ABSTRACT

We present a new approach for finding matchings in dense graphs by building on Szemerédi’s celebrated Regularity Lemma. This allows us to obtain non-trivial albeit slight improvements over longstanding bounds for matchings in streaming and dynamic graphs. In particular, we establish the following results for $n$-vertex graphs:

(i) A deterministic single-pass streaming algorithm that finds a $(1 - o(1))$-approximate matching in $o(n^2)$ bits of space. This constitutes the first single-pass algorithm for this problem in sublinear space that improves over the $\frac{1}{2}$-approximation of the greedy algorithm.

(ii) A randomized fully dynamic algorithm that with high probability maintains a $(1 - o(1))$-approximate matching in $o(n)$ worst-case update time per each edge insertion or deletion. The algorithm works even against an adaptive adversary. This is the first $o(n)$ update-time dynamic algorithm with approximation guarantee arbitrarily close to one.

Given the use of regularity lemma, the improvement obtained by our algorithms over trivial bounds is only by some $(\log n)^{\Theta(1)}$ factor. Nevertheless, in each case, they show that the “right” answer to the problem is not what is dictated by the previous bounds.

Finally, in the streaming model, we also present a randomized $(1 - o(1))$-approximation algorithm whose space can be upper bounded by the density of certain Ruzsa-Szemerédi (RS) graphs. While RS graphs by now have been used extensively to prove streaming lower bounds, ours is the first to use them as an upper bound tool for designing improved streaming algorithms.

Maximum Matching, Streaming Algorithms, Dynamic Algorithms, Regularity Lemma

1 INTRODUCTION

Given a graph $G = (V, E)$, a matching $M$ in $G$ is any collection of edges that share no endpoints. Finding maximum matchings has been a cornerstone of algorithm design starting from the work of König [64] over a century ago. Nevertheless, many fundamental questions regarding the complexity of this problem have remained unresolved, specifically in modern models of computations such as streaming or dynamic graphs. Indeed, in both mentioned models, despite significant attention, there has been no improvement in certain key cases over longstanding barriers that have remained in place since the introduction of the model itself.

In this paper, we make an ever so slight improvement over these barriers, showing that the right answer to the problem must be different than what is dictated by prior bounds. Our results combine tools from extremal combinatorics, primarily Szemerédi’s Regularity Lemma [80] and its extensions, with multiple ideas (old and new) tailored to each model specifically. To put our results in more context, we start with the history of the problem in each model separately.
Graph Streaming. In this model, edges of an $n$-vertex graph appear one by one in a stream in an arbitrary order. The algorithm can read the edges in the arrival order while using a limited memory smaller than the input size, and output the solution at the end of the stream. The holy grail of algorithms here is one that uses $O(n \cdot \text{polylog}(n))$ memory and a single pass over the stream. The study of graph streaming algorithms were initiated by Feigenbaum et al. [43] who already observed that there is a straightforward 1/2-approximation algorithm for matching in $O(n \log n)$ space\(^1\); greedily maintain a maximal matching in the stream. They further proved that finding an exact maximum matching requires $\Omega(n^2)$ space, which matches the trivial algorithm that stores the entire input via its adjacency matrix.

Almost two decades since [43], there are still no better algorithms for matchings than these two straightforward solutions. On the lower bound front, a series of work by Goel et al. [50] and Kapralov [59] culminated in a recent work of Kapralov [60] that rules out better than $1/(1 + \ln 2) \approx 0.59$ approximation in $n^{1+o(1/\log \log n)}$-space. This lack of progress has led researchers to consider various relaxations of the problem, in particular by allowing a few more passes over the input (e.g., in [9, 44, 46, 58–68]) or assuming random arrival of edges in the stream (e.g., in [10, 11, 25, 42, 67]). At this point, beating 1/2-approximation factor of the greedy algorithm in $O(n \cdot \text{polylog}(n))$ space, or even much larger than that, has become one of the most open questions of the graph streaming literature; see, e.g., [44, 60, 67, 71, 82] for various references to this question.

(Fully) Dynamic Graphs. In this model, we have an $n$-vertex graph that undergoes an arbitrary sequence of edge insertions and deletions. The goal is to maintain the solution to the problem, say an approximate maximum matching of the graph, with a quick update time per each insertion or deletion. Dynamic algorithms for matchings were studied first in this model by Ivkovic and Lloyd [57] in 1993 and continue to be a highly active area of research (see, e.g., [8, 19, 20, 22–24, 26, 27, 29–33, 37, 52, 53, 63, 72, 73, 76, 78, 83] and references therein).

There is a folklore algorithm that for any $\varepsilon > 0$, maintains a $(1 - \varepsilon)$-approximate matching in $O(n/\varepsilon^2)$ (amortized) update time: Assume inductively that we have a $(1 - \varepsilon/2)$-approximate matching $M$ of the current graph; (i) for the next $(\varepsilon/2) \cdot |M|$ updates do nothing and return $M$ still as the answer; after that, (ii) compute a $(1 - \varepsilon/2)$-approximate matching of the current graph in $O(m/\varepsilon)$ time using the Hopcroft-Karp algorithm [56] where $m$ is the number of edges in the graph and repeat from step (i). Since $m = O(n \cdot |M|)$ in any graph with maximum matching size bounded by $O(|M|)$, the amortized update time will be $O(n/\varepsilon^2)$, and the correctness can be easily verified. This algorithm can also be deamortized using standard batching ideas.

For sparser graphs, this folklore algorithm was improved by Gupta and Peng [53] to achieve an $O(\sqrt{m/\varepsilon^2})$ update time where $m$ denotes the (dynamic) number of edges. Faster algorithms are only known for smaller approximations between 1/2 and 2/3 which can respectively be maintained in $O(1)$ [79] (see also [19]) and $O(\sqrt{n})$ update-times [29]. See also a recent result of [23] for update-time/approximation trade-offs between 1/2 and 2/3, and the recent breakthroughs of [21, 34] in beating 1/2-approximation in polylogarithmic time for estimating size of maximum matching. Yet, for the original $(1 - \varepsilon)$-approximation question, raised e.g. in [53], an $O(n)$ update time still remains a barrier in general.

1.1 Our Contributions

We present the first algorithms that beat the aforementioned barriers for finding matchings in streaming and dynamic graphs with non-trivial albeit quite small factors:

Result 1 (Formalized in Theorem 3). There is a randomized $(1 - o(1))$-approximate matching algorithm in single-pass streams with adversarial order of edge arrivals in $n^2/(\log^* n)^{O(1)}$ space and polynomial time.

This is the first $o(n^2)$-space algorithm for matchings in adversarial-order streams with better than 1/2-approximation guarantee. In fact, it was not known previously how to achieve a $(1 - o(1))$-approximation in $o(n^2)$ space even on random-arrival streams and even if we allow any constant number passes over the input (see [1, 2, 13, 17, 46, 70] for representative examples of multi-pass streaming matching algorithms\(^2\)). Moreover, combined with the lower bound of $O(n^2)$ space by [43] for computing exact matchings, Result 1 shows the first provable separation between the space complexity of computing nearly-optimal versus exact-optimal matchings in single-pass streams.

Result 2 (Formalized in Theorem 2). There is a randomized $(1 - o(1))$-approximate matching algorithm in fully dynamic graphs against an adaptive adversary with $n/(\log^* n)^{O(1)}$ worst case update time.

This is the first algorithm for matchings in fully dynamic graphs that achieves $o(n)$ update time for all densities with close to one approximation guarantee (this was not known before even for oblivious adversaries).

The key idea behind both these results is to maintain a matching cover—introduced by Goel et al. [50] in spirit of cut/spectral sparsifiers—that is a “sparse” subgraph which approximately preserve matchings in each induced subgraph of the input graph. We present a polynomial time algorithm for constructing $o(n^2)$-size matching covers using Szemerédi’s Regularity Lemma [80] and along the way extend them to general graphs ([50] only proves their existence and for bipartite graphs). We then show this new construction can be maintained in streaming and dynamic graphs using several new ideas combined with standard tools from prior work specific to each model. We elaborate more on our techniques in Section 2.

We also present a third result specific to the graph streaming model. All previous lower bounds for approximating matchings in

\(^1\)Throughout, we always measure the space of streaming algorithms in \text{bits}.

\(^2\)See the papers of Feldman and Zarafi [14] and Assadi and Behnezhad [11], respectively, for the state of the art in each case, and more details on previous work on each relaxation.
In conclusion, our paper shows that these longstanding barriers in computing large matchings in streaming and dynamic graphs can at least be broken by some non-trivial albeit quite small factors. Moreover, these algorithms rely on techniques and ideas that are vastly different from prior approaches used in these two models. We hope our work paves the path toward further progress on these longstanding open questions.

