Shortened Title: Electric double-layer interactions

Abstract
The present review summarizes and assesses recent theoretical and experimental advances, with special emphasis on the effective interaction between charge-stabilized colloids, in the bulk or in confined geometries, and on the ambiguities of defining an effective charge of the colloidal particles. Some consideration is given to the often neglected discrete solvent effects.
I. INTRODUCTION

Electric double layers form spontaneously whenever surfaces carrying ionizable groups are suspended in a polar solvent, most frequently water. The high dielectric constant $\epsilon$ of the latter favours the dissociation of the functional surface groups, so that the surface acquires a net charge per unit area, $\sigma$. Oppositely charged counterions are released into the solvent, which generally also contains a finite concentration of microscopic anions and cations (microions), providing thus additional coions and counterions. The electric double-layer results from the build-up of a charge density (or "cloud") of opposite sign to that of the surface charge, which tends to screen the electrostatic potential due to the latter. The width of the double-layer, which is a measure of its capacity, is determined by the competition between the thermal motion of the microions, which tends to spread out, or homogenize their distribution, in order to increase their entropy, and the electrostatic interactions, which attract the counterions towards the surface, while repelling the coions.

The present review deals with electric double-layers around mesoscopic charged particles, which will be referred to as polyions (frequently also called macroions), and more specifically with the effective interactions between electric double-layers associated with different polyions. Such double-layers are ubiquitous in many physical, geophysical, chemical and biological systems, including complex fluids, clay soils, polyelectrolytes (e.g. DNA) or cell membranes. The main focus of the review will be on colloidal dispersions of spherical, rod-like or lamellar polyions, or micelles resulting from the self-assembly of ionic surfactants [1]. Advanced experimental techniques, like surface force machines or video microscopy in combination with optical tweezers, allow a direct measurement of the forces acting between charged surfaces or polyions. Such direct measurements contrast with indirect determinations of effective forces via small angle X-ray or neutron scattering measurements of static structure factors [2]. For the theoretician, the main challenge is the highly asymmetric nature of dispersions involving mesoscopic polyions, and microscopic solvent molecules and ions. Clearly, at least three widely different length scales are involved, namely the characteristic size (radius) $a$ of the polyions, a typical width of the electric double-layer, of the order of the Debye screening length $\lambda_D$, and a typical correlation length $l$ of the solvent, of the order of a few molecular diameters. Under most physical conditions the double inequality $a \gg \lambda_D \gg l$ holds, so that a coarse-grained statistical description of the suspension is clearly warranted. This strategy may be cast in the unifying framework of the density functional theory (DFT) of inhomogeneous fluids [3], as explained in the following section. A number of key issues, which are presently the object of intense experimental and theoretical scrutiny, will be addressed in subsequent sections of this review. They include the following questions and topics:

- The limitations of the standard Poisson-Boltzmann or mean-field theory of electric double-layers and the importance of spatial correlations between microions. A particularly important question relates to the possibility of an attractive component of the effective interaction between polyions, induced by microion correlations.
- The notion of effective polyion charge (or charge renormalization), as controlled by dissociation equilibria and counterion adsorption (or condensation), and of charge regulation.
- The relation between effective interactions between polyions, and the phase behaviour of their dispersions.
- The effect of confinement on the effective interactions between colloids, and more generally the influence of electrostatic boundary conditions at interfaces.
- The introduction of solvent granularity into the statistical description of double-layers.

This review will emphasise the more recent experimental and theoretical developments in this very active field, covering mostly work published during the past decade. Earlier work is adequately covered in some previous reviews of the subject [4–7]. Electrostatic CGS units will be used throughout.

II. MULTI-COMPONENT VERSUS EFFECTIVE ONE-COMPONENT DESCRIPTION

Consider a suspension of $N$ polyions, of radius $a$ and charge $Z$, in a polar solvent with co and counterions, of radii $a_{\pm}$ and charges $z_{\pm}\epsilon$; the radius of the solvent molecules is comparable to the microion radii $a_{\pm}$, i.e. of the order of 0.1 nm. In micellar solutions, $1 \text{ nm} < a < 10 \text{ nm}$, and $10 < |Z| < 100$, while in most colloidal dispersions, $10 \text{ nm} < a < 10^3 \text{ nm}$, and $10^2 < |Z| < 10^4$. A statistical description of the highly asymmetric multi-component system is a considerable challenge, which requires some degree of coarse-graining. In most theoretical investigations of micellar or colloidal systems, the solvent is regarded as a mere continuum, characterized by its macroscopic dielectric constant.
This amounts to a "primitive model" (PM) level of description, where polyions and microions are assumed to be charged hard spheres (non-spherical polyions will be considered later in this review) interacting via the Coulomb potential $\sim e^2/er$, outside the excluded volume range of inter-particle distances $r$. It is implicitly assumed that the mesoscopic polyions have the same macroscopic dielectric constant $\epsilon$ as the solvent, thus avoiding complications due to dielectric discontinuities (e.g. image charges).

Even within the PM, the theoretician is still faced with the polyion-microion asymmetry. In micellar solutions, where the size and charge ratios $a/a_\pm$ and $|Z|/|z_\pm|$ are roughly a factor of 10, the asymmetry may still be handled within the multicomponent PM level of description, using the theoretical techniques of the theory of classical fluids. In particular, the partial pair distribution functions $g_{\alpha\beta}(r)$ (where $\alpha$ and $\beta$ are species indices) may be calculated from the usual fluid integral equations, including the hypernetted chain (HNC) and mean spherical approximations (MSA), or their variants and hybrid combinations. Alternatively these correlation functions may be obtained from Monte Carlo (MC) or Molecular Dynamics (MD) simulations of the asymmetric PM. The multicomponent PM point of view is, in practice, limited to micellar systems with $|Z| < 10^2$, because integral equation closures are increasingly unreliable for asymmetric systems, and their numerical solution tends to become unstable. Similarly simulations become more and more difficult, and are at present limited to $|Z| \leq 60$. The multi-component PM description becomes untractable in the much more asymmetric colloidal range, which requires a coarse-grained description, based on effective interactions between polyions, to be discussed below.

Important simplifications occur within the PM in a number of limiting situations.

a) In the limit of infinitely low concentration $n$ (number per unit volume) of polyions, only a pair of these, within a solution of microions, need to be considered. The effective interaction between the two polyions (p) is then exactly given by the potential of mean force, $v_{pp}(r) = -k_B T \log[g_{pp}(r)]$. The multicomponent problem reduces to that of an electrolyte of microions in the external field due to two fixed polyions, which leads to considerable simplifications in simulations or the numerical solution of integral equations.

b) The problem may be further simplified by taking the limit $a \to \infty$; the initial dispersion then reduces to the much simpler system of an electrolyte confined between two parallel planes carrying a, generally uniform, surface charge $\sigma$. The classic problem of two interacting planar double-layers goes back to the work of Gouy, and has been the object of considerable theoretical and experimental work, some of which will be discussed in a subsequent section.

c) In the opposite limit of high concentration, each polyion is, at least temporarily, trapped in the "cage" formed by neighbouring polyions. This regime is reasonably described by a one-body model, where a single polyion is located at the centre of a Wigner-Seitz cell, together with an inhomogeneous distribution of microions, such that the total charge inside the cell is zero. For practical purposes the cell is chosen of a simple geometry reflecting the shape of the polyion (e.g. a spherically symmetric cell around a spherical polyion), and the electrostatic boundary conditions are chosen such as to mimic the average effect of the surrounding polyions. Despite the considerable simplifications which they imply, cell models allow valuable insight into concentrated dispersions, and will be discussed further on.

A unifying framework for the statistical description of interacting electric double-layers, or, more generally, of inhomogeneous fluids and interfaces, is provided by density functional theory (DFT).

### A. DFT and effective interactions

In view of the considerable polyion-microion asymmetry, it seems natural to combine a discrete representation of the former with a field description of the latter. Let $\{\mathbf{R}_i\}(1 \leq i \leq N)$ denote the positions of the $N$ polyions, assumed here to be spherical, and let $V_{N}^{\text{dir}}(\mathbf{R}_i)$ be their direct interaction energy for a given configuration; $V_{N}^{\text{dir}}$ is, to a good approximation, pairwise additive, with a pair potential $v_{pp}(R)$ including a short-range excluded volume repulsion, the long-range Coulomb repulsion $Z^2e^2/\epsilon R$ and a van der Waals attraction (dispersion force), of intensity characterized by a Hamaker constant $H$. The inhomogenous distributions of co- and counterions, in the "external" field of the polyions, are characterized by the local densities (or concentrations) $\rho_\alpha(r)(\alpha = +, -)$. The equilibrium densities satisfy the variational principle:

$$\frac{\delta \Omega[\rho^+_\alpha(r), \rho^-_\alpha(r)]}{\delta \rho^\alpha_\alpha(r)} \bigg|_{\rho^\alpha_\alpha = \rho^\alpha_\alpha} = 0; \quad \alpha = +, -$$  \hspace{1cm} (1)
where Ω is the grand potential functional of the trial densities, given by:

$$\Omega [\rho^+_{\alpha}, \rho^-_{\alpha}] = F [\rho^+_{\alpha}, \rho^-_{\alpha}] - \sum_{\alpha} \int \Phi_{\alpha}(r) \rho^*_{\alpha}(r) \, dr$$

