc/ps}} = \frac{G_f^2}{48\pi s} \frac{\beta_f}{\beta_x} \left( s(s - M^2_X) + 6m_f M_X s + m_f^2 (16 M^2_X - s) \right), \]  
(A27)

\[ \sigma_v \approx \frac{G^2 M^2_X}{8 \pi} \left( 1 + \xi^2 \right) \left[ \sqrt{1 - \xi^2} + v^2 \frac{1 + 16 \xi + 17 \xi^2}{24 \sqrt{1 - \xi^2}} \right]. \]  
(A28)

\[ \sigma_{\text{FSS}}^{\text{sc/ps}} = \frac{G_f^2}{96\pi s} \frac{\beta_f}{\beta_x} \left( \frac{5s^2 + 80m_f^2 M^2_X}{s} - 2s(7m_f^2 + 7M^2_X + 6m_f M_X) \right), \]  
(A29)

\[ \sigma_v \approx \frac{G^2 M^2_X}{8 \pi} \left( 1 + \xi^2 \right) \left[ \sqrt{1 - \xi^2} + v^2 \frac{14 + 40 \xi + 29 \xi^2}{24 \sqrt{1 - \xi^2}} \right]. \]  
(A30)

\[ \sigma_{\text{FIV}}^{\text{vec/ax}} = \frac{G^2}{24\pi s} \frac{\beta_f}{\beta_x} \left( \frac{s(4s - 7M^2_f)}{s} + 6m_f M_X s - m_f^2 (7s - 40M^2_f) \right), \]  
(A31)

\[ \sigma_v \approx \frac{G^2 M^2_X}{4 \pi} \left[ \frac{3 \pm 2 \xi + \xi^2}{1 - \xi^2} \sqrt{1 - \xi^2} + v^2 \frac{12 \pm 31 \xi^2 + 18 \xi^4 + 29 \xi^4}{24 \sqrt{1 - \xi^2}} \right]. \]  
(A32)

\[ \sigma_{\text{FIV}}^{\text{vec/ax}} = \frac{G^2}{12\pi s} \frac{\beta_f}{\beta_x} \left( \frac{7s^2 + 76m_f^2 M^2_X}{s} - 4s(4m_f^2 + 4M^2_f + 3m_f M_X) \right), \]  
(A33)

\[ \sigma_v \approx \frac{G^2 M^2_X}{2 \pi} \left[ \frac{2 + \xi^2}{1 - \xi^2} \sqrt{1 - \xi^2} + v^2 \frac{32 \pm 64 \xi^2 + 36 \xi^3 + 47 \xi^4}{24 \sqrt{1 - \xi^2}} \right]. \]  
(A34)

\[ \sigma_{\text{FIV}}^{\text{ch}} = \frac{G^2}{48\pi s} \frac{\beta_f}{\beta_x} \left( 4m_f^2 M^2_X + s(s - m_f^2 - M^2_f) \right), \]  
(A35)

\[ \sigma_v \approx \frac{G^2 M^2_X}{8 \pi} \left[ \sqrt{1 - \xi^2} + v^2 \frac{(2 - \xi^2 + 2 \xi^4)}{24 \sqrt{1 - \xi^2}} \right]. \]  
(A36)

\[ \sigma_{\text{FIV}}^{\text{Cr}} = \frac{G^2}{24\pi s} \frac{\beta_f}{\beta_x} \left( \frac{(s - 4M^2_f)(s - m_f^2)}{s} + 6m_f^2 M^2_X \right), \]  
(A37)

\[ \sigma_v \approx \frac{G^2 M^2_X}{4 \pi} \left[ \xi^2 \sqrt{1 - \xi^2} + v^2 \frac{16 - 32 \xi^2 + 19 \xi^4}{24 \sqrt{1 - \xi^2}} \right]. \]  
(A38)