2 TECHNICAL OVERVIEW

Matching sparsifiers, which loosely speaking, are sparse subgraphs that approximately preserve the maximum matching have long been known to be an important tool for fully dynamic and (variants of) streaming algorithms. Some prominent examples include edge-degree constrained subgraphs (EDCS) [28, 29] and its generalizations [12, 23], kernels [8, 26, 30, 31], and matching skeletons [50]. One of our main contributions, and the key to both Result 1 and Result 2, is a new matching sparsifier based on Szemerédi’s Regularity Lemma.

Our matching sparsifier, more strongly, is a matching cover—a la Goel et al. [50]—which not only preserves an approximate maximum matching of the graph, but rather “covers” smaller matchings of it as well. Let us formalize this. For a given graph \( G \), we write \( \mu(G) \) to denote the maximum matching size of \( G \), and write \( G(A, B) \) to denote the bipartite subgraph of \( G \) between some disjoint vertex subsets \( A, B \). We say a subgraph \( H \) of \( G \) is an \( \alpha \)-matching cover for bipartite graphs

\[
|A| \leq \frac{\log n}{\alpha} \quad \text{and} \quad |B| \leq \frac{\log n}{\alpha}.
\]

In this paper, we prove that there is an \( O(n^{\omega}) \)-time\(^5\) offline algorithm that computes an \( o(n^2) \)-edge \( \alpha \)-matching cover of any \( n \)-vertex graph (not necessarily bipartite). Our algorithm builds on Szemerédi’s Regularity Lemma (and its algorithmic version due to Alon et al. [5]). We first explain how our offline algorithm for obtaining a matching cover works, and then outline its use in obtaining improved dynamic matching and streaming algorithms.

2.1 Matching Covers via Regularity Lemma

Roughly speaking, Szemerédi’s regularity lemma [80] says that the vertices of any graph can be partitioned into a small irregular part \( C_0 \) with \(|C_0| = o(n)\), plus \( k \) other equal-size parts \( C_1, \ldots, C_k \) for some \( k \in [o(1), \log n] \). The latter \( k \) parts have the property that all but \( o(1) \)-fraction of the \( C_i, C_j \) pairs are regular: for any pair of subsets \( X \subseteq C_i, Y \subseteq C_j \) with large enough size, the edge density between \( X, Y \) is similar to that of \( C_i, C_j \). Therefore, if the edges

\[^5\]Here and throughout, \( \omega = 2.37386 \) is the matrix multiplication exponent with current best bounds achieved by Alman and Williams [3].
between $C_i, C_j$ are dense to start with, the density will also be high between every large enough $X \subseteq C_i, Y \subseteq C_j$ pair.

It is not difficult to see that by regularity, any large matching between a dense regular pair $C_i, C_j$ can be mostly preserved if we subsample edges between them at a sufficiently high rate $p = o(1)$. In particular, the subsampled graph will be a matching cover of the graph induced by edges between the regular pair $C_i, C_j$. This suggests a natural strategy for building an $o(1)$-matching cover with $o(n^2)$ edges: subsample the edges between dense regular $C_i, C_j$ pairs at rate $p = o(1)$ and take all other edges. We would like to show that this is an $o(1)$-matching cover for some $\alpha = o(1)$.

This idea runs into the following problem. Suppose we have an $(an)$-size matching $M$ whose edges are evenly distributed across all $\binom{n}{2}$ pairs of $C_i, C_j$, then the number of edges of $M$ between each $C_i, C_j$ pair is only $O(\alpha \cdot n/k^2)$. This means that only an $O(\alpha/k)$ fraction of vertices in $C_i, C_j$ are matched to each other – this is unfortunately way too small to invoke the regularity property.

We get around this issue by first focusing on solving an $\alpha$-hitting set problem: find one edge between endpoints of any $(an)$-size matching – we will show later on using a similar argument as in [50] that this is sufficient for obtaining an $\alpha$-matching cover. Now to fix our problem about an $(an)$-size matching whose edges are distributed across many pairs, we present a strategy for consolidating the support of a matching over different pairs. This consolidation argument shows that whenever there is a large matching between dense regular $C_i, C_j$ pairs, there must also exist another (almost as) large matching $M'$ that is supported on the same set of vertices $V(M)$ but only uses edges between a small number of such $C_i, C_j$ pairs. As a result, there must exist one pair of $C_i, C_j$ where a substantial fraction of vertices is matched to each other, to which we are now able to apply regularity to prove the existence of an edge between them in the subsampled graph (which solves our $\alpha$-hitting set problem). At a high level, our argument for consolidating the support of the matching is proved by (i) viewing the matching $M$ as a fractional matching in a meta graph obtained by contracting each $C_j$ into a supernode; and (ii) rounding the fractional matching by an edge sampling process.

All in all, using the algorithm of [5] for finding the regularity lemma partition in $O(n^{\omega})$ time, and a direct sampling algorithm between dense regular pairs, this step gives us an $O(n^{\omega})$ time and $O(n)$ space algorithm for finding an $o(1)$-matching cover of size $n^2/(\log^* n)^{2+1}(1)$ for some $\alpha = 1/(\log^* n)^{2+1}$.

### 2.2 Applications of Matching Cover

**A fully dynamic matching algorithm.** The matching cover algorithm above is offline. But observe that since the algorithm takes $O(n^{\omega}) = n^{3-\Theta(1)}$ time, the time spent per edge in a dense instance is sublinear in $n$. This gives hope that perhaps such a matching cover can be maintained in $o(n)$ time, and indeed we show this to be the case.

Our algorithm roughly proceeds by re-computing an $o(1)$-matching cover every $\tilde{O}(n^{\omega})$ updates, and then using the $O(\sqrt{m})$-update time data structure by Gupta and Peng [53] to maintain a nearly optimal matching in the matching cover through the subsequent $\tilde{O}(n^{\omega-1})$ updates. Since the matching cover only has $o(n^2)$ edges, we immediately get an update time of $o(n)$ for the Gupta-Peng algorithm. To argue the correctness, we show that the matching cover found by our offline algorithm has the additional feature that it is robust to edge updates: not only is it an $o(1)$-matching cover of the graph at the time we compute it, but it remains an $o(1)$-matching cover throughout any arbitrary sequence of $n^{2-\omega(1)}$ updates. This suffices to show that our algorithm can dynamically maintain an approximate matching with an additive error $o(n)$.

When the number of edges is close to $n^2$, this additive approximation becomes a $(1-o(1))$-multiplicative approximation, since the maximum matching size is itself $\Omega(n)$. On the other hand, when the number of edges is $o(n^2)$, directly applying the Gupta-Peng data structure gives us a nearly-optimal matching in $o(n)$ update time. Our final algorithm then balances the dense and the sparse regimes together to maintain a $(1-o(1))$-approximate matching in $o(n)$ update time.

**Streaming algorithms.** Our streaming algorithm in Result 1 is also based on using matching covers as a natural sparsifier for matchings. The algorithm works through a series of buffers of edges $B_1, B_2, \ldots$. The first buffer $B_1$ reads the edges from the input until it gets “full,” i.e., receives some $o(n^2)$ edges (which is some constant factor non-streaming algorithm and sends its edges to the buffer $B_2$; then, we “restart” $B_1$ by emptying all its current edges and letting it collect more edges from the stream. The same approach is repeated across all other buffers as well. The number of these buffers can be bounded as only a constant fraction of edges in one buffer can make their way to the next one, eventually reaching a buffer that never gets full. This also implies that fewer edges will be further “sparsified” in each matching cover, thus the error occurred due to the approximation guarantee of the matching cover does not get amplified “too much”. Thus, using this algorithm along with our matching cover algorithm for regularity lemma, leads to an $o(n^2)$-space $(1-o(1))$-approximation algorithm for single-pass streaming matchings.

The strategy we outlined above works for any choice of matching cover (as long as we can compute it in a small space offline), thus, we can alternatively implement the matching cover subroutine by simply enumerating all subgraphs of the input (in exponential time) and the optimal one. An argument due to Goel et al. [50]—extended in our paper to general graphs—shows that density of optimal matching covers can be bounded by the density of certain RS graphs. To obtain Result 3, we also need to turn the additive approximation guarantee of the matching cover into a multiplicative bound. This is done using vertex-sparsification methods of Assadi et al. [16] and Chitnis et al. [39] (as specified in [15]) that reduce the number of vertices in the graph down to its maximum matching size without reducing the matching size by much. This turns the additive guarantee of the matching cover into a multiplicative one, giving us Result 3 as well.

Finally, one key step in making the above algorithms work is to store the $o(n^2)$ edges they have in the buffers more efficiently than
spending Θ(\log n) bits per each (which is prohibitive for us given the extremely small improvement in the space the algorithms get over the trivial \( O(n^2) \) bound). This is done by storing the edges via the succinct dynamic dictionary of Raman and Rao [75] (see Section 3.4) and then performing all the computation in this compressed space instead.