(2)

In (3), \( F \) denotes the intrinsic free energy functional, while \( \Phi_{\alpha}(r) = \mu_{\alpha} - \Phi_{\alpha}^{ext}(r) \), with \( \mu_{\alpha} \), the chemical potential of species \( \alpha \), and \( \Phi_{\alpha}^{ext} \), the external potential acting on ions of this species, equal to the sum of the interactions with the \( N \) polyions:

$$\Phi_{\alpha}^{ext}(r) = \sum_{i=1}^{N} v_{\alpha i}(r - R_i)$$

(3)

Note that in view of (3), the equilibrium density profiles \( \rho_{\alpha}(r) \), and the resulting grand potential \( \Omega \), depend parametrically on the polyion configuration. The chemical potentials \( \mu_{\alpha} \) are either fixed at some reservoir value (semi-grand canonical ensemble), or determined a posteriori by the canonical ensemble constraints:

$$\frac{1}{V} \int_V \rho_{\alpha}(r) \, dr = n_{\alpha}$$

(4)

where \( V \) is the total volume of the dispersion and \( n_{\alpha} \) is the mean (macroscopic) concentration of \( \alpha \)-ions.

Explicit calculations of the density profiles require some approximation for the generally unknown free energy functional \( F \), which is traditionally split into ideal and excess parts, \( F = F_{id} + F_{ex} \); \( F_{id} \) is known exactly:

$$F_{id} [\rho^+_{\alpha}, \rho^-_{\alpha}] = k_B T \sum_{\alpha = +, -} \int_V \rho_{\alpha}(r) \log \left( \Lambda_{\alpha}^3 \rho_{\alpha}(r) - 1 \right) \, dr$$

(5)

If \( n_{\alpha}^{(0)} \) denotes the concentrations of some homogeneous reference state (i.e. in the absence of polyions), and \( \rho_{\alpha}(r; \xi) = n_{\alpha}^{(0)} + \xi \Delta \rho_{\alpha}(r) \) \( (0 \leq \xi \leq 1) \) denotes a continuous set of density profiles, such that \( \rho_{\alpha}(r; \xi = 1) \) leads back to \( \rho_{\alpha}(r) \), the equilibrium density profiles in the presence of polyions, then \( F_{ex} \) is given by the formally exact expression:

$$F_{ex} [\rho^+_{\alpha}, \rho^-_{\alpha}] = F_{ex} \left( n^+_{\alpha}^{(0)}, n^-_{\alpha}^{(0)} \right) + \sum_{\alpha} \mu_{\alpha}^{ex} \int \Delta \rho_{\alpha}(r) \, dr$$

$$- k_B T \sum_{\alpha} \sum_{\beta} \int_0^1 d\xi (\xi - 1)$$

$$\times \int \, dr \int \, dr' \Delta \rho_{\alpha}(r) c_{\alpha \beta} \left[ \{ \rho_{\alpha}(\xi) \}; r, r' \right] \Delta \rho_{\beta}(r')$$

(6)

\( \mu_{\alpha}^{ex} \) is the excess part of the chemical potential, while the \( c_{\alpha \beta} \left[ \{ \rho_{\alpha}(\xi) \} \right] \) are the set of direct correlation functions for the inhomogeneous electrolyte with local densities \( \rho_{\alpha}(r; \xi) \). For Coulombic systems, these decay asymptotically as \( -v_{\alpha \beta}(r)/k_B T = -z_{\alpha} z_{\beta} l_B / r \) (where \( l_B = e^2/\epsilon k_B T \) is the Bjerrum length). It proves convenient to subtract this from the \( c_{\alpha \beta} \), leaving the short-ranged part \( c_{\alpha \beta}^{sr} \). The excess free energy function then splits into a mean-field Coulombic contribution, and a correlation part:

$$F_{ex} [\rho^+_{\alpha}, \rho^-_{\alpha}] = F_{Coul} + F_{corr}$$

$$= \frac{e^2}{2e} \int \, dr \int \, dr' \rho(r) \rho'(r') |r - r'| + F_{corr}$$

(7)

where \( \rho(r) = z^+ \rho^+_{\alpha}(r) + z^- \rho^-_{\alpha}(r) \) is the microion charge density. The correlation term is formally given by (3), with \( c_{\alpha \beta}^{sr} \) replacing \( c_{\alpha \beta} \).

Starting from these exact expressions, there are basically two strategies to proceed with approximations.

a) The most common strategy focuses on the density profiles, and the resulting free energies. \( F_{corr} \) is approximated by a local density ansatz (LDA) or by some weighted density approximation (WDA) which generally requires the direct correlation functions in a homogeneous reference state as input. Once the variational problem has been solved for the approximate free energy functional, the effective interaction energy between polyions is given by :
\[ V_N (\{R_i\}) = V_N^{\text{dir}} (\{R_i\}) + \Omega (\{R_i\}) \]  

(8)

where the equilibrium grand potential accounts for their indirect interactions, induced by the double-layer-forming microions, which have effectively been traced out. It is very important to realize that this contribution depends on the thermodynamic state of the dispersion, and is generally not pair-wise additive.

If correlations are neglected altogether, \( F_{\text{ex}} \) reduces to the mean-field Coulombic part, and (8) immediately leads to the equilibrium profiles

\[ \rho_\alpha (r) = \zeta_\alpha \exp \left\{ - \left[ \Phi^{\text{dir}}_\alpha (r) + z_\alpha e \psi(r) \right] / k_B T \right\} \]  

(9)

where \( \zeta_\alpha \) is the fugacity of species \( \alpha \) (equal to its reservoir concentration in the absence of correlations), \( \Phi^{\text{sr}}_\alpha \) is the short-range (excluded volume) part of the interaction of an ion \( \alpha \) with the \( N \) polyions, and \( \psi(r) \) is the total electrostatic potential at \( r \), which satisfies Poisson’s equation:

\[ \nabla^2 \psi (r) = - \frac{4 \pi e}{\epsilon} \left[ \rho^{\text{ext}}(r) + \rho(r) \right] \]  

(10)

with \( \rho^{\text{ext}}(r) \) the "external" charge density carried by the \( N \) polyions. Eqs (9) and (10) constitute the multi-centre version of mean-field non-linear Poisson-Boltzmann (PB) theory. Despite their apparent simplicity, numerical solution of the PB equations in the presence of \( N \) polyions is a formidable task. In practice, eq. (10) is often solved in the domain outside the polyions, and the contribution of the latter to the electrostatics is treated as a boundary value problem.

b) A second, more ambitious strategy is to seek information on both the density profiles, and the pair correlations between microions within the double-layers. This may be achieved by relating the direct correlation functions, appearing in (7), to their functional inverses, the total correlation functions \( h_{\alpha\beta} \), via the Ornstein-Zernike relations for inhomogeneous fluids [8], supplemented by an approximate closure relation between the \( h \) and \( c \) functions. This strategy leads to coupled equations for the density profiles and the pair correlation functions, as in the widely used inhomogeneous hypernetted chain (IHNC) theory [21]. In view of its numerical complexity, this strategy can only be applied to very simple geometries. In practice it is limited to planar geometry and will be discussed in a subsequent section.

B. Cell model

As stated earlier, cell models, involving a single polyion, prove useful to study concentrated dispersions, including colloidal crystals. The paradigm is provided by the much studied case of a globular polyion of radius \( a \), placed at the centre of a spherical cavity of radius \( R \) determined by the polyion concentration, i.e. \( R = (3/4 \pi n)^{1/3} \), containing counterions and salt which ensure overall charge neutrality. The density profiles \( \rho_\alpha (r) \) and \( \rho_\alpha (r) \) depend only on the distance \( r \) from the centre (1d problem). Gauss’s law implies the boundary conditions (b.c.) that the electric field vanish on the surface of the cell, i.e. \( d\psi/dr |_{r=R} = 0 \). The field on the surface of the particle (i.e. at \( r = a \)) is determined by the surface charge density \( \sigma \). Finally, due to the b.c. at \( r = R \), the osmotic pressure \( P \) of the microions is given by [19] :

\[ P = k_B T [\rho_+ (R) + \rho_- (R)] \]  

(11)

PB theory, embodied in eqs. (1) and (11), reduces here to a spherically symmetric one-centre problem, giving rise to a simple second order non-linear differential equation for the local potential \( \psi(r) \), which is easily solved numerically [22,23]. Improvements over the mean-field approximation are achieved by including correlations within the LDA or the WDA [23,24]. The resulting osmotic pressures are consistently lower than those predicted by PB theory, by a factor of three or more for highly charged polyions. This trend is confirmed by MC simulations of the microions in the cell, subjected to the electrostatic potential of the polyion [24,25].