3. Vector Wimp

\[ \sigma_{\text{vec/ax}}^{\text{FIV}} = \frac{G^2}{2160\pi s} \frac{\beta_f}{\beta_x} \left[ \frac{s^4 + 22m_f^2 M^2_X + 13 M^4}{s} \right]. \]  
(A47)

\[ \sigma_{\text{vec/ax}}^{\text{FIV}} = \frac{G^2}{2160\pi s} \frac{\beta_f}{\beta_x} \left[ \frac{s^4 + 22m_f^2 M^2_X + 13 M^4}{s} \right]. \]  
(A48)

\[ \sigma_{\text{ch}}^{\text{FIV}} = \frac{G^2}{864\pi M^2_X} \frac{\beta_f}{\beta_x} \left( s - m_f^2 \right) \]  
(A49)

\[ \sigma_v \approx \frac{G^2}{36\pi} \sqrt{1 - \xi^2} \left[ \frac{(1 - \xi^2)}{4 \xi^2} \right]^2 \left[ 1 + \frac{v^2}{24} \left( \frac{(19 \xi^2)}{6} + (16 \xi^2) M_X M_\Omega + (25 \xi^2 + 6) M^2_\Omega \right) \right]. \]  
(A50)
Furthermore we define the reduced mass of the WIMP
interacting cross section at zero momentum transfer, $G_{\text{eff}}$ and coupling is independent of the quark (defined benchmark models. In a universal scenario, the definitions:

$Y$ukawa-like model ($M_\chi^2 E_{\text{m}}^2$ + $16M_\chi^2$)
$+ 2s(6m_f^2 \pm 20m_f M_{\Omega} + 16M_\chi^2 + 15M_\Omega^2)$
$+ 8M_\chi^2 s (24m_f^2 + 15M_\Omega(4m_f^2 + 3M_\chi^2) + 50m_f M_{\Omega}(2m_f^2 + M_\chi^2) + 119m_f^2 M_\chi^2 + 40M_\chi^4)$,

$$\sigma_{\nu} \approx \frac{G^2}{9\pi} \sqrt{1 - \xi^2} \left[ (1 - \xi^2)(3M_\chi^2 \pm 2\xi M_\chi M_{\Omega} + (3\xi^2 + 4)M_\chi^2) + \frac{\mu^2}{24} (3(2 + 7\xi)^2)M_\chi^2 \right.$$
$$\pm 6\xi(2 + \xi^2)M_\chi M_{\Omega} + (16 + 30\xi^2 + 29\xi^4)M_\chi^4 \right].$$ (A52)

Appendix B: Cross Sections for Direct Detection

We now give results for the dark matter–nucleon scattering cross section at zero momentum transfer, $G_{\nu}$, for all defined benchmark models. In a universal scenario, the effective coupling is independent of the quark ($G_q = G$), whereas it grows proportionally to the quark mass in a Yukawa-like model ($G_q = G m_q/m_c$). We use the following definitions:

$$f_p = \sum_{q=u,d,s} f_q G_q m_q + \frac{2}{27} \sum_{q=u,d,s} f'_q \sum_{q=c,b,t} G_q m_q,$$ (B1)
$$d_p = \sum_{q=u,d,s} G_q \Delta_p^q,$$ (B2)
$$b_p = 2G_u + G_d,$$ (B3)
$$b'_p = b_p M_\chi + 2G_u m_u + G_d m_d.$$ (B4)

with the numerical values for $f_q$ and $\Delta_q$ listed in [60, 61]:

$$f_u = 0.020 \pm 0.004,$$ (B5)
$$f_d = 0.026 \pm 0.005,$$ (B6)
$$f_s = 0.118 \pm 0.062,$$ (B7)
$$\Delta_u = -0.427 \pm 0.013,$$ (B8)
$$\Delta_d = 0.842 \pm 0.012,$$ (B9)
$$\Delta_s = -0.085 \pm 0.018.$$ (B10)

Furthermore we define the reduced mass of the WIMP proton system,

$$\mu = \frac{M_\chi M_p}{M_\chi + M_p}.$$ (B11)

The cross sections can be evaluated in a nonrelativistic approximation for the WIMP and by using the quark proton form factors listed above. See e.g. [31]. If a model is not listed, its scattering cross section equals zero, e.g. for pseudoscalar interactions that always vanish in a nonrelativistic model. Again, we agree with the respective results in [33, 34] for comparable operators.

Cross sections for real final state particles can easily be derived from the following list by setting the vector form factors $b_p$ and $d_p$ to zero and rescaling $f_p$ and $d_p$ by a factor of 2.