3 PRELIMINARIES

Notation. For any integer \( t \geq s \geq 1 \), we let \([t] := \{1, \ldots, t\}\) and let \([s, t] := \{s, \ldots, t\}\). We use the term with high probability, abbreviated w.h.p., to imply probability at least \( 1 - 1/n^c \) for any desirable large constant \( c \geq 1 \) (that might affect the hidden constants in our statements).

For a graph \( G = (V, E) \), we use \( V(G) = V \) to denote the set of vertices and \( E(G) = E \) to denote the edges. For any subsets of edges \( F \subseteq E \) and disjoint subsets of vertices \( X, Y \subseteq V \), we use \( X(F) \) and \( Y(F) \) to denote the edges of \( F \) incident on \( X \) and \( Y \), respectively, and \( F(X, Y) \) to denote the edges of \( F \) going between \( X \) and \( Y \). Similarly, we use \( G[X] \) and \( G[X, Y] \) to respectively denote the subgraph of \( G \) induced on vertices \( X \) and the bipartite subgraph of \( G \) between vertices \( X \) and \( Y \). For any \( p \in [0, 1] \), we use \( G[p] \) to denote a random subgraph of \( G \) that includes each edge of \( G \) independently with probability \( p \).

For any graph \( G \), \( \mu(G) \) denotes the size of the maximum matching in \( G \). We have,

**Fact 3.1.** Any graph \( G \) has at most \( 2n \cdot \mu(G) \) edges.

The proof of Fact 3.1 is simply based on picking an arbitrary edge of the graph and adding to a matching, removing at most \( 2n \) edges incident on this edge, and repeating until the graph is empty.

We will also need the following version of Hall’s theorem.

**Proposition 3.2** (Extended Hall’s marriage theorem; cf. [54]). Let \( G = (L, R, E) \) be any bipartite graph with \( |L| = |R| = n \). Then \( \max(|A| - |N_G(A)|) = n - \mu(G) \), where \( A \) ranges over all subsets of \( L \) and \( R \), and \( N_G(A) \) denotes the neighbors of \( A \) in \( G \).

3.1 Szemerédi’s Regularity Lemma

Szemerédi’s Regularity Lemma [80] is a powerful tool in extremal combinatorics. Loosely speaking, it says that every dense graph can be well-approximated by a “small” collection of random-like subgraphs. To formally state the lemma, we need a few definitions.

Let \( G = (V, E) \) be any given graph, and \( A, B \subseteq V \) be any disjoint vertex subsets. We write \( e(A, B) \) to denote the number of edges between \( A \) and \( B \). If \( A, B \neq \emptyset \), we define the **density** of edges between \( A \) and \( B \) by:

\[
d(A, B) := \frac{e(A, B)}{|A||B|}.
\]

For a parameter \( \gamma \in (0, 1) \), we say \( (A, B) \) is \( \gamma \)-regular if for every \( X \subseteq A \) and \( Y \subseteq B \) satisfying \( |X| \geq \gamma \cdot |A| \) and \( |Y| \geq \gamma \cdot |B| \), we have \( |d(A, B) - d(X, Y)| < \gamma \).

Let \( C_0, C_1, \ldots, C_k \) be a partition of the vertex set \( V \). We say this partition is **equitable** if the classes \( C_1, \ldots, C_k \) all have the same size. We will call \( C_0 \) the exceptional class. We say this partition is \( \gamma \)-regular if both of the following statements are true:

1. It is equitable and \( |C_0| \leq \gamma n \).
2. All but at most \( \gamma \left( \frac{k}{2} \right) \) of the pairs \( C_i, C_j \) for \( 1 \leq i < j \leq k \) are \( \gamma \)-regular.

Instead of the original formulation of Szemerédi’s Regularity Lemma in [80], we state an algorithmic version of it due to Alon et al. [5].

**Proposition 3.3** ([5]). There exists a function \( Q : \mathbb{R}^+ \times \mathbb{R}^+ \to \mathbb{R}^+ \) satisfying \( \log^* Q(x, y) \leq \text{poly}(x, y) \) for all \( x, y \), such that, given any \( n \)-vertex graph \( G = (V, E) \) and \( \gamma \in (0, 1) \), one can find in \( n^{Q(\log n, 1/\gamma)} \) time a \( \gamma \)-regular partition of \( V \) into \( k+1 \) classes such that \( t \leq k \leq Q(t, 1/\gamma) \).

The algorithm in Proposition 3.3 can also be implemented in a space-efficient manner (which is needed for our streaming algorithms). The proof is deferred to the full version.

**Proposition 3.4.** Given query access to the adjacency matrix, the algorithm in Proposition 3.3 can be implemented in \( O(n \cdot Q(t, 1/\gamma) \log n) \) space and \( \text{poly}(n, Q(t, 1/\gamma)) \) time.

3.2 Fox’s Triangle Removal Lemma

Similar to the Regularity Lemma, the Triangle Removal Lemma is another highly useful tool in extremal combinatorics. While original proofs of this lemma were based on the regularity lemma, Fox [47] presented a proof that bypasses regularity lemma and thus obtains stronger bounds. We will use this result also in one of our streaming algorithms.

**Proposition 3.5** ([47]). There exists an absolute constant \( b > 1 \) such that the following is true. For any \( \gamma \in (0, 1) \) let \( \delta := \delta(\gamma) \) be inverse of the tower of two of height \( b \cdot \log (1/\gamma) \), i.e., \( \delta^{-1} = 2 b \log(1/\gamma) \). Then, any \( n \)-vertex graph with at most \( \delta \cdot n^3 \) triangles can be made triangle-free by removing at most \( \gamma \cdot n^3 \) edges.

3.3 Ruzsa-Szemerédi Graphs

A matching \( M \) in a graph \( G \) is called an induced matching if the subgraph \( G \) induced on vertices of \( M \) only contains the edges of \( M \) itself; in other words, there are no other edges between the vertices of this matching.

**Definition 3.6.** For integers \( r, t \geq 1 \), a graph \( G = (V, E) \) is called an \((r, t)\)-Ruzsa-Szemerédi graph (RS graph for short) if its edge-set \( E \) can be partitioned into \( t \) induced matchings \( M_1, \ldots, M_t \), each of size \( r \). For any integer \( n \geq 1 \) and parameter \( \beta \in (0, 1/2) \), we use \( \text{RS}(n, \beta) \) to denote the maximum number of edges in any \( n \)-vertex RS graph with induced matchings of size \( \beta \cdot n \).

RS graphs have been extensively studied as they arise naturally in property testing, PCP constructions, additive combinatorics, streaming algorithms, graph sparsification, etc. (see, e.g., [4, 6, 7, 12, 35, 45, 49, 50, 55, 61, 81]). In particular, a line of work initiated by Goel et al. [50] have used different constructions of these graphs to prove communication complexity and streaming lower bounds for graph streaming algorithms [11, 14, 16, 18, 38, 41, 50, 59, 60, 65]. In this
work however, we shall use them as an upper bound tool. The only other upper bound application of these graphs in a similar context that we are aware of is the communication protocols of [50]; they show that to obtain a one-way communication protocol for \(e \cdot n\)-additive approximation of matchings, roughly \(O(RS(n, e))\) communication is sufficient and also necessary.

We establish a simple property of the \(RS(n, \beta)\) function in Definition 3.6 that relates density of different RS graphs with similar parameters (see full version for the proof).

**Claim 3.7.** For any integer \(n \geq 1\) and real \(0 < \beta < 1\), \(RS(2n, 3\beta) \leq O(1) \cdot RS(n, \beta)\).

### 3.4 Succinct Dynamic Dictionaries

We need to use succinct dynamic dictionaries from prior work however, we shall use them as an upper bound tool. The only other upper bound application of these graphs in a similar context that we are aware of is the communication protocols of [50]; they show that to obtain a one-way communication protocol for \(e \cdot n\)-additive approximation of matchings, roughly \(O(RS(n, e))\) communication is sufficient and also necessary.

We establish a simple property of the \(RS(n, \beta)\) function in Definition 3.6 that relates density of different RS graphs with similar parameters (see full version for the proof).

**Claim 3.7.** For any integer \(n \geq 1\) and real \(0 < \beta < 1\), \(RS(2n, 3\beta) \leq O(1) \cdot RS(n, \beta)\).

### 4 A MATCHING COVER VIA REGULARITY

**Lemma 3.6** that relates density of different RS graphs with similar parameters (see full version for the proof).

**Claim 3.7.** For any integer \(n \geq 1\) and real \(0 < \beta < 1\), \(RS(2n, 3\beta) \leq O(1) \cdot RS(n, \beta)\).

#### 4.1 First Step: A Hitting Set Argument

In this section, we give an algorithm for finding an \(\alpha\)-hitting set, defined below. We later show in Section 4.2 that this can be turned into a matching cover.

**Definition 4.2.** A subgraph \(H\) of an \(n\)-vertex graph \(G\) is an \(\alpha\)-hitting set of \(G\) if for any disjoint subsets of vertices \((A, B)\) in \(G\) satisfying \(|A| = |B| = an \text{ and } \mu(G[A, B]) = an\), there is at least one edge between \(A\) and \(B\) in \(H\).