Cell model calculations have been extended to other geometries, e.g. rods or platelets in cylindrical cells. They prove very useful in the determination of effective polyion charges, as discussed in the next section.
III. CHARGE REGULATION AND RENORMALIZATION

Most published work on electric double-layers is based on the assumption of constant charge on the polyions, e.g. in the form of a constant and uniform surface charge. This is clearly an oversimplification, as would be the other extreme assumption of constant surface potential, for two reasons: the strong coupling between electrostatics and chemical dissociation equilibrium at the surface (charge regulation), and the adsorption and strong physical binding of counterions to the surface, often referred to as counterion condensation, which leads to a reduction of the apparent polyion charge seen at larger distances (charge renormalization).

A. Charge regulation

The bare (or structural) surface charge of most polyions results from the dissociation of functional groups like sulphate or carboxylic groups, the number of which may be measured by titration [25]. Generally the ionization is only partial, and the dissociation equilibrium, governed by a law of mass action, depends on the local ionic environment, e.g. on local salt concentration or pH. Any variation of this environment, linked to the relative motion of neighbouring polyions, will lead to a fluctuation of the surface charge, but for given macroscopic conditions, one may define some average bare charge. From a theoretical point of view, the coupling of the surface chemistry to the local inhomogeneities induced by electrostatics poses a difficult challenge. Early attempts were based on a combination of the law of mass action with PB theory [26]. A more microscopic point of view is adopted in the "charge regulation primitive model" (CRPM) [27] (see also Ref [28]), which adds a strong attraction of chemical origin to the short-range part $v_{sr}^{\alpha}$ of the polyion-microion pair potential, such that:

$$\exp \left\{ -v_{sr}^{\alpha}(r)/k_B T \right\} = V_\alpha \delta(r - d_\alpha); \quad r < \frac{1}{2}(a + a_\alpha)$$

$$= 1; \quad r > \frac{1}{2}(a + a_\alpha)$$

(12)

This corresponds to an infinitely deep and narrow potential well localized on a sphere of radius $d_\alpha$ from the centre of the polyion; in practice $d_\alpha$ must be chosen to be smaller than the polyion radius $a$, to prevent the chemical binding of the same microion to two polyions.

The pair structure of the model has been analysed by diagrammatic expansion, and by numerical solutions of the HNC equation for small polyions corresponding to mineral oxide particles [27]. The charge regulation strongly affects the effective interaction between spherical particles, to be discussed later.

B. Charge renormalization

The bare (or structural) charge resulting from the dissociation equilibrium is frequently very large, typically $|Z| \geq 10^4$ for polyion radii $a \geq 10^2$ nm. To describe electric double-layers near such highly charged polyions, the traditional phenomenological approach is to divide the counterions into two populations. The first includes ions that are tightly bound (or adsorbed) to the surface by the strong electric field $E = 4\pi \sigma / \epsilon$, thus forming a so-called Stern layer of "condensed" counterions. A rough estimate of the thickness $\Delta$ of a Stern layer is obtained by balancing the electrostatic work $E \times z_\epsilon \times \Delta$ against the thermal energy $k_B T$. The resulting $\Delta = \epsilon k_B T / 4\pi \sigma z_\epsilon$ is of the order of a few $\AA$ in water at room temperature for typical surface charge densities and monovalent counterions; thus $\Delta$ is comparable to the size of microions, so that the "condensate" may be expected to be roughly a monolayer. This monolayer, of opposite sign to the surface charge, strongly compensates the latter, reducing the total polyion charge to an effective charge $Z^*$ significantly smaller than the bare charge $Z$. The remaining counterions feel a much reduced "external" potential and form the "diffuse" part of the double-layer, which can often be treated within linearized PB theory (LPB).

The phenomenological approach is to consider $Z^*$ as a parameter adjusted to experimental data, e.g. polyion structure factors determined by light scattering [2,29,31], but much recent theoretical effort has gone into determining the effective charge from first principles. Most schemes are based on the observation that the asymptotic behaviour of the potential or density profiles is correctly described by the simple exponential screening predicted by LPB theory.
In terms of the screening length and dielectric constant of the solution (as opposed to the pure solvent), which can all be expressed by matching the LPB osmotic pressure to “exact” MC estimates, the resulting $Z^*$ is always lower than $Z$. $Z^*$ is roughly proportional to the polion radius $a$. The effects of microion correlations on the values of $Z^*$ have been investigated with LDA and WDA versions of DFT, and by MC simulations. Correlations tend to lead to a further decrease of $Z^*$ compared to $Z$, and even to a maximum value, followed by an actual decrease of $Z^*$ as a function of $Z$. If the effective charge is obtained by matching the LPB osmotic pressure to “exact” MC estimates, the resulting $Z^*$ turns out to depend only weakly on the ratio $a/R$, i.e. on the concentration of polions.

A more fundamental approach to a definition of effective charges is based on a careful analysis of the asymptotic decay of density profiles and correlation functions. This may be achieved within the “dressed ion” reformulation of linear response theory, i.e. of the polarization of an electrolyte by the average electrostatic potential. Within the PM, the point charges of the microions are replaced by a local, spread-out charge distribution incorporating the short-range fraction of the polarization charge around each bare ion, which is thus replaced by a dressed ion. The short-range fraction of the polarization charge is defined in terms of short-range contributions $h_{\alpha\beta}^\beta$ to the pair correlation functions $g_{\alpha\beta}(r) = h_{\alpha\beta}^\beta(r) - 1$; the $h_{\alpha\beta}^\beta$ are related to the short-range parts $c_{\alpha\beta}^\beta$ of the direct correlation functions, introduced after eq. (13), via coupled Ornstein-Zernike (OZ) relations. This leads to an exact, non-local generalization of the LPB equations, and a residue analysis of the corresponding Fourier transform of the potential $\psi_i(r)$ around an ion $i$ leads to the following asymptotic decay for large $r$:

$$
\psi_i(r) \sim \frac{z_i^{\alpha} \exp(-\kappa r)}{e^\beta r}
$$

(15)

This is precisely of the LPB (or Debye-Hückel) form, but with renormalized values $z_i^{\alpha}$, $\kappa$, and $e^\beta$ of the valence, inverse screening length and dielectric constant of the solution (as opposed to the pure solvent), which can all be expressed in terms of the $h_{\alpha\beta}^\beta$; the latter may be calculated by supplementing the OZ relations with some approximate closure, e.g. HNC.
In the weak-coupling limit of very low ionic bulk concentration, \( z^*_\pm \rightarrow z_\pm, \kappa \rightarrow \kappa_D \) and \( \epsilon^* \rightarrow \epsilon \). Simple Stillinger-Lovett sum rule considerations show that proper inclusion of the finite size of \( \sigma_\alpha \) of the ions leads to an enhancement of screening, i.e. \( \kappa > \kappa_D \) \([38]\). For sufficiently strong coupling (i.e. at high ionic concentrations), the exponential decay \([3] \) goes over to a damped oscillatory behaviour characterized by a pair of complex conjugate inverse decay lengths \( \kappa \) and \( \kappa^* \) \([38,40]\). The location of the cross-over from monotonous to oscillatory decay depends on the approximate closure.

The ”dressed ion” reformulation for the bulk PM may be extended to the case where one ionic species consists of polyions, and hence \( z^*_\pm \) is to be identified with the effective charge \( Z^* \) of the latter \([36]\). A similar treatment has been applied to planar electric double layers, to determine effective surface charge densities \([41]\). The latter tend to saturate for monovalent counterions, increasingly so as their concentration increases, while for concentrated solutions of divalent ions, the effective surface charge goes through a maximum before decreasing as the bare surface charge increases. This behaviour is reminiscent of that observed in a spherical cell \([23,24]\).

The effective polyion charge \( Z^* \) is not easily accessible to experiment. Indirect determinations are based on the assumption of the validity of some simple functional form of the effective pair interaction between polyions, generally a screened Coulomb (or DLVO) potential. The thermodynamic properties and pair structure of a system of polyions interacting via this potential can be determined accurately from fluid integral equations or simulations \([12,43]\). The effective charge \( Z^* \) is then adjusted to provide the best theoretical fit to experimental data, e.g. the polyion pair structure as measured by scattering experiments \([22,33]\), or the freezing line as a function of salt concentration and bare particle charge \([44]\). The latter measurements confirm the saturation predicted by the PB cell model \([22,23]\), but should be re-analysed since the underlying simulation data do not take into account an important ”volume” contribution to the free energies, which strongly affects the phase diagram at low salt concentration \([44]\).

Recent experiments, carried out at very low electrolyte concentration, on silica particles, with weakly dissociating silanol surface groups, and on latex particles, with strongly dissociating sulfonic acid groups, were able to measure simultaneously the bare polyion charges by conductometric titration, and the effective charges by conductivity measurements \([17,18]\). The bare charge was controlled by varying the amount of added NaOH. Under these experimental conditions, \( Z^* \) was not observed to saturate, but to follow very nearly a square root law \( Z^* \sim \sqrt{Z} \) for both colloidal systems.