1. Scalar WIMP

$$\sigma_{SS}^0 \text{ Sc.} = \frac{\mu^2}{4\pi M_\chi^2} f_p^2,$$ (B12)

2. Fermion WIMP

$$\sigma_{SV}^0 \text{ Vec.} = \frac{\mu^2}{\pi} b_p^2,$$ (B13)

$$\sigma_{DF}^0 \text{ Ax.} = \frac{\mu^2}{4\pi} \left( f_p + \frac{1}{M_{\Omega}} \right)^2,$$ (B14)

$$\sigma_{FS}^0 \text{ Ps.} = \frac{\mu^2}{16\pi} b_p f_p,$$ (B15)

3. Vector WIMP

$$\sigma_{VS}^0 \text{ Sc.} = \frac{\mu^2}{4\pi M_\chi^2} f_p^2,$$ (B16)

$$\sigma_{VF}^0 \text{ Vec.} = \frac{\mu^2}{4\pi} \left( f_p + \frac{1}{M_{\Omega}} \right)^2,$$ (B17)

$$\sigma_{DF}^0 \text{ Ax.} = \frac{\mu^2}{4\pi} \left( f_p + \frac{1}{M_{\Omega}} \right)^2,$$ (B18)

$$\sigma_{FS}^0 \text{ Ps.} = \frac{\mu^2}{16\pi} b_p f_p,$$ (B19)

$$\sigma_{VF}^0 \text{ Chi.} = \frac{\mu^2}{4\pi} b'_p,$$ (B20)

$$\sigma_{DF}^0 \text{ Ax.} = \frac{\mu^2}{4\pi} \left( f_p + \frac{1}{M_{\Omega}} \right)^2,$$ (B21)

$$\sigma_{FS}^0 \text{ Ps.} = \frac{\mu^2}{16\pi} b_p f_p,$$ (B22)

$$\sigma_{VF}^0 \text{ Chi.} = \frac{\mu^2}{4\pi} b'_p.$$ (B23)
\[ \sigma_{\nu F \ Ax.}^0 = \frac{\mu^2}{4\pi} \left( f_p + \frac{b_p}{M_f} \right)^2, \] (B29)

\[ \sigma_{\nu F \ Chi.}^0 = \frac{\mu^2}{4\pi} b_p^2, \] (B30)

\[ \sigma_{V V \ Vec.}^0 = \frac{\mu^2}{\pi} b_p^2. \] (B31)

4. **Photon Loop**

If the WIMP only couples to leptons, the WIMP–proton interaction can only happen at the loop level. In that case, a low energy photon that couples to a virtual lepton pair interacts with the whole proton. This only happens for models with s–channel vector bilinears \( \psi \gamma^\mu \psi \), i.e. models which include either a, \( b_p \), or a, \( b_p \), term in the low energy tree level cross section. Results can therefore be derived as follows,

\[ \sigma_{\text{Loop}}^0 = \frac{\alpha^2 \mu}{81\pi^2} F^2(q^2) \sigma_{\text{Tree}}^0 \mid_{\text{reduced}}, \] (B32)

where the reduced cross section has to be understood as the tree level cross section given above after setting \( b_p, b_p = 1 \) and \( f_p, d_p = 0 \). This ensures that we only take the vector interaction parts. If the tree level cross section includes a \( b_p \) term, the loop factor is given as,

\[ F(q^2) \equiv \sum_l G_l f(q^2, m_l). \] (B33)

For \( b_p \) terms, it reads,

\[ F(q^2) \equiv \sum_l (m_l + M_\chi) G_l f(q^2, m_l). \] (B34)

In both cases, the loop function can be evaluated as,

\[ f(q^2, m) \equiv \frac{1}{q^2} \left[ 5q^2 + 12m^2 - 6(q^2 + 2m^2) \beta_q \coth \beta_q - 3q^2 \ln m^2/\Lambda^2 \right], \] (B35)

\[ \beta_q \equiv \sqrt{1 - 4m^2/q^2}. \] (B36)

We follow the conservative assumption of a maximum scattering angle to find \( q^2 = -4\mu^2 v^2 \) with \( \mu \) describing the reduced mass of the WIMP nucleus system and \( v = 500 \text{ km/s} \) being the typical escape velocity of a WIMP in a dark matter halo. Because of the new \( q \)-dependence of the cross section and the fact that the photon only couples to the protons inside the nucleus, the official XENON results have to be rescaled according to,

\[ \sigma_{\text{Loop}} = \sigma_{\text{Tree}} \left[ \frac{F(q^2)}{F(q^2) \cdot Z} \right]^2, \] (B37)

where \( \tilde{q} = q(M_N = M_P) \) uses the reduced mass \( \mu \) of the WIMP proton system instead. This weakens the cross section limits by about a factor of 10.