The following lemma is our main guarantee of this section.

**Lemma 4.3.** Given any \(n\)-vertex graph \(G\), for some \(\alpha = (\log^* n)^{-\Omega(1)}\), there is an \(O(n^\alpha \log n)\) time algorithm, formalized below as Algorithm 1, for finding an \(\alpha\)-hitting set \(H\) of \(G\) with at most \(n^2/(\log^* n)^{\Omega(1)}\) edges.

It is not hard to see that Algorithm 1 outputs a subgraph with \(O(n^\alpha \log n)\) edges, since essentially the dense parts of the decomposition are subsampled and there are ‘few’ other edges in the graph. The following claim formalizes this.

**Claim 4.4.** The output \(F\) of Algorithm 1, w.h.p., has at most \(O(\gamma n^2)\) edges.

The harder part of the proof, is to show that the sparse subgraph returned by Algorithm 1 is indeed a matching cover. We continue with the following claim.

**Claim 4.5.** W.h.p., it holds for all \(X \subseteq C_i, Y \subseteq C_j\) such that \((C_i, C_j)\) a good pair, \(|X| \geq \gamma |C_i|\), and \(|Y| \geq \gamma |C_j|\) that \(|F_3(X, Y)| > n^2/\log^4 n\).

Next, we prove the following lemma on consolidating the support of an arbitrary fractional matching so that each non-zero variable takes a sufficiently large value.

**Algorithm 1.** The construction of the matching cover for Theorem 1.

Let \(t \leftarrow (\log^* n)^\delta, \gamma \leftarrow (\log^* n)^{-\delta}\) for some constant \(\delta \in (0, 1)\) such that \(Q(t, 1/\gamma) \leq \log n\).

(i) Run the algorithm in Proposition 3.3 to obtain a \(y\)-regular partition \(C_0, \ldots, C_k\) with \(t = (\log^* n)^\delta \leq k \leq Q(t, 1/\gamma) \leq \log n\).

(ii) Let \((C_i, C_j)\) for \(i \neq j\). We say \((C_i, C_j)\) is good if (i) \(i, j \neq 0\), (ii) it is \(y\)-regular, and (iii) \(d(C_i, C_j) \geq 8y\). Otherwise, we say \((C_i, C_j)\) is bad.

(iii) Let \(F_3 \subseteq E\) be a subset of edges obtained by \(F := F_1 \cup F_2 \cup F_3\) where

(a) \(F_1\) contains the edges between the bad pairs; i.e. \(F_1 := \bigcup_{i \leq j} C_{i} \times C_{j}\).

(b) \(F_2\) contains the edges within each class; i.e. \(F_2 := \bigcup_{0 \leq i \leq k} E \cap (C_i \times C_i)\).

(c) \(F_3\) is obtained by sampling the edges between good pairs with probability \(p = 10/\log^2 n\); i.e. \(F_3 := \bigcup_{C_i \times C_j} (E \cap (C_i \times C_j))[p]\).

(iv) Return \(F\).
Lemma 4.6. Let x be any fractional matching (not necessarily in the matching polytope). For any \( \epsilon \in (0, 1) \), there is a fractional matching \( y \) such that all the following hold:

1. For any vertex \( v \), \( y_v \leq x_v \), where here \( y_v := \sum_{e \ni v} y_e \) and \( x_v := \sum_{e \ni v} x_e \).
2. suppy(\( y \)) \( \subseteq \) supp(x). That is, if \( y_e > 0 \) for some edge \( e \), then \( x_e > 0 \).
3. For any edge \( e \), either \( y_e = 0 \) or \( y_e \geq \frac{\epsilon^2}{12 \ln(1/\epsilon)} \).
4. \( |y| \leq |x| - 2\epsilon n \), where here \( |y| := \sum_{e \ni v} y_e \) and \( |x| := \sum_{e \ni v} x_e \).

We are now ready to prove that Algorithm 1 returns a \((1-\epsilon)\)-matching-cover w.h.p.

Lemma 4.7. The output of Algorithm 1 is, w.h.p., an \( \alpha \)-hitting set of \( G \) for \( \alpha = \Theta(\gamma(1/\gamma)^{1/3}) = (\log n)^{-\Omega(1)} \).

4.2 Second Step: From Hitting Set to Matching Cover

We now prove that any subgraph satisfying the hitting set requirement (Definition 4.2) is also a matching cover (Definition 4.1). This will follow from Hall’s theorem (Proposition 4.2), and the proof similar to that of Lemma 9.3 in [30].

Lemma 4.8 (From Hitting Set to Matching Cover). Let \( G = (V, E) \) be any graph that is not necessarily bipartite. Then any subgraph \( H \) of \( G \) that is an \( \alpha \)-hitting set is also an \( \alpha \)-matching-cover of \( G \).

We are now ready to prove Theorem 1.

Proof of Theorem 1. The output of Algorithm 1 being an \( \alpha \)-hitting set was proved in Lemma 4.7. By Lemma 4.8, the output subgraph is an \( \alpha \)-matching-cover. This matching cover having at most \( O(n^2/\alpha \log n)^{\Omega(1)} \) edges was proved in Claim 4.4. Finally, the running time follows from the algorithm of Proposition 3.3 for finding the regularity decomposition, and the fact that \( O(t, 1/\gamma) \leq \log n \) in Algorithm 1. 

5 A FULLY DYNAMIC ALGORITHM VIA MATCHING COVERS

In this section, we show that the matching cover of Section 4 can be used to prove the following result in the fully dynamic model.

Theorem 2. There is a randomized, fully dynamic algorithm that maintains with high probability a \((1 - \alpha)\)-approximate matching under (possibly adversarial) edge updates. The algorithm has initialization time \( O(n^2 \alpha \log n) \) and worst-case update time \( n/(\log n)^{\Omega(1)} \).

We start by giving an overview of our algorithm. We first describe a strategy that enables us to maintain an approximate matching with additive error \( o(n) \), and latter explain how to make the approximation guarantee multiplicative. We re-compute an \((1-\epsilon)\)-matching cover of the current graph every \( \Theta(n^{\alpha-1} \log^2 n) \) updates, and then pretend as if the matching cover is the entire graph, and use the \( O(\sqrt{m}) \) update-time algorithm of Gupta and Peng [53], stated below as Proposition 5.1, to maintain a nearly optimal matching.

Algorithm 2. A fully dynamic algorithm for Theorem 2.

Input: An \( n \)-vertex fully dynamic graph \( G \) subject to edge insertions and deletions.

Output: A (dynamically changing) \((1 - \epsilon)\)-approximate maximum of \( G \).

Parameters: We set \( t, \gamma, \delta \) as in Algorithm 1, and set \( \epsilon = 10(\log n)^{-\delta/64} \).

Sparse regime:

1. Whenever the number of edges in \( G \) falls below \( n^2/(\log n)^{\delta/8} \), switch to the dense regime.

2. Use Proposition 5.1 on the whole graph \( G \) to maintain a \((1 - \epsilon)\)-approximation.

Dense regime:

1. Whenever the number of edges in graph \( G \) falls below \( n^2/(\log n)^{\delta/8} \), restart the algorithm of Proposition 5.1 on the whole graph \( G \) to maintain a \((1 - \epsilon)\)-approximate matching of it, and switch to the sparse regime.

2. Do the following every \( n^{\alpha-1} \log^2 n \) updates (including before the first update):
   a. Use Algorithm 1 to construct an \((1-\epsilon)\)-matching cover of \( G \) in \( O(n\alpha \log n) \) time (see Theorem 1).
   b. Restart the algorithm of Proposition 5.1 for maintaining a \((1 - \epsilon)\)-approximation of subgraph \( F \).

3. Upon insertion of an edge \( e \), let \( F \leftarrow F \cup \{e\} \) and trigger an edge insertion to the algorithm of Proposition 5.1 we use on \( F \).

4. Upon deletion of an edge \( e \), if \( e \in F \), let \( F \leftarrow F \setminus \{e\} \) and trigger an edge deletion to the algorithm of Proposition 5.1 we use on \( F \); otherwise ignore the deletion.

First, it is easy to see that the amortized update time of this strategy is \( o(n) \), as the computation time \( O(n^2 \log n) \) of the matching cover gets amortized over \( \Theta(n^{\alpha-1} \log^2 n) \) updates to \( o(n) \), and the number of edges in the matching cover is \( o(n^2) \). Then to argue the correctness, we have to show that the matching cover found by our offline algorithm is robust to edge updates - that is, it remains an \((1-\epsilon)\)-matching-cover throughout the following \( \Theta(n^{\alpha-1} \log^2 n) \) updates. This is indeed a feature of our offline algorithm: in particular, the number of edges between each pair of large enough \( X \subseteq C_i, Y \subseteq C_j \) for dense, regular \( C_i, C_j \) pairs is \( O(n^2) \), which means that the hitting set property will be preserved as long as \( \ll n^2 \) edges have been deleted, and as a result the subgraph obtained by our algorithm remains an \((1\)-matching-cover throughout the following \( \Theta(n^{\alpha-1} \log^2 n) \ll n^2 \) updates, as desired.