### IV. PLANAR GEOMETRY

The simplest, and most widely studied double-layer geometry is that of uniformly charged, infinite planes in an ionic solution \([17]\). These planes may represent stacks of thin charged lamellae, like clay platelets or rigid membranes, or correspond to the surfaces of spherical colloidal particles separated by a distance \( h \ll a \), so that the curvature of the facing surfaces may be neglected in first approximation. In the former situation, one may consider the simplified model of a single charged plane within a slab of thickness \( h \) equal to the mean spacing between lamellae in the stack; this would be the 1d equivalent of the cell model. The two situations are shown schematically in Figure 1: \( \sigma \) denotes the surface charge density, \( \epsilon \) is the macroscopic dielectric constant of the solvent (within a PM representation) and \( \epsilon^* \) is the dielectric constant of the colloidal particles. When \( \epsilon^* \neq \epsilon \), which is the rule rather than the exception, the dielectric discontinuity at \( z = \pm h/2 \) must be properly incorporated in the boundary condition, e.g. by the introduction of electrostatic image charges \([49]\). In most published theoretical work the assumption \( \epsilon^* = \epsilon \) is made for the sake of simplicity.

Microion density profiles \( \rho_+ (z) \) and \( \rho_- (z) \) depend only on \( z \), and the intrinsic free energy functional per unit area perpendicular to the \( z \) axis is still given by eqs \([1]-[3]\), with the volume integrals replaced by 1d integrals over the interval \([-\frac{h}{2}, \frac{h}{2}] \). Fixed charge (or Neumann) boundary conditions imply that the potential satisfy:

\[
- \frac{d\psi}{dz} \bigg|_{z=\pm \frac{h}{2}} = \pm \frac{4\pi \sigma}{\epsilon}
\]

(16)

The key physical quantity, which is in principle measurable using a surface force apparatus \([0]\), is the force per unit area acting between two charged planes and their associated electric double-layers. This force per unit area is the net osmotic pressure (or disjoining pressure) \( \Delta P = P - P_{\text{bulk}} \), where \( P \) is the osmotic pressure exerted by the microions...
between the charged plates, and \( P_{\text{bulk}} \) is the pressure of the electrolyte in the reservoir which fixes the chemical potentials of the microions. \( P \) may be calculated via the mechanical route, by averaging the local stress tensor, or by the thermodynamic route, by differentiation of the total free energy, or grand potential, with respect to \( h \). Both routes lead to a natural separation of the pressure \( P \) into kinetic, electrostatic and collisional parts [49]:

\[
P = P_{\text{kin}} + P_{\text{el}} + P_{\text{coll}}
\]  

(17)

where

\[
P_{\text{kin}} = k_B T \sum_\alpha \rho_\alpha(z)
\]  

(18)

and explicit expressions for \( P_{\text{el}} \) and \( P_{\text{coll}} \) in terms of density profiles and inhomogeneous pair correlation functions are given in ref. [49]. Note that, while each of the terms in eq. (17) depends on the coordinate \( z \), their sum must be independent of \( z \) for mechanical equilibrium. In practice, simplified expressions are obtained by calculating \( P \) in mid-plane (\( z = 0 \) in Fig. 1) or at the surface of the charged planes. In the latter case the expression for \( P \) reduces to the simple contact theorem [5]:

\[
P = k_B T \sum_\alpha \rho_\alpha (z = \pm (h/2 - a_\alpha)) - \frac{2\pi \sigma^2}{\epsilon}
\]  

(19)

This expression is not very convenient for simulation purposes, since \( P \) appears as a difference of two large numbers, the first of which involves the contact value of the counterion density profile, affected by large numerical uncertainties. The calculation at midplane is then preferable, since the \( \rho_\alpha \) are expected to be close to their bulk values there, but the average force between microions on both sides of this plane must be evaluated [50].

A. Poisson-Boltzmann approximation

The mean-field approximation, where correlations between microions, due to excluded volume and Coulomb interactions, are neglected, is well understood since the pioneering work of Gouy [17]; density profiles and forces are known analytically, or given by simple quadratures [51]. The pressure is given throughout by:

\[
P = k_B T \sum_\alpha \rho_\alpha(z) - \frac{\epsilon}{8\pi} |E(z)|^2
\]  

(20)

where \( E(z) = -d\psi(z)/dz \) is the mean local electric field. This is most easily evaluated in the mid-plane, where \( E = 0 \) by symmetry, i.e. \( P = k_B T \sum_\alpha \rho_\alpha(0) \), showing that the force between equally charged plates is always repulsive within PB theory.

In the limit of low surface charge and electrolyte concentration, PB theory may be linearized, and the disjoining pressure reduces to:

\[
\Delta P = 2\sigma^2 e^{-\kappa_d h}
\]  

(21)

A charge renormalization to account for non-linearities, very similar to the procedure within the cell model described earlier, leads to a much reduced effective surface charge \( \sigma^* \), and to a saturation for large bare charges \( \sigma \) [52].

B. The effect of microion correlations

While PB theory always predicts a purely repulsive interaction between planar electric double-layers, it was suggested by Oosawa as early as 1968 [52] that the force might turn attractive if microion correlations were taken into account. The first convincing evidence for double-layer attraction came from MC simulations which indicated large deviations from the predictions of PB theory in the presence of divalent counterions [50]. This early prediction of an attractive minimum in the effective force between planar double-layers at short separations \( h \) was confirmed by subsequent simulations in the presence of salt (1 : 2 and 2 : 2 electrolytes) [49,54] and polyvalent counterions [55], by inhomogeneous HNC calculations [49], and an improved version based on the reference HNC (RHNC) closure [56,57], and by LDA and WDA versions of DFT [58,59].
The reduction of the double-layer repulsion and eventual correlation-induced attraction may be understood by considering the contact theorem \([19]\), or the expression for the pressure in midplane. At contact the correlations keep the counterions in the first layer apart, thus limiting the piling up following from the uncorrelated mean field treatment, and reducing the contact value of the counterion density; according to eq. \((19)\) this leads to a lowering of the pressure, which can even become negative (corresponding to an effective attraction), due to the negative Coulombic contribution. The lowering of the counterion concentration immediately at contact leads to an enhanced attraction of the next layers of counterions to the surface, so that correlations enhance the counterion density in that region. This enhancement in turn entails a depletion of the counterion density in the midplane, while electrostatic correlations make a negative contribution \((P_{el})\) which generally dominates the smaller, positive collisional part. Overall these various effects lead to a much reduced \(\Delta P\) compared to the repulsive PB interaction. The attraction observed for very short separations may be explained by a 2d lattice-like structuring of the adsorbed counterions, when the counterion patterns on opposite surfaces are shifted relative to each other to minimize the electrostatic interactions \([60]\).

The reason why an attraction is in general observed only with divalent (e.g. Ca\(^{++}\)) counterions is that the entropic cost associated with their "condensation" near the surface is smaller than for monovalent ions, since only half as many counterions are needed to provide the same electrostatic shielding. Another related aspect of microion correlations is the phenomenon of charge reversal (or inversion). The apparent charge density of the surface placed at \(z = -h/2\), seen at the abscissa \(z\) is \([31]\):

\[
\sigma^* (z) = \sigma + e \int_{-h}^{z} z \rho_{\alpha}(z)dz
\]

Within PB theory \(\sigma^*\) never changes sign, but in the presence of correlations this may occur at a critical \(z\), beyond which \(\sigma^*\) is of opposite sign to \(\sigma\), due to an over-compensation of the bare surface charge by the counterions. Thus a test-charge will be attracted, rather than repelled, by a plane carrying a surface charge \(\sigma\) of the same sign, beyond a critical separation. Charge inversion can only occur when the microion density profiles have a non-monotonic behaviour. The over- compensation of the surface charges of two parallel plates is enhanced when the counterions are linked together to form polyelectrolyte chains, due once more to the reduction of entropic repulsion \([61,62]\).

Charge inversion and effective attraction between platelets may even be observed in the case of monovalent counterions, provided the coions are larger than the counterions \([37]\).

Attractive forces between charged surfaces immersed in aqueous solutions of CaCl\(_2\) and Ca(NO\(_3\))\(_2\) have been measured directly with a surface force apparatus \([13]\). The existence of correlation-induced attraction between charged surfaces of equal sign has important consequences on colloid stability, and provides a plausible explanation for the common observation that the addition of multivalent ions to solutions or suspensions of polymers often leads to precipitation.

V. SPHERICAL POLYIONS

Aqueous solutions and dispersions of spherical or quasi-spherical polyelectrolytes, including globular proteins and charge-stabilized colloidal particles, like silica mineral particles or polymer latex spheres, have been thoroughly studied experimentally and theoretically for many decades. Much of the interest stems from the realization that such colloidal systems exhibit a phase behaviour reminiscent of that of simple molecular systems, albeit on very different scales. A particularly attractive feature of colloidal dispersions is that the effective interactions between particles may be tuned by the experimentalist, e.g. by varying the concentration of added electrolyte, thus providing an additional handle on phase behaviour. The beautiful early microscopy observations by Hachisu et al. \([64]\) unambiguously showed the existence, at low volume fractions, of colloidal crystals and crystalline alloys, which Bragg-reflect visible light and are, in particular, responsible for the iridescence of opals.