### Appendix C: Differential Cross Section for \( e^+e^- \rightarrow \chi \chi \gamma \)

#### 1. **Abbreviations**

We use the following abbreviations for the final cross section list in Table III:

- Polarisation prefactors:
  \[ C_S \equiv 1 + P^+ P^-, \quad C_V \equiv 1 - P^+ P^-, \] (C1)
  \[ C_L \equiv (1 - P^-)(1 + P^+), \quad C_R \equiv (1 + P^-)(1 - P^+). \]

- Terms with combined couplings:
  \[ G_{X \pm Y} \equiv g_X^2 \pm g_Y^2; \quad G_{XY} \equiv g_X g_Y. \] (C2)

- Relativistic velocities:
  \[ \beta \equiv \sqrt{1 - \frac{4M_\chi^2}{s}}, \quad \beta \equiv \sqrt{1 - \frac{4M_\chi^2}{s(1 - x)}}. \] (C3)

- Kinematical functions:
  \[ F_{x\theta} \equiv \frac{\alpha}{\pi} \frac{(x - 1)^2 + 1}{x \sin^2 \theta}, \] (C4)
  \[ V_{x\theta} \equiv \frac{x^2 \cos(2\theta) + (3x - 8)x + 8}{4((x - 1)^2 + 1)}. \] (C5)

We show terms that arise in the analytical evaluation of the differential photon cross section in \( e^+e^- \rightarrow \chi \chi \gamma \) but not in the Weizs"acker–Williams approximation in (C6)-(C10). They all vanish in the soft–photon limit \( x \to 0 \).

\[
A_{SF} = \frac{(1 - V_{x\theta})}{4M_\Omega^2} \frac{\tilde{s}}{1 - x} \left[ (g_s + g_p)^4 C_R + (g_s - g_p)^4 C_L \right]
\]

\[
A_{SF'} = \frac{\alpha}{8\pi M_\Omega^2} \frac{x}{1 - x} \left[ (g_s + g_p)^4 C_R + (g_s - g_p)^4 C_L \right]
\] (C6) (C7)
\[ A_{\Phi S} = \frac{(1 - V_{e\theta})}{4} \left[ C_S(s - 4M^2_\chi) + \frac{1}{1 - x} C_S(2M^2_\chi + s) \right] \] (C8)

\[ A_{VF} = 20G^2_F C_S(1 - V_{e\theta}) \frac{x}{1 - x}(s^2 + 4M^2_\chi s - 8M^4_\chi) + \left[ \frac{g^4_{CL} + g^4_{CR}}{M^4_\Omega} \right] \left[ - \frac{1}{32} x^4 \sin^2(2\theta) \sin(3s^2 + 26M^2_\chi s - 32M^4_\chi) \right] + \frac{x}{(x - 1)^2((x - 1)^2 + 1)} \]

\[ + \frac{6}{((x - 1)^2 + 1)} \sin(2s^2 + 7M^2_\chi s - 24M^4_\chi) - \frac{1}{4} \frac{1}{(1 - V_{e\theta})(7s^3 + 32M^2_\chi s^2 - 16M^2_\chi + 112M^4_\chi)} + \frac{1}{4} \frac{(1 - V_{e\theta})}{(1 - x)} \sin(2s^2 + 2M^2_\chi s + 6M^4_\chi) \] (C9)

\[ A_{VF} = \left[ \frac{g^4_{CL} + g^4_{CR}}{M^4_\Omega} \right] \left[ - \frac{1}{32} x^4 \sin^2(2\theta) \sin(3s^2 + 32M^2_\chi s - 24M^4_\chi) + \frac{x}{((x - 1)^2 + 1)} \sin(2s^2 + 12M^2_\chi s + 56M^4_\chi) \right] - \frac{1}{4} \frac{(1 - V_{e\theta})(7s^3 + 144M^2_\chi s^2 - 168M^2_\chi s + 1280M^4_\chi)}{2} + \frac{1}{4} \frac{(1 - V_{e\theta})}{(1 - x)} \sin(2s^2 + 48M^2_\chi s + 56M^4_\chi) + \frac{1}{4} \frac{(1 - V_{e\theta})(9s^3 - 272M^2_\chi s + 104M^4_\chi) + 2}{(1 - x)} \sin(2s^2 + 2M^2_\chi s + 6M^4_\chi) \right] . \] (C10)