To turn the additive approximation guaranteed to a multiplicative one, we will deal with “sparse” and “dense” regimes separately. Specifically, when the number of edges is at most \( n^2/(\log n)^{\Omega(1)} \), we simply use the Gupta-Peng algorithm to maintain a \((1 - \epsilon)\)-approximation in \( n/(\log n)^{\Omega(1)} \) update time. On the other hand, when the graph is dense, we first use the matching cover of Theorem 1 to sparsify the graph while preserving its maximum matching.
then run Proposition 5.1 on this sparse graph to maintain a \((1 - \epsilon)\)-approximate matching of it in \(n/(\log^* n)^{\Omega(1)}\) update-time. We also set up a “buffer zone” in the thresholds for switching between the two algorithms so that we do not pay the switching overhead too often.

We now present our algorithm. Here, we only show an algorithm with initialization time \(O(n^2 \log n)\) and amortized update time \(n/(\log^* n)^{\Omega(1)}\), which we believe suffices to demonstrate the main idea. We defer the discussion on how to make the update time worst-case in the full version.

**Proposition 5.1** ([53]). There is a deterministic, fully dynamic algorithm for maintaining a \((1 - \epsilon)\)-approximate matching with initialization time \(O(m_0 \epsilon^{-1})\) and worst-case update time \(O(\sqrt{m \epsilon^{-2}})\), where \(m_0\) is the number of edges in the initial graph, and \(m\) is the maximum number of edges in the graph throughout the updates.

Our algorithm is formally presented in Algorithm 2. We now turn to analyze Algorithm 2. First, we prove that it has our desired update-time via amortization. As we will later show how the algorithm can be deamortized. The proof is deferred to the full version.

**Claim 5.2.** The amortized update-time of Algorithm 2 is \(n/(\log^* n)^{\Omega(1)}\).

Next, we prove that Algorithm 2 maintains a \((1 - o(1))\)-approximate matching w.h.p.

**Claim 5.3.** At any point, the output of Algorithm 2 is w.h.p. a \((1 - o(1))\)-approximate maximum matching of \(G\). This holds, in particular, against an adaptive adversary that is aware of both the output and the state of the algorithm.

Proof. For the sparse regime, this directly follows from the correctness of Proposition 5.1 since we run it on the entire graph \(G\). We thus focus on the dense regime.

First, note that in the dense regime there are at least \(m \geq n^2/(2(\log^* n)^{\delta/8})\) edges in the graph. Observe that any \(n\)-vertex \(m\)-edge graph has a matching of size at least \(m/(2n - 1)\): iteratively pick an arbitrary free edge, add it to the matching, and remove its endpoints from the graph; each step only removes at most \((2n - 1)\) edges, thus the matching must have size at least \(m/(2n - 1)\). From this, we get that whenever the algorithm is in the dense regime, there is a matching of size at least \(\mu(G) \geq n/(4(\log^* n)^{\delta/8})\) in it.

Next, we claim that at any point in the dense regime, \(F\) is an \(\alpha\)-matching cover of \(G\) (Definition 4.1), where as defined in Lemma 4.7,

\[
\alpha = \Theta((\log(1/\gamma))^{1/3}) = \Theta((\log^* n)^{-\delta} \log((\log^* n)^{\delta}))^{1/3}) = O((\log^* n)^{-\delta/4}).
\]

By Lemma 4.8, to show this, it suffices to show that \(F\) is an \(\alpha\)-hitting set of \(G\) (Definition 4.2) at any point in the dense regime. To see this, observe that immediately after we call Algorithm 1, \(F\) must be an \(\alpha\)-hitting set of \(G\) simply by the guarantee of Theorem 1. However, for the next \(n^{\alpha-1}(\log^* n)\) updates until we re-run Algorithm 1, both the graph \(G\) and \(F\) change due to the updates to the graph. Observe that edge insertions cause no problem since any edge added will be added to \(F\) as well. But edge deletions may cause a problem. In particular, recall that we subsample \(o(1)\) fraction of edges of the good pairs in Algorithm 1, and if they are all removed then we no longer have an \(\alpha\)-hitting set. Indeed, given that the adaptive adversary is aware of this sampled subset, he can attempt to remove these edges one by one. The crucial observation, here, is that right after we call Algorithm 1, Claim 4.5 guarantees that there are w.h.p. at least \([F_3(X,Y)] \geq n^2/\log^6 n\) subsampled edges between any two large enough subsets \(X \subseteq C_i, Y \subseteq C_j\) of any good pair \((C_i, C_j)\).

On the other hand, our guarantee of Theorem 1 that \(F\) is an \(\alpha\)-hitting set only requires \([F_3(X,Y)] > 0\). As a result, even if the adversary attempts to remove edges of \(F_3\) one by one within the next \(n^{\alpha-1}(\log^* n)\) updates, \(F_3(X,Y)\) will remain non-empty and so \(F\) remains an \(\alpha\)-hitting set.

Moreover, since \(F\) is an \(\alpha\)-matching cover of \(G\), we get from Definition 4.1, taking \(M^*\) to be an arbitrary maximum matching of \(G\) and taking sets \(A\) and \(B\) to each include one endpoint of each edge in \(M^*\) arbitrarily, we get that

\[
\mu(F) \geq \mu(F[A,B]) \geq \mu(G[A,B]) - an = |M^*| - an = \mu(G) - an.
\]

Putting together the bounds above, we get that at any point during the updates in the dense regime, \(F\) includes a matching of size at least

\[
\mu(F) \geq \mu(G) - an = \mu(G) - O(n/(\log^* n)^{\delta/4}) \geq (1 - o(1))\mu(G),
\]

where the last equality holds since \(\mu(G) \geq \Omega(n/(\log^* n)^{\delta/8})\) as discussed above. Running the algorithm of Proposition 5.1 on top of this, we maintain a \((1 - \epsilon)(1 - o(1))\mu(G) = (1 - o(1))\mu(G)\) size matching overall.

\[\square\]

### 6 SINGLE-PASS STREAMING ALGORITHMS

We prove Result 1 and Result 3 in this section. Both algorithms rely on using matching covers iteratively in the same way and differ primarily on how they compute matching covers and some additional steps. Because of this, we first present and prove a generic result that uses matching covers in a blackbox way to obtain a streaming algorithm for finding matching covers and then extend it separately to obtain for Result 1 and Result 3. When presenting our results, we focus more on the correctness of our algorithms, but defer proofs of the space usage to the full version.

#### 6.1 A Streaming Algorithm for Matching Covers

We present an algorithm that computes the matching cover of a graph presented in a stream by iteratively computing matching covers of smaller subsets of the stream without losing “much” on the quality of the final matching cover. For technical reasons that will become clear later, we need this algorithm to work for multi-graphs as well.

**Proposition 6.1.** For any integer \(k \geq 1\) and any \(\alpha \in (0, 1/10)\), there exists a single-pass streaming algorithm that computes an \(\alpha\)-matching cover of \(n\)-vertex multi-graphs with at most \(m\) edges in space

\[
O\left(\frac{m}{k} \cdot \log\left(\frac{n^2 \cdot k}{m}\right) + MC(n, \alpha/2k) \cdot \log\left(\frac{n^2}{MC(n, \alpha/2k)}\right) \cdot \log k\right);
\]

here, we assume we are given a subroutine Matching-Cover that given adjacency matrix access to any \(n\)-vertex graph with \(m/k\) edges,
can compute an \((a/2k)\)-matching cover with \(\text{MC}(n, a/2k) \leq m/2k\) edges in \(O(m/k \cdot \log(n^2 \cdot k/m))\) space. The streaming algorithm requires calling Matching-Cover \(O(k)\) times and is deterministic as long as the Matching-Cover subroutine is deterministic.

The algorithm in Proposition 6.1 is based on a novel use and modification of the widely used “Merge and Reduce” technique in the streaming literature (used previously e.g., for quantile estimation [62, 69] or cut/spectral sparsifiers [71]). We give a high level overview of the algorithm here and present the formal description in Algorithm 3.

The algorithm maintains \(t := O(\log k)\) different buffers \(B_1, \ldots, B_t\) of edges throughout the stream (all these buffers store their edges using the succinct dynamic dictionary of Proposition 3.8 to save space). Buffer \(B_i\) simply starts reading edges from the stream until it collects \(m/k\) edges; it will then use the (offline) subroutine Matching-Cover over these edges with parameter \(\alpha' = a/2k\) to obtain an \(\alpha'\)-matching cover of the subgraph of input on edges in \(B_i\). Edges of this matching cover are then inserted to buffer \(B_2\) and we empty buffer \(B_1\), which will continue reading edges from the stream again. In the mean time, whenever buffer \(B_2\) gets "full", this time meaning that it receives twice as many edges as \(\text{MC}(n, \alpha')\), we compute another \(\alpha'\)-matching cover using Matching-Cover, this time over the edges in \(B_2\), pass them to buffer \(B_3\), and empty \(B_2\) which continues receiving edges from buffer \(B_1\). This process is done the same way across all buffers until all edges of the stream have passed (we prove buffer \(B_t\) never gets full so not having a buffer \(B_{t+1}\) is not a problem). At the end, we argue that the edges that are remained across all buffers \(B_1, \ldots, B_t\) at the end of the stream form an \(\alpha\)-matching cover of the input.