The coexistence of ordered crystalline and disordered fluid phases has been monitored by very careful experiments using confocal laser scanning microscopy, which allows the direct observations of ordered and disordered configurations, and ultra-small-angle X-ray scattering (USAXS), which provides statistically averaged information on ordering of colloids via the static structure factor \(S(k)\) \([17,18]\). These measurements provide three-dimensional phase diagrams by varying the colloid concentration \(n\) or packing fraction \(\eta = 4\pi n a^3/3\), the effective colloid charge \(Z^*\) (as determined by conductivity measurements), and the monovalent salt concentration \(n_s\), equal to the concentration \(n_+\) of coions,
typically in the range $10^{-6} - 10^{-5}$M. The observed phase diagrams exhibit a striking re-entrant behaviour, e.g. for fixed $n$ and $n_\alpha$, the colloidal dispersion crystallizes into an ordered BCC lattice upon increasing $Z^*$, as one might expect, but remelts into a disordered fluid phase upon further increase of $Z^*$, . This re-entrant behaviour may be qualitatively understood in terms of an increase of the total ionic strength, linked to an increase of the counterion concentration $n_\alpha$ with $Z^*$, which enhances the screening power of the microions and hence reduces the range of the screened Coulomb repulsion between polyions. However, the standard DLVO representation of the latter [65] fails to provide a quantitative explanation of the experimental data [24].

Another striking feature of low concentration dispersions ($\eta < 0.05$), reported by the Kyoto School, is the appearance of strongly inhomogeneous patterns in highly deionized samples. USAXS measurements and confocal laser scanning microscopy show clear evidence of regions of relatively high colloid concentration, which may be crystalline [77], amorphous [68] or fluid [69] in character, coexisting with regions of extremely low concentration, or voids. Apart from direct visual observation, the existence of voids, and the fraction of the total volume occupied by them, may be inferred from a comparison between the mean inter-particle spacing, $d_n \sim n^{-1/3}$, calculated under the assumption of a homogeneous dispersion, and the spacing $d_x$ deduced from the position of the main X-ray diffraction peak in the structure factor $S(k)$. The observation that $d_n$ is significantly less than $d_x$ points to the existence of voids occupying a fraction $f = 1 - (d_x/d_n)^3$ of the total sample volume. The considerable literature on the subject is summarized in ref [70]. The existence of voids, and the related, but controversial [71], observation of a complete separation between a high concentration colloidal "liquid" phase, and a much more dilute "gas" phase [72], are claimed to be evidence for a long range attractive component of the effective pair interaction between colloidal particles carrying charges of equal sign. The same attraction is also invoked to explain the re-entrant liquid-solid coexistence described earlier [66].

However recent direct measurements of the effective interaction between pairs of colloidal particles show no evidence of an attraction, at least at low concentration. Such direct measurements are based on video microscopy. In the simplest method, a large number of instantaneous configurations of a dilute suspension are recorded, and the colloid-colloid pair distribution function $g(r)$ is calculated from the measured distribution of inter-particle distances [73]. The effective pair potential coincides with the potential of mean force in the low concentration limit [8] and is hence given by:

$$v(r) = -k_B T \log[g(r)]$$  \hspace{1cm} (23)

An alternative method follows the relative Brownian motion of a pair of colloidal particles released from initial positions where they were localized by optical tweezers [74]. Both sets of measurements confirm that the effective pair potential is purely repulsive, and may be fitted to a screened Coulomb (DLVO) form by adjusting the effective charge $Z^*$ and the inverse screening length $\kappa D$, compatible with estimated salt concentrations. However this same DLVO potential, used within a harmonic approximation, seems to be unable to reproduce the measured bulk modulus of a colloidal crystal at much higher concentrations [75][76], although the difference between experiment and theory may be linked to the omission of the "volume" contribution to the effective interaction energy between polyions, to be discussed in the following section.

A. DLVO theory revisited

The effective pair potential between spherical polyions, first derived by Derjaguin and Landau, and Verwey and Overbeek [35], is easily recovered within the framework of DFT. Upon tracing out the microion degrees of freedom, the effective interaction energy between polyions is given by eq. (3), once the grand potential $\Omega$ has been determined from the variational principle (3). The required intrinsic free energy functional is defined by eqs. (6) and (9). Neglecting $F_{corr}$ in the latter amounts to mean-field theory, and the Euler-Lagrange equation associated with the variational principle (3) leads back to the PB equation (10) for the local electrostatic potential $\psi(r)$. Since the external charge associated with $N$ polyions is a multi-centre distribution, the numerical task of solving the PB equation for $N$ interacting polyions is a formidable one, which can only be handled numerically using advanced optimization techniques, coupling Molecular Dynamics (MD) simulations with DFT [77][79].

A more phenomenological approach may be adopted, whereby the bare polion charge is reduced to a considerably lower effective value by a Stern layer of tightly bound counterions. The coupling between the polyions and the remaining microions (forming the so-called "diffuse" double-layer) is accordingly strongly reduced, so that the corresponding density profiles $\rho_\alpha(r)$ vary much more smoothly in the vicinity of the polion surfaces. In that case the integrands of
the ideal contributions to $F$ in eq. (8) may be expanded to second order in the deviations $\Delta \rho_\alpha(r) = \rho_\alpha(r) - n_\alpha$ of the local densities from their bulk values, i.e.:

$$
F_{id} \approx \sum_{\alpha = \pm} \left\{ F_{id}(V, T, n_\alpha) + \frac{k_B T}{2n_\alpha} \int_V |\Delta \rho_\alpha(r)|^2 \, dr \right\}
$$

(24)

where $F_{id}(V, T, n_\alpha)$ is the Helmholtz free energy of an ideal gas of density $n_\alpha$. The free energy functional defined by (6) and (8), neglecting $F_{corr}$, is now a quadratic functional of the local densities, and the resulting Euler-Lagrange equation reduces to a linear multi-centre PB (LPB) equation for the local potential $\psi(r)$, in the familiar form:

$$
(\nabla^2 - \kappa_D^2) \psi(r) = -\frac{4\pi}{\epsilon} \rho^{ext}(r)
$$

(25)

This linear equation is easily solved by Fourier transformation in the bulk, with the boundary condition that the potential and its gradient vanish at infinity. Since $\rho^{ext}$ is a linear superposition of contributions from the $N$ polyions, the same is true of $\psi(r)$ and the resulting $\rho_\alpha(r)$. Since microions cannot penetrate the spherical polyions, the excluded volume condition, $\rho_\alpha(r) = 0$: $|r - R_i| < a(1 \leq i \leq N)$, must be imposed via a constraint, or by the use of a polyion-microion pseudo potential [45,46]. Note that, strictly speaking, the linear superposition of densities only holds provided the electric double-layer associated with a given polyion does not overlap a neighbouring polyion (“weak overlap approximation”). This is not a significant limitation except at high polyion packing fraction. The excluded volume condition leads to an additional polyion charge renormalization such that the effective charge $Z^*$ is multiplied by the DLVO factor $e^{2N}/(1 + \kappa_D a)$; the product will henceforth be designated by $Z^*$. The local potential is finally of the form:

$$
\psi(r) = \sum_{i=1}^{N} \psi^{(i)}(r) = \sum_{i=1}^{N} Z^* e \exp \left(-\kappa_D |r - R_i| \right) / |r - R_i|
$$

(26)

When (26) and the resulting $\rho_\alpha(r)$ are substituted into the quadratic free energy functional, the effective interaction energy $V_N$ between the $N$ polyions reduces to:

$$
V_N(\{R_i\}) = V_0 + \sum_{i<j} v(|R_i - R_j|)
$$

(27)

where $V_0(T, n, n_+, n_-)$ is a state-dependent "volume" term [8], the detailed expression of which is given in [10] and [11]. This term has been generally overlooked, but it strongly influences the calculated phase behaviour of charge-stabilized colloidal dispersions, as discussed later. The main contribution to the volume term is the sum of cohesive electrostatic free energies arising from the electrostatic attraction between each polyion and its associated double layer of opposite charge. The physical interpretation of $V_0$ is discussed in detail in ref. [8]. The effective pair potential is precisely of the well known DLVO form [8], namely:

$$
v(R) = \frac{Z^* e^2}{\epsilon} \frac{e^{-\kappa_D R}}{R}
$$

(28)

Note that the pair-wise additivity in eq. (27) is a direct consequence of the quadratic nature of the approximate free energy functional; the exact ideal contribution (5) to the free energy would lead to many-body effective interactions.

There are alternative contraction procedures to reduce the initial asymmetric, multicomponent PM to an effective one-component system, based on the OZ equations and approximate closures, like the MSA, for the partial pair distribution functions $g_{\alpha \beta}(r)$ [14,15]. The simple assumption of the asymptotic behaviour $c_{\alpha \beta}(r) \rightarrow v_{\alpha \beta}(r) / k_B T$ of the direct correlation functions is sufficient to show that the effective pair interaction is asymptotically of the DLVO form [28], and reduces to (28) in the appropriate limits. Corrections to the DLVO potential at short range may be obtained from numerical solutions of the fluid integral equations, and confirm the purely repulsive nature of the effective pair potential at low colloid concentration, at least when all microions are monovalent [13].