Algorithm 3. An algorithm for Proposition 6.1.

**Input:** A multi-graph \(G = (V, E)\) in the stream with \(n\) edges and at most \(m\) edges. We are also given integer \(k \geq 1\) and approximation parameter \(\alpha > 0\), and access to the (offline) subroutine Matching-Cover as specified in Proposition 6.1.

**Output:** An \(\alpha\)-matching cover of \(G\).

**Parameters:** We set \(t := O(\log k + 2)\) and \(\alpha' := a/2k\).

(i) Maintain the following buffers of edges \(B_1, \ldots, B_t\) using succinct dynamic dictionary of Proposition 3.8 (we specify the details in Lemma 6.2):

(a) Buffer \(B_1\): add any arriving edge \((u, v)\) arrives in the stream to \(B_1\). Once size of \(B_1\) reaches \(m/k\), run Matching-Cover to find an \(\alpha'\)-matching-cover of the subgraph \((V, B_1)\) of \(G\) and add all those edges to \(B_2\). Restart \(B_1\) by deleting all its current edges.

(b) Buffers \(B_i\) for \(i > 1\): once size of \(B_i\) reaches \(2 \cdot \text{MC}(n, \alpha')\), run Matching-Cover to find an \(\alpha'\)-matching-cover of the subgraph \((V, B_i)\) of \(G\) and add all those edges to \(B_{i+1}\). Restart \(B_1\) by deleting all its current edges.

(ii) Return \((B_1 \cup \ldots \cup B_t)\) at the end of the stream.

The analysis of the algorithm involves showing that: (i) fewer and fewer edges find their way to higher-indexed buffers, (ii) the repeated application of Matching-Cover does not blow up the approximation guarantee by too much, and (iii) all this can be implemented in a relatively small space. We now present the formal algorithm and its analysis.

We start by analyzing the space complexity of Algorithm 3.

**Lemma 6.2.** Algorithm 3 can be implemented in space of \(O\left(\frac{m}{k} \cdot \log\left(\frac{n^2 \cdot k}{m}\right) + t \cdot \text{MC}(n, \alpha') \cdot \log\left(\frac{n^2}{\text{MC}(n, \alpha')}\right)\right)\).

We now prove the correctness of Algorithm 3. To do so, we need the following definitions:

- Let \(H^1, \ldots, H^{k_i}\) denote the \(k_i\) separate matching covers constructed by the algorithm over the edges of buffer \(B_i\), one for each time that we restart \(B_i\). Let \(G^1 := H^1 \cup \ldots \cup H^{k_i}\) denote the graph that is sent to buffer \(B_{i+1}\) throughout the algorithm (for notational convenience, we also define \(G^i = G\) as the input graph, namely, the graph that is sent to buffer \(B^1\)).

- For any \(i \in [2 : t - 1]\), similarly, let \(H_i^1, \ldots, H_i^{k_i}\) denote the \(k_i\) separate matching covers constructed by the algorithm over the edges of buffer \(B_i\). Let \(G_i^{i+1} := H_i^1 \cup \ldots \cup H_i^{k_i}\) denote the graph that is sent to buffer \(B_{i+1}\) throughout the algorithm.

We claim that the number of subgraphs at buffer \(B_i\) drops by a factor of \(\delta^i\) compared to \(B_{i+1}\), and defer the proof to the full version.

**Claim 6.3.** For any \(i \in [t - 1]\), \(k_i \leq k/2^{i-1}\) and \(k_t = 0\) meaning that bucket \(B_t\) never generates a matching cover (namely, it never gets full).

The following lemma captures the loss on the size of maximum matching that the algorithm maintains from one buffer to the next one. In other words, the cost we have to pay for introduction of each level of buffers.

**Lemma 6.4.** For any \(i \in [t - 1]\) and any disjoint subsets of vertices \(X, Y \subseteq V\),

\[
\mu\left(G^{i+1} \cup B_i^f \cup \ldots \cup B_j^f\right) \leq \mu\left(G_i^{i+1} \cup B_{i+1}^f \cup \ldots \cup B_j^f\right) - k_i \cdot \alpha' \cdot n.
\]

where \(B_j^f\) for \(j \in [t]\) is the final content of the buffer at the end of the stream.

**Proof.** Fix any \(i \in [t - 1]\) and a maximum matching \(M_i^f\) of \((G_i^f \cup B_{i-1}^f \cup \ldots \cup B_j^f)\) on \(X, Y\). We construct a matching \(M_{i+1}^f\) in \((G^{i+1} \cup B_i^f \cup \ldots \cup B_j^f)\) on \(X, Y\) such that \(|M_{i+1}^f| \geq |M_i^f| - k_i \cdot \delta \cdot n\). This will then immediately implies the lemma. To continue we need some more definition.

For any \(H_j^f\) for \(j \in [k_i]\), let \(B_j^f\) denote the content of buffer \(B_j\) when the algorithm creates \(H_j^f\). This way, \(H_j^f\) is a matching-cover of \((V, B_j^f)\). Moreover, \(B_1^f, \ldots, B_{k_i}^f\) together with \(B_i^f\) partition all the edges that are ever sent to buffer \(B_i\), namely, the graph \(G_i^f\). These edges are also further disjoint from \(B_{i-1}^f, \ldots, B_1^f\) since the latter set
of edges were never sent to buffer $B_i$. We can partition the edges of $M'_{i,j}$ between these sets and along the way define our matching $M_{i+1}$ as well:

- For any $j \in [k_i]$, let $M_{i,j}^* := M_{i,j} \cap B_i^j$ and $M_{i,j}$ be the maximum matching in $H_j^j$ between $X(M_{i,j}^*)$ and $Y(M_{i,j}^*)$.
- For any $i' \in [i]$, let $M_{i'}^{*,f} := M_{i'} \cap B_i^{j'}$ and $M_i' := M_{i'}^{*,f}$ which is between $X(M_{i'}^{*,f})$, $Y(M_{i'}^{*,f})$.
- Define $M_{i+1} := M_{i+1}^* \cup \ldots \cup M_{i,k_i}^* \cup M_i^{f} \cup \ldots \cup M_i^{f}$.

We note that $M_{i+1}$ is a matching between $X$ and $Y$ because the sets of vertices $X(M_{i,j}^*)$ and $X(M_{i,j}^*)$ for $j \in [k_i]$, as well as $X(M_{i'}^{*,f})$ and $Y(M_{i'}^{*,f})$ for $i' \in [i]$ are all disjoint given they are defined with respect to a fixed matching $M_i^*$ over disjoint sets of edges. Moreover, $M_{i+1}$ belongs to $(G_{i+1} \cup B_i^j \cup \ldots \cup B_i^{j'})X, Y$ as $H_j^j$ is part of $G_{i+1}$ for $j \in [k_i]$. It thus only remains to bound the size of $M_{i+1}$.

For all $i' \in [i]$, $M_{i}^{f}$ and $M_{i'}^{*,f}$ are the same so there is nothing to do here. For $j \in [k_i]$, we have,

$$|M_{i,j}| = \max \{ H_j^j |X(M_{i,j}^*), Y(M_{i,j}^*)| \} \geq \mu \left( B_i^j |X(M_{i,j}^*), Y(M_{i,j}^*)| \right) - \alpha' \cdot n$$

(as $H_j^j$ is a $\alpha'$-matching-cover of $B_i^j$ and by Definition 4.1)

$$|M_{i+1}| = \sum_{j=1}^{k_i} |M_{i,j}| + \sum_{i' = 1}^{i} |M_{i'}^{f}| \geq \sum_{j=1}^{k_i} (|M_{i,j}^*| - \alpha' \cdot n) + \sum_{i' = 1}^{i} |M_{i'}^{*,f}| = |M_{i}^{*}| - k_i \cdot \alpha' \cdot n.$$ 

concluding the proof. □

We can now conclude the bound on the approximation ratio of the algorithm.