The phase diagram of a monodisperse system of particles interacting via the DLVO pair potential [28] has been determined by extensive MC simulations as a function of colloid and salt concentrations, the latter determining the inverse Debye screening length $\kappa_D$ [12,13]. As expected from the purely repulsive nature of the effective pair potential, the phase diagram exhibits a first-order transition between a single (disordered) fluid phase and (ordered) FCC or BCC crystalline phases, BCC being the stable phase in the $\kappa_D \rightarrow 0$ limit, which corresponds to the widely
studied "one-component plasma" (OCP) model\cite{83}. However the coarse-graining procedure leading from the initial multicomponent polyelectrolyte/microion "mixture" to the effective one-component system also introduces the volume term $V_0$ into the effective interaction energy between polyions. Since $V_0$ is a non-linear function of the polyelectrolyte density $n$, due to the overall charge neutrality condition $n^Z+ n^+_z+n^-z=0$, this term must be included in the free energy for a proper determination of the phase behaviour \cite{15,14,82}. At high concentrations of added salt, the variation of $V_0$ with $n$ is sufficiently slow not to affect the phase behaviour significantly. At salt concentrations lower than $10^{-5}\text{M}$, the volume term drives a van der Waals-like instability of the fluid, which separates into two phases of very different colloid concentrations, reminiscent of the "gas" and "liquid" phases of ordinary molecular fluids. Depending on the effective colloid surface charge, this phase separation is completely disconnected from the freezing transition driven by the repulsive pair interaction \cite{28}, and exhibits upper and lower critical points (re-entrant behaviour) in the $n-n_0$ plane (see Figure 2); or it merges with the freezing line, leading to a considerable broadening of the fluid-solid coexistence region, and the possibility of upper and lower triple points, as seen in Figure 3. The possibility of a fluid miscibility gap in polyelectrolytes had been conjectured already in 1938 by Langmuir, who referred to it as "unipolar coacervation"\cite{84}, and the complex phase scenario of references \cite{14,10,82} has recently been confirmed by an extension of Debye-Hückel theory to the highly asymmetric PM\cite{85}. These calculations provide a natural explanation for the observed phase behaviour of charge-stabilized colloids, including the formation of voids\cite{17,72}, without the assumption of a long-range attractive component in the effective pair interaction which is frequently made\cite{86}, but lacks a firm theoretical basis.

B. Beyond DLVO

It was shown earlier that the effective force between two uniformly charged plates may turn attractive at short distances if correlations between microions are properly accounted for. A similar effect is expected to hold between two spherical polyions, as first conjectured for two isolated spheres by Patey\cite{15} on the basis of numerical solutions of the HNC equation. When two spheres are sufficiently close, such that the shortest separation $h$ between their surfaces is much less than their radius $a$, the problem reduces essentially to that of two charged planes discussed earlier: a short-range correlation-induced attraction may be expected for divalent counterions. A collective polarization mechanism of adsorbed counterions operates in the opposite limit $h \gg a$, and leads to a "doubly screened" attractive component, proportional to $e^{-2\kappa D R}$, which is always dominated by the DLVO repulsion \cite{85}. It is important to stress that effective attractions between spherical polyions require a finite concentration of the latter in the absence of salt, i.e. when only counterions are present\cite{87,88}. No such restriction holds at finite salt concentration, where the problem of two isolated polyions is a meaningful limit.

A similar "doubly screened" attraction between spherical polyions occurs in the charge regulation PM introduced earlier (c.f. eq. (12)); explicit HNC calculations have been carried out for small mineral oxide particles\cite{27}. Note that the effective interaction between two isolated colloids is purely attractive (for $R > 2a$) in the case of a symmetrical adsorption of co and counterions ($V_+ = V_-$ in eq. (12)), because the colloidal particles are then, on average, neutral.

C. Computer simulations

Density-functional molecular dynamics simulations were performed for monovalent counterions without\cite{78,89} and with\cite{79} added salt. The effective interaction between the polyions was found to be repulsive, and in qualitative agreement with DLVO theory, provided the charge was renormalized according to the cell model prescription incorporating the excluded volume correction\cite{91}. This approach includes counterion correlations, but is not completely equivalent to a full simulation of the PM since an approximate polyelectrolyte-counterion pseudopotential is used and the exact density functional of the electrolyte is unknown. Due to the high charge asymmetry between poly- and microions, a full simulation of the PM requires the inclusion of many counter- and salt ions and is not feasible on present-day computers. There are two ways to escape from this: either by considering only a small number of polyions or by reducing the charge asymmetry significantly. By considering only two polyions within the PM, the effective pair potential can be calculated within a simulation by averaging over the microscopic ions, while keeping the polyion positions fixed. For monovalent microions, the simulation yields repulsive forces correctly described by DLVO theory both with\cite{92} and without\cite{89} added salt. For divalent counterions, attractive forces are obtained, which may be attributed to counterion correlations\cite{88} and Coulomb depletion\cite{24}, resulting from a depletion zone of counterions between two nearly touching polyions due to the strong counterion repulsion. A typical snapshot of the counterions around two fixed polyions and the averaged force versus polyion distance are shown in Figure 4. A system of three
polions was simulated in order to extract effective triplet interactions which were found, however, to be small with respect to the pairwise part [13].

On the other hand, there are quite a number of full simulations of the PM with a reduced charge asymmetry corresponding to micellar rather than colloidal polions. Most of the work is summarized in a review by Vlachy [96]. As for more recent work, the role of salt valency has been investigated in some detail [97]. Moreover Linse and Lobaskin pushed the charge asymmetry to $Z : T = 60 : 1$, $60 : 2$, $60 : 3$ using efficient cluster move algorithms [14,15] and treating 80 polions simultaneously [14]. For the $60 : 3$ asymmetry clear indications for a phase separation were reported which can be attributed to an effective attraction between polions.

VI. POLIONS IN CONFINED GEOMETRIES

The bulk behaviour of polionic dispersions is expected to change significantly in the presence of neutral or charged interfaces confining the dispersion to a restricted volume. Such confinement occurs naturally in the vicinity of the sample container, which may be approximated locally by an infinite plane restricting the suspension to a half space. Many experiments are carried out in a slit geometry, with the suspension confined between parallel planes (e.g. glass plates); if the interplanar spacing is comparable to the diameter $2a$ of the polions, the suspension behaves like a quasi-two-dimensional (2d) many-body system exhibiting interesting phase behaviour [106].

The electrostatic effects of confinement are essentially threefold. (i) The interface between two different dielectric media, e.g. the suspension and the glass of the container wall, must be characterized by appropriate boundary conditions; in particular the dielectric discontinuity implies the presence of electrostatic image charges. (ii) The confining surfaces lead to a reduction in screening power of the electrolyte, which ceases to be exponential in directions parallel to the surface [107]. (iii) If the surfaces are charged, they attract or repel the polion and microions, and release additional counterions into the suspension.

These effects will modify the electrostatic interactions between double-layers associated with polions close to the confining walls. This has been clearly demonstrated by a number of direct measurements of the effective forces between spherical polions confined near a glass wall, or in narrow slits, using digital video microscopy techniques similar to those mentioned earlier for measurements in the bulk. Measurements of the colloid pair distribution function $g(r)$ carried out at sufficiently low concentration allow the effective pair potential to be extracted directly from eq. (23) [102,103], while data collected from more concentrated samples, where the effective potential $v(r)$ is expected to differ significantly from the potential of mean force defined by eq. (24), require an elaborate inversion procedure based on fluid integral equations (properly adapted to a 2d geometry) [104,105], or on an iterative method involving computer simulations [102]. These experiments leave little doubt for the existence of an attractive component of the effective pair potential at low ionic strength (i.e. for salt concentrations estimated to be below about $10^{-3} M$), when the polions are highly confined, as achieved in narrow slits [102,104], or by localizing them close to a single plane by optical tweezers [103,104,107]. The observed attractive well in $v(r)$ is relatively shallow (depth of the order of $k_B T$), and long-ranged; typically $v(r)$ becomes negative for interparticle distances considerably larger than the particle diameter $2a$. The experiments carried out for two particles close to a charged plate with the centre-to-centre vector parallel to the plate, clearly show that the attractive well disappears when the particles are moved away from the plate; the measured $v(r)$ returns to its bulk DLVO form (28) when the distance to the plate is several particle diameters [103,104,107]. An additional twist for suspensions of colloidal particles confined to a slit is provided by the introduction of quenched obstacles, in the form of larger, charged colloids, which form a disordered porous 2d matrix. As the concentration of such obstacles is increased, the effective interaction potential between the smaller colloids is observed to develop a second attractive component extending to larger inter-particle separations [108]. Closely related observations of metastable colloidal crystallites suggest that facets of such crystals behave very much like charged plates, inducing effective attractions between nearby polions due to many-body interactions.

The DFT formulation of DLVO theory in the bulk has been extended to the case of confined particles. The electrostatic potential due to a point polion near a planar surface separating two media of dielectric constants $\epsilon$ and $\epsilon'$ was determined within LPB theory by Stillinger as early as 1961 [109]. The case of two spherical polions of finite radius a near an uncharged planar surface was examined within LPB theory in [110]. Since microions cannot leak beyond the dividing surface, the spherical symmetry of the electric double layers around each of the polions is broken. The effective repulsion between the polions is enhanced, and decays like $1/R^3$, where $R$ is the separation parallel to the surface, as expected from the considerations in [101].
If the confining surface carries an electric charge density $\sigma$, as would be the case for a glass plate in contact with an aqueous dispersion, the planar electric double-layer building up near the surface will modify the local co and counterion concentrations in the vicinity of nearby polyions, and hence influence their mutual interaction. Considering with an aqueous dispersion, the planar electric double-layer building up near the surface will modify the local co and counterion concentrations in the vicinity of nearby polyions, and hence influence their mutual interaction. Considering

The simplest model system is the electric double layer around a single infinitely long cylindrical polyion of radius $a$ which is homogeneously charged with line charge density $\lambda$. LPB theory leads to the electric potential $\Psi(r) = \lambda K_0(\kappa_D r)/aK_1(\kappa_D a)$ where $r$ is the distance from the rod axis and $K_0(x), K_1(x)$ are Bessel functions of imaginary argument. Consequently, LPB theory predicts the effective interaction $v(r)$ between two parallel rods per unit length to be of the following form:

$$v(r) = \frac{\lambda^2}{(\kappa_D a K_1(\kappa_D a))^2} K_0(\kappa_D r)$$

where the factor $1/(\kappa_D a K_1(\kappa_D a))]$ is the excluded volume correction. Contrarily to the three-dimensional case, LPB theory can be solved analytically within a cylindrical cell around the charged rod for vanishing salt concentration. The analytical solution for the counterion density field around the colloidal rod exhibits a strong peak at contact providing a theoretical framework of Manning counterion condensation. As for spherical macroions, one cannot extract an effective interaction from the PB solution for a single double-layer directly. One possibility is to proceed as for the spherical PB cell model. Matching the LPB theory at the cell boundary, one derives the effective interaction potential $v(r) = \lambda^2/\epsilon K_0(\kappa r)$, where $\kappa$ and $\lambda^*$ are renormalized according to the cell model prescription.

VII. ROD-LIKE POLYIONS

There is a large variety of rod-like polyions ranging from synthetic suspensions to biological macromolecules. These include colloidal $\beta$-FeOOH [19], imogolite [20], boehmite [21,22], polytetrafluoroethylene [23], ellipsoidal polystyrene latex particles [24], cylindrical micellar aggregates [25], as well as virus solutions from tobacco-mosaic (TMV) [26,27], or bacterial fd [30,31] and Pf1 viruses [32]. Another motivation to study rod-like colloids comes from the self-assembly of charged stiff biopolymers such as DNA strands [33,34], F-actin fibers [35] and microtubules [36] which constitute rod-like polyions on a supramolecular rather than on a colloidal length scale.

There is a large variety of rod-like polyions ranging from synthetic suspensions to biological macromolecules. These include colloidal $\beta$-FeOOH [19], imogolite [20], boehmite [21,22], polytetrafluoroethylene [23], ellipsoidal polystyrene latex particles [24], cylindrical micellar aggregates [25], as well as virus solutions from tobacco-mosaic (TMV) [26,27], or bacterial fd [30,31] and Pf1 viruses [32]. Another motivation to study rod-like colloids comes from the self-assembly of charged stiff biopolymers such as DNA strands [33,34], F-actin fibers [35] and microtubules [36] which constitute rod-like polyions on a supramolecular rather than on a colloidal length scale.
A more direct theory, which requires a larger numerical effort, is to solve the two-dimensional PB theory for two parallel rods in a slit geometry and extract the effective force from there. In a recent numerical study [141] no attraction was found, consistent with the exact result [116] in three dimensions.

Beyond the PB level of description, computer simulations for the effective interaction between two parallel, homogeneously charged rods have been performed for divalent counterions and no added salt [142]. An effective attraction between the rods was found. The question is whether the attraction is due to correlations [143] or to fluctuations [144,145]. If the former is true, the attraction should increase with decreasing temperature and may even persist for zero temperature, while fluctuation-induced attraction should increase with temperature. On the basis of a simple model [146], Levin and coworkers gave significant support for a correlation picture. This can be intuitively understood as the gain in electrostatic energy upon bringing together staggered arrays of adsorbed counterions [60,147]. Fluctuation [148,149] and polarization effects [150] may still play an important additional role. For parallel rods on a triangular lattice, a negative pressure was found by computer simulation with divalent counterions [151], which can be attributed to some attractive component in the effective interactions.

Qualitatively, the situation closely resembles the case of spherical macroions. But there are also differences. First, Manning condensation theory applies only to rod-like polymers. A possible mechanism of attraction of nearly touching rods by sharing Manning-condensed counterions was proposed, which is only possible for rods [152]. Secondly, the Coulomb depletion mechanism for attraction [94] was found to be irrelevant for parallel rods.

For finite rod lengths and arbitrary orientations of the rods, the effective interaction between two rods will depend both on the rod orientations and on their center-of-mass separation. Starting from point charges distributed along the rods, LPB theory results in a Yukawa-segment model [153] which was confirmed by density-functional Molecular-Dynamics simulations for monovalent counterions [140], provided the charge and the screening constant \( \kappa \) are renormalized according to the cell model prescription. The associated phase diagram for parameters suitable for the TMV suspension was calculated, involving different liquid crystalline phases [154].

A full simulation of the PM was performed for stiff polyelectrolytes [155], resulting in bundle formation, which is a possible sign of an effective attraction. Clearly, the effective pair potential picture is insufficient for bundles [156] and many-body interactions play a significant role [148,149].

**VIII. LAMELLAR POLYIONS**

Lamellar polyions may be schematically looked upon as rigid or flexible charged surfaces or platelets, providing a 2d counterpart of charged rods or polyelectrolytes. Examples are the geologically and technologically important smectite clays [157] and self-assembled bilayers of ionic surfactants, which constitute the proto-type of biological membranes [51].

Consideration will first be given to electric double-layers around infinitely thin, uniformly charged circular or square platelets, which constitute a reasonable model of smectite clay particles, and in particular of the widely studied synthetic Laponite mineral particles. To a good approximation the latter are rigid, thin discs, of thickness \( d \approx 1 \text{nm} \), radius \( a \approx 15 \text{nm} \), carrying a structural surface charge \( \sigma \approx -e/(\text{nm})^2 \). Natural montmorillonite clays are silicate mineral platelets of similar chemical composition and crystal structure, but of irregular and polydisperse shape, and of much larger lateral dimension, implying some degree of bending flexibility.

Dry powders of clay will swell upon the addition of water, releasing counterions into the interlamellar volume, and building up interacting electric double-layers; the swelling is essentially driven by the double-layer repulsion of mostly entropic origin. During the initial stages of swelling, the spacing \( h \) between platelets remains small compared to their lateral extension, so that a moderately swollen lamellar phase may be reasonably modelled by a stack of infinite charged planes [158]. The results for planar geometry, discussed earlier, apply then directly to the swollen phase. In particular, limited swelling, often observed in the presence of divalent counterions, may be related to the cohesive behaviour (effective attraction between planes, or negative disjoining pressure) due to correlation effects within the PM [159]. An important issue in the understanding of the swelling behaviour is the competitive condensation of counterions of different valence and/or size [159,160]. The PM model is, however, expected to be inadequate when the interlamellar spacing \( h \) is only of the order of a few micron sizes. Under those conditions the molecular nature
of the solvent (water) must be explicitly taken into account. Constant pressure MC simulations clearly show the importance of counterion hydration in determining the swelling behaviour, and point to the role of K+ ions as a clay swelling inhibitor \[161\]. When swelling proceeds until the interlamellar spacing \( h \) becomes comparable to the platelet radius \( a \), finite size (edge) effects become important. The force acting on a platelet follows from the integration of the stress tensor \( \Pi \) over the two faces \( \Sigma_+ \) and \( \Sigma_- \) of the platelet:

\[
F = -\int_{\Sigma_+ \cup \Sigma_-} \Pi \, ds
\]

where \( ds = \hat{n} \, ds \) is the surface element oriented along the outward normal \( \hat{n} \), and the stress tensor has the standard form:

\[
\Pi = \left[ P(r) + \frac{e}{8\pi} |E|^2 \right] I - \frac{e}{4\pi} E(r) \otimes E(r)
\]

which generalizes the uniaxial expression \( D \). Within LPB theory, eq. \( D \) leads to the following expression for the force between two coaxial discs separated by \( h \), immersed in an ionic solution of inverse Debye length \( \kappa_D \) \[162\]:

\[
F_z(h) = (\pi a^2) \times \frac{4\pi \sigma^2}{\epsilon} \int_0^\infty J_1^2(x) \frac{1}{x} \exp\left\{ -\frac{h}{a} \sqrt{x^2 + \kappa_D^2 a^2} \right\} \, dx
\]

Numerical solutions of the non-linear PB equation, for the same coaxial geometry, show that the LPB expression \( D \) strongly overestimates the force \[163\], as in the spherical case, thus requiring a proper renormalization of the surface charge density \( \sigma \). Recent MC simulations show that the force may become attractive for divalent counterions, as in the case of infinite charged planes, but that the finite size of the discs leads to significant differences in the relative weight of electrostatic and contact contributions \[164\].