**Lemma 6.5.** Algorithm 3 outputs an $\alpha$-matching cover of any input multi-graph $G$.

**Proof.** Recall that for every $i \in [r]$, $B_i^{f}$ denotes the final content of the buffer $B_i$. Moreover by Claim 6.3, buffer $B_i$ never gets full and thus $B_i^{f} = G_i$. Finally, the algorithm returns $H := (B_1^{f}, \ldots, B_r^{f})$. Fix any disjoint sets of vertices $X, Y \subseteq V(G)$. We have,

$$\mu(H[X,Y]) = \mu \left( B_1^{f} \cup B_2^{f} \cup \ldots \cup B_r^{f} |X,Y| \right)$$

(by the definition of $H$)

$$\geq \mu \left( G^{f} \cup B_1^{f} \cup \ldots \cup B_r^{f} |X,Y| \right)$$

(as $B_i^{f} = G_i$)

$$\geq \mu \left( G^{f-1} \cup B_1^{f} \cup \ldots \cup B_r^{f} |X,Y| \right) - \left( \sum_{i=1}^{t-1} k_i \cdot \alpha' \cdot n \right)$$

(by Lemma 6.4 for $i = t - 1$)

$$\geq \mu(G[X,Y]) - \sum_{i=1}^{t-1} k_i \cdot \alpha' \cdot n$$

(by repeatedly applying Lemma 6.4 for all $i < t - 1$ and since $G^1 = G$)

$$\geq \mu(G) - \sum_{i=1}^{t-1} (k/2^{t-1}) \cdot \alpha' \cdot n$$

(by Claim 6.3, $k_i \leq k/2^{t-1}$)

$$\geq \mu(G) - 2k \cdot \alpha' \cdot n$$

(by the sum of the geometric series)

$$\geq \mu(G) - \alpha \cdot n.$$ 

(by the choice of $\alpha' = \alpha/2k$)

This implies that for every disjoint subsets of vertices $X, Y \subseteq V(G)$, we have $\mu(H[X,Y]) \geq \mu(G[X,Y]) - \alpha \cdot n$, thus making $H$ an $\alpha$-matching cover of $G$ by Definition 4.1. □

**Proof of Proposition 6.1.** The bound on the space complexity of the algorithm follows from Lemma 6.2 by plugging the value of $\alpha' = \alpha/2k$ and $t = \log k + 1$. The correctness follows from Lemma 6.5. Finally, Algorithm 3 is deterministic modulo any potential randomness used by Matching-Cover. □

**6.2 A Streaming Matching Algorithm via Regularity Lemma**

We now use Proposition 6.1 together with our Theorem 1 to formalize Result 1 as follows.

**Theorem 3 (Formalization of Result 1).** There is a randomized single-pass streaming algorithm that with high probability computes a $(1 - o(1))$-approximate matching of a graph presented in a stream with adversarial order of edge arrivals in $n^2/((\log^* n)^{O(1)})$ space and polynomial time.

**Proof.** Note that, to apply Proposition 6.1, we need a subroutine Matching-Cover for computing an $(\alpha/2k)$-matching cover (for parameters $\alpha$ and $k$ to be determined soon) on any $n$-vertex graph with $n^2/k$ edges. Theorem 1 provides such an algorithm with parameters

$$\frac{(\alpha/2k)}{} = \frac{1}{(\log^* n)^{\delta_1}} \quad \text{and} \quad MC(n, \alpha/2k) = \mathcal{O} \left( \frac{n^2}{(\log^* n)^{\delta_2}} \right),$$

for some absolute constants $\delta_1, \delta_2 \in (0, 1)$. Let $\alpha = 1/((\log^* n)^{3\delta_1})$ and $k = 1/((\log^* n)^{3\delta_2})$, which satisfies the conditions above. Moreover, by Proposition 3.4, we can implement Algorithm 1 of Theorem 1 in polynomial time and space $O(n^2/(\log^* n)^{O(1)})$, given only adjacency matrix access to its input graph. This way, by Proposition 6.1, we obtain a single-pass streaming algorithm that with high probability computes an $\alpha$-matching cover in space $n^2/(\log^* n)^{O(1)}$.

The main algorithm in the theorem is as follows. We store the first $2n^2/k$ edges in the stream using succinct dynamic dictionary of Proposition 3.8 in $n^2/(\log^* n)^{O(1)}$ space. In parallel, we also run the algorithm mentioned above to obtain an $\alpha$-matching cover of $G$. The space complexity and polynomial runtime of the algorithm is thus already established.

We now prove the correctness. If $\mu(G) \leq n/k$, then by Fact 3.1, we have stored all edges of the graph and thus at the end can
simply return a maximum matching of the stored edges; to do so, we simply run Hopcroft–Karp algorithm [56] by providing it with the adjacency matrix of the stored edges using member query on the succinct dynamic dictionary (which only requires $O(n \log n)$ additional space beside the input). Thus, in this case, we obtain an exact maximum matching of the input graph.

If $\mu(G) > n/k$, then we can pick $X$ and $Y$ in the definition of matching cover output by the algorithm of Proposition 6.1 to be the endpoints of the maximum matching of $G$, and have,

$$\mu(H) \geq \mu(G) - \alpha \cdot n \geq (1 - \alpha \cdot k) \cdot \mu(G) = (1 - 1/(\log^* n)^{2\epsilon/3}) \cdot \mu(G),$$

which is $(1 - o(1)) \cdot \mu(G)$ as desired. This concludes the proof. \qed

6.3 A Streaming Matching Algorithm via RS Graph Upper Bounds

We formalize Result 3 as follows in this subsection (RS$(n, \beta)$ below was defined in Definition 3.6).

**Theorem 4 (Formalization of Result 3).** There exists an absolute constant $\eta > 0$ such that the following is true. There is a randomized single-pass streaming algorithm that for any $1 \leq k \leq n$ and $\varepsilon \in (0, 1/100)$, with high probability, computes a $(1 - \varepsilon)$-approximate matching of a graph presented in a stream with adversarial order of edge arrivals in exponential time and space

$$O\left(n^2 / k \log^2 k + \text{RS}(n, \eta \cdot \varepsilon^2 / k) \cdot \log \left( \frac{n^2}{\text{RS}(n, \eta \cdot \varepsilon^2 / k)} \right) \cdot \log^2 k \cdot \log (k / \varepsilon) \right).$$

Moreover, the algorithm can return an additive $\varepsilon \cdot n$ approximation deterministically in exponential time and space

$$O\left(n^2 / k + \text{RS}(n, \eta / 16k) \cdot \log \left( \frac{n^2}{\text{RS}(n, \eta / 16k)} \right) \cdot \log k \cdot \log (k / \varepsilon) \right).$$

Roughly speaking, by ignoring lower order terms and in asymptotic notation, Theorem 4 gives a streaming algorithm for $(1 - o(1))$-approximation of matchings in a single pass with adversarial order of edge arrivals using essentially $(n^2 / k + \text{RS}(n, o(1/k)))$ space for any integer $k \geq 1$.

Before proving Theorem 4, let us present a corollary of this theorem with concrete bounds on the space by using Fox’s triangle removal lemma (Proposition 3.5) to bound the RS-graph density terms in Theorem 4 (this appears to be the only known method for bounding density of RS graphs with $o(n)$-sized induced matchings; moreover, we are not aware of any reference that bounds the density of the type of RS graphs we need, thus we present a proof of that here also for completeness).

**Corollary 6.6.** There is a deterministic single-pass streaming algorithm that computes a $(1 - o(1))$-approximate matching of a graph presented in a stream with adversarial order of edge arrivals in $n^2 / 2^{O(\log^* n)}$ space and exponential time.

We defer the proof of this corollary to the full version. To continue, we need to recall some additional tools from prior work, specific specific to our algorithms in this subsection.

### 6.3.1 Additional Tools from Prior Work

#### Matching covers via RS graphs

Goel et al. [50] showed that matching covers and RS graphs are intimately connected: on bipartite graphs, the density of best construction for either can be bounded by the density of other one for closely related parameters. We need this result for general graphs as well which follows from the result of [50] using a simple argument.

**Proposition 6.7** (An extension of [50, Theorem 9.2] to general graphs). For any $\alpha \in (0, 1)$ and $n \geq 1$, there exists an $\alpha$-matching cover of any $n$-vertex graph with number of edges bounded by

$$\text{MC}(n, \alpha) \leq \text{RS}(n, \alpha/8) \cdot \text{O}(\log(1/\alpha)).$$

**Proof.** The result of [50] is formally as follows (to match the definitions in our paper, our formulation is slightly different from the statements in [50] but they are equivalent):

[50, Theorem 9.2]: For any bipartite graph $G' = (L', R', E')$ with $n$ vertices on each side and $\alpha' \in (0, 1)$, there exists a subgraph $H'$ with $\text{RS}(2n, 3\alpha'/4) \cdot \text{O}(\log(1/\alpha'))$ edges such that for any disjoint subsets of vertices $X \subseteq L'$ and $Y \subseteq R'$,

$$\mu(H'[X, Y]) \geq \mu(G'[X, Y]) - \alpha' \cdot (2n).$$

We now use this to prove the bound for general graphs as well. Let $G = (V, E)$ be any (not necessarily bipartite) graph. Consider the bipartite double cover of $G$ obtained by copying vertices of $G$ twice into sets $V_1$ and $V_2$ and connecting any vertex $u_1 \in V_1$ to $v_2 \in V_2$ if $(u, v) \in E$ is an edge in $G$. Let $G'$ denote this graph and so $G'$ is a bipartite graph with $n$ vertices on each side.

Compute an $\alpha'$-matching cover $H'$ of this bipartite graph using Theorem 9.2 of [50] for parameter $\alpha' = \alpha/2$ (for $\alpha$ given to us in the proposition statement). Thus, $H'$ contains $\text{RS}(2n, 3\alpha'/4) \cdot \text{O}(\log(1/\alpha'))$ edges. Create a subgraph $H$ (not necessarily bipartite) on the same vertices as $G$ by adding the edges $(u, v)$ to $H$ iff either $(u_1, v_2)$ or $(v_1, u_2)$ was an edge in $H'$. This way, the number of edges in $H$ will be at most

$$\text{RS}(2n, 3\alpha'/4) \cdot \text{O}(\log(1/\alpha')) \leq \text{RS}(n, \alpha'/8) \cdot \text{O}(\log(1/\alpha')).$$

where the inequality is by Claim 5.7 that relates density of RS graphs with similar parameters.

We now argue that $H$ is an $\alpha$-matching cover of $G$. Fix any disjoint subsets of vertices $X, Y$ in $G$. Consider $X_1 \subseteq V_1$ and $Y_2 \subseteq V_2$ corresponding to these two subsets over vertices of $G'$ (and $H'$):

$$\mu(H'[X_1, Y_2]) \geq \mu(G'[X_1, Y_2]) - \alpha' \cdot (2n)$$

(by Definition 4.1 as $H'$ is an $\alpha$-matching cover of $G'$) 

$$\geq \mu(G[X, Y]) - \alpha' \cdot (2n),$$

as by the construction of $G'$ any edge $(u, v) \in E[G[X, Y]]$ also has a copy $(u_1, v_2) \in E[G'[X_1, Y_2]$ and thus $\mu(G'[X_1, Y_2]) \geq \mu(G[X, Y])$. Moreover, since $X$ and $Y$ are disjoint, the endpoints of the maximum matching in $H'[X_1, Y_2]$ are disjoint from each other; thus, they are mapped to unique edges in $H$ also between $X$ and $Y$, implying that

$$\mu(H[X, Y]) = \mu(H'[X_1, Y_2]) \geq \mu(G[X, Y]) - 2\alpha' \cdot n.$$
Noting that $a' = a/2$ in the above equations, concludes the proof. □

**Vertex-sparsification for matchings.** We also use the reductions of Assadi et al. [16] and Chitnis et al. [39] for reducing the number of vertices while preserving maximum matching size approximately. The original versions of these reductions in the two works only achieved constant probability of success and boost this to a high probability bound by applying it $O(\log n)$ times in parallel. In our setting, we cannot afford this direct success amplification. Thus, we instead use the following variant proven by Assadi et al. [15] that achieves a high success probability directly.

**Proposition 6.8 ([15, Lemma 3.8]; see also [16, 39]).** For any graph $G = (V, E)$, integer $\alpha \geq 1$, and parameter $\theta \in (0, 1)$, uniformly at random pick a function $h : V \to [8 \cdot \alpha \cdot \theta]$. Consider this multi-graph $H = (V_H, E_H)$ obtained from $G$ and $h$:
- $V_H$ is the range of the function $h$, thus $|V_H| = 8 \cdot \alpha \cdot \theta$.
- For any edge $(u, v) \in G$, there is an edge $(h(u), h(v)) \in E_H$.

If $\mu(G) \leq \alpha \cdot \theta$, then,
$$\Pr_G \left( \mu(H) < (1 - \theta) \cdot \mu(G) \right) \leq \exp \left( -\frac{\mu(G)}{4} \right).$$

### 6.3.2 Proof of Theorem 4

We now use these prior tools combined with our Proposition 6.1 to prove Theorem 4. Recall that Proposition 6.1 returns an $\alpha$-matching cover which can only guarantee an additive approximation not a multiplicative one. Thus, we first use the vertex-sparsification of Proposition 6.8 to reduce the number of vertices in $G$ to $O(\mu(G))$—by guessing $\mu(G)$ in geometric values—so that an additive approximation also becomes a multiplicative one. We then use Proposition 6.7 to compute the matching covers in Algorithm 3 of Proposition 6.1.

**Algorithm 4.** The randomized algorithm in Theorem 4.

**Input:** A graph $G = (V, E)$ in the stream with $n$ edges and at most $|V|^2 / 2$ edges. We are also given integer $k \geq 1$ and approximation parameter $\epsilon \in (0, 1)$ as in Theorem 4.

**Output:** A $(1 - \epsilon)$-approximate maximum matching of $G$.

(i) For $i = 1$ to $t := \log k$ iterations in parallel:
(a) Let $\alpha_i := n^{2i+1} \cdot 32 \cdot \alpha_i$. Pick a hash function $h_i : V \to [n^{2i+1}]$.
(b) Consider the multi-graph $G_i$ obtained from $G$ and $h_i$ using Proposition 6.8; each edge of $G$ arriving in the stream can be mapped to an edge of $G_i$ or removed.
(c) Run Algorithm 3 on $G_i$ with parameters $k$ and $\alpha = \epsilon^2 / 4$ and $m = \Theta \left( \frac{n}{k} \right)$ to obtain an $\alpha$-matching cover $H_i$.
We use the matching cover construction of Proposition 6.7 as the subroutine Matching-Cover (as specified in Claim 6.9 below).
(ii) Store the first $n^2 / k$ edges of the stream using succinct dynamic dictionary of Proposition 3.8 as the subgraph $H_0$.
(iii) Return a maximum matching in $H_0 \cup H_1 \cup \ldots \cup H_t$ (specified in Claim 6.9 below).

We bound the space and approximation of Algorithm 4 in the following two claims, respectively.

**Claim 6.9.** Algorithm 4 (deterministically) requires space of
$$O \left( \frac{n^2}{k} \cdot \log^2 k + RS(n, \epsilon^2) \cdot \log \left( \frac{n^2}{RS(n, \epsilon^2)} \right) \cdot \log^2 k \cdot \log \frac{k}{\epsilon} \right).$$

**Claim 6.10.** Algorithm 4 outputs a $(1 - \epsilon)$-approximate matching with high probability.

Proof. Suppose first that $\mu(G) \leq n^{2k} / 2k$. By Fact 3.1, $G$ in this case has at most $2n \cdot \mu(G) \leq n^2 / k$. Thus, in step (ii) of the algorithm, we are simply storing all edges and thus the algorithm returns an exact answer.

Now suppose $\mu(G) > n^{2k} / 2k$. This means that there is an index $i \in [t]$ such that $\frac{n^{2i+1}}{k} \leq \mu(G) < \frac{n^{2i+2}}{k}$. For this choice of $i$, we have $\alpha_i \leq \mu(G) < 2 \alpha_i$. By Proposition 6.8, for $\theta = \epsilon / 2$ and $\alpha = 2 \alpha_i$, $H_i \subseteq V \to [32 \alpha_i / \epsilon]$, we have, $\Pr_{H_i} \left( \mu(G_i) < (1 - \epsilon / 2) \cdot \mu(G) \right) \leq \exp \left( -\frac{\mu(G)}{8} \right) \approx 1 / \log(n)$, where we used that fact $32 \alpha_i / \epsilon = 8 \cdot \epsilon / \theta$. We condition on the complement of this event which happens with high probability.

Based on this, we further have that $n_i := |V(G_i)| = \frac{n^2}{k} \cdot 32 \cdot \alpha_i \leq \frac{n^2}{k} \cdot \mu(G) \leq \frac{\mu(G)}{\epsilon}$.

Since $H_i$ is an $\alpha$-matching cover of $G_i$, by letting $X$ and $Y$ in Definition 4.1 to be the endpoints of the maximum matching of $G_i$, we have, $\mu(H_i) \geq \mu(G_i) - \alpha n_i \geq (1 - \epsilon / 2) \cdot \mu(G) - \frac{\mu(G)}{\epsilon^2 / 4} \geq (1 - \epsilon) \cdot \mu(G)$. Thus, returning the maximum matching of $H_i$ as part of $H_0 \cup \ldots \cup H_t$ achieves a $(1 - \epsilon)$-approximation. □

Theorem 4 for randomized case now follows from Claims 6.9 and 6.10. For the deterministic part with additive approximation guarantee, we simply forgo guessing $\mu(G)$ as well as using vertex-sparsification of Proposition 6.8 at all; instead, we just run Algorithm 3 over the entire input and use Proposition 6.7, the same way as above exactly, as the subroutine Matching-Cover for computing an $\alpha$-matching cover. Since now we only need an additive $\epsilon \cdot n$ guarantee, we can take $\alpha = \epsilon$ directly which implies the improved bounds on the space as well.