Finite concentration effects in highly swollen stacks of parallel platelets of finite size may be examined within a cell model, compatible with the shape of the platelet. A coaxial cylindrical cell is chosen for a disc-shaped platelet, while a parallelepipedic cell is better adapted to square platelets \[162,165\]. Note that the platelet concentration determines the cell volume, but not the aspect ratio of the cell, e.g. the ratio \( R/h \) in the case of a cylindrical cell of radius \( R \) and height \( h \) equal to the inter-lamellar spacing; the optimum aspect ratio for given volume and electrolyte concentration is determined by minimizing the free energy of the microions in the cell. The latter has been calculated within LPB theory which can be solved analytically \[162,166\], and within non-linear PB theory, which requires numerical solution; the latter is greatly simplified within a Green’s function formulation \[163,166\].

The osmotic pressures calculated as a function of Laponite concentration within PB theory agree reasonably well with experimental data \[167\], for reservoir salt concentrations of the order of \( 10^{-3} \text{M} \) or larger, but differ dramatically from the predictions of 1d PB theory for stacks of infinite platelets, pointing to the importance of edge effects in highly swollen clays \[166\].

In very dilute dispersions of clay platelets, such that the distance between the centres of neighbouring polynomials is significantly larger than the particle radius, the platelets can rotate more or less freely (sol phase). As the concentration increases, a gel phase is formed, depending on salt concentration. Several recent experiments have attempted to establish a link between the mesoscopic fractal structure of the gel, and its rheological properties \[167,169\], but no clear-cut scenario has yet emerged, due to metastability and ageing of the dispersions \[170\].

A theoretical description of the sol-gel transition of clay dispersions hinges on a knowledge of the highly anisotropic effective interaction between charged platelets in an electrolyte. The charged segment, or site-site model, introduced earlier for charged rods has been generalized to charged circular platelets, and used in MD simulations of Laponite dispersions \[171\].

For well separated platelets, the effective pair potential reduces to a sum of screened interactions between the electrostatic multipoles associated with the anisotropic electric double layers around each platelet \[172\]. A simplified version of such an effective interaction, involving infinitely thin discs carrying an unscreened quadrupole moment, has been used in MC simulations which predict a reversible sol-gel transition \[173\].

Lipid bilayers and membranes constitute another class of lamellar polyions, which are flexible. Electrostatic interactions renormalize the bending rigidity of these flexible membranes \[51\], a subject of ongoing work beyond the
scope of this review. In relation to the correlation-induced attraction between like-charged planes discussed earlier, the fluidity of membranes provides an additional mechanism for attraction between membranes, resulting from the lateral charge fluctuations within the planes of the latter [174].

IX. DISCRETE SOLVENT EFFECTS

So far all theoretical considerations of interacting electric double-layers were based on the PM, which ignores the molecular nature of the solvent. The PM thus neglects excluded volume effects of the latter, as well as hydration of ions and the expected reduction of the local dielectric constant near highly charged surfaces, due to polarization of nearby water molecules. Neglect of these and other solvent effects is expected to be particularly inadequate in situations where the spacing between two charged polyion surfaces is only of the order of a few molecular diameters.

To go beyond the PM level of description, simple models have been used to describe the solvent molecules (generally water). The crudest model is to represent the latter by neutral hard spheres of appropriate diameter, while neglecting a macroscopic dielectric constant \( \varepsilon \) in the Coulombic interactions between ions; this model accounts only for excluded volume effects. The next refinement is to consider hard spheres with embedded point dipoles, to account for the highly polar nature of the solvent [173], while a reasonable local coordination of the solvent molecules can only be achieved by adding higher order multipoles [176–178]. In MC or MD simulations, much more sophisticated pair potentials may be used, involving three or more interaction sites on each water molecule, as in the widely used SPC/E potential [179].

A purely HS solvent is implicit in the modified PB formulation of Kralj-Iglic and Iglic [180] and others [114,181]. As expected, the modified PB equation leads to a saturation of the counterion density at contact, for high surface charge densities. The force between two charged surfaces in a mixture of charged and neutral hard spheres was calculated by Tang et al. [182] within a DFT generalizing the earlier theory of the same authors for a PM electrolyte [59]; the force is a strongly oscillatory function of the spacing between the plates, due to HS layering, and is rather insensitive to surface charge and salt concentration. The latter observation, which holds when solvent, anions and cations are of the same size, does not carry over to the more realistic case of unequal diameters, which has been investigated within IHNC theory [183]. At low surface charge, the total force between platelets is reasonably approximated by a superposition of the pure HS solvent "hydration" force, and the electrostatic contribution of the ions, as calculated within the PM, in the case of equal diameters [183,184].

The dipolar HS model for the solvent was first used to determine the structure of the electric double layer near a single charged wall within the MSA [183,184]. More accurate and complete results on the planar electric double layer in a dipolar solvent were obtained from numerical solutions of the coupled RHNC equations for the three density profiles [185]. These calculations give Statistical Mechanics evidence for the reduction of the local dielectric constant near the charged surface, and for significant electrostriction. A generic density functional, based on Rosenfeld’s successful "fundamental measure" theory for hard core fluids [188], has been put forward, which can be adapted to any polyion geometry [189]; when applied to a single planar double layer, this theory shows a considerable enhancement of the counterion density at contact, when a dipolar, rather than bare HS solvent is used.

The effective solvation force between two charged plates immersed in an ionic solution of charged and dipolar HS was calculated within a quadratic free energy functional of the local density, charge density and polarization, generalizing eqs. [24] and [29] (with direct correlation functions approximated by bulk MSA solutions) [191]. This calculation provided the first convincing evidence of the strong influence of a granular (as opposed to continuous) solvent on the solvation forces at short range.

The most complete investigation so far of the potential of mean force between two spherical polymers immersed in an ionic solution with a "realistic" solvent involving hard spheres with point dipoles and tetrahedral quadrupoles [174] appears to be the work by Kinoshita et al. [192], who solved the RHNC equations for this highly asymmetric multicomponent "mixture", for ratios \( 10 \leq a/a_s \leq 30 \), where \( a \) and \( a_s \) are the polyion and solvent molecule radii. While maintaining \( a_s \) fixed at 0.14nm, a value appropriate for water, these authors varied the counterion radius. Their most striking finding is that larger counterions are more strongly adsorbed to the polyion in the presence of a molecular solvent, leading to a greater reduction of the Coulomb repulsion between the polymers, and even to the possibility of an effective attraction for monovalent counterions, when their radius exceeds \( a_s \) by more than 20%. The trend towards a reduction of effective repulsion with increasing counterion size is the exact opposite of the prediction of the PM, a clear illustration of the pitfalls of the latter in describing the short-range behaviour of solvation forces!
Obviously more work on discrete solvent models is needed.

**X. OUTLOOK**

Although the understanding of effective interactions between electric double layers has clearly advanced in the last decade through a combination of new theoretical approaches, quantitative measurements and large-scale computer simulations, there are still many open questions. Future research should focus on the influence of image charges due to dielectric discontinuities between the solvent and the container walls or the polyelectrolytes themselves. Real samples possess, moreover, an intrinsic polydispersity in size, charge and shape which becomes relevant for a quantitative comparison between theory and experimental data. Another rapidly growing field concerns flexible polyelectrolyte chains whose stiffness is governed by their persistence length. A theoretical approach needs input from both nonlinear screening and polymer theories. Colloids can also be stabilized by polyelectrolytes, and the resulting effective interaction becomes qualitatively different from that between charged spheres, particularly near the overlap concentration. The microscopic incorporation of the solvent is still in its early stage and full molecular theories describing hydration forces and hydrogen bonding are highly desirable for aqueous suspensions. Lastly alternative approaches, such as recent field theoretical formulations, might lead to additional insight.

Figure captions

Figures 1a, 1b: Two different plate geometries.

Figure 2: Phase diagram for a charged suspensions in the $\eta - n_s$ plane with $\eta = 4\pi n a^3/3$ and $Z = 350$, $a = 380\text{nm}$, $\epsilon = 13.9$ (pentanol) and monovalent counterions at room temperature. Possible phases are fluid (F), gas (G), liquid (L), and face-centered-cubic (FCC) crystals. Tie-lines denote coexistence conditions.

Figure 3: Same as Figure 2, but now for $Z = 1000$, $a = 350\text{nm}$, $\epsilon = 25.3$ (ethanol). There is a triple point of coexisting gas, liquid and crystal.

Figure 4: Effective force $F$ in units of $F_0 = \frac{Z^2 e^2}{\epsilon a^2} \times 10^{-4}$ between two polyions versus reduced distance $r/a$. The squares are for aqueous suspensions. The force is repulsive in good agreement with DLVO-theory (dashed line). The circles are for a solvent with a strongly reduced dielectric constant $\epsilon$ and show attraction. The parameters are given in detail in Ref. [94]. The inset shows a counterion configuration around two fixed polyions.
