Abstract

Modern neural networks are often augmented with an attention mechanism, which tells the network where to focus within the input. We propose in this paper a new framework for sparse and structured attention, building upon a max operator regularized with a strongly convex function. We show that this operator is differentiable and that its gradient defines a mapping from real values to probabilities, suitable as an attention mechanism. Our framework includes softmax and a slight generalization of the recently-proposed sparsemax as special cases. However, we also show how our framework can incorporate modern structured penalties, resulting in new attention mechanisms that focus on entire segments or groups of an input, encouraging parsimony and interpretability. We derive efficient algorithms to compute the forward and backward passes of these attention mechanisms, enabling their use in a neural network trained with backpropagation. To showcase their potential as a drop-in replacement for existing attention mechanisms, we evaluate them on three large-scale tasks: textual entailment, machine translation, and sentence summarization. Our attention mechanisms improve interpretability without sacrificing performance; notably, on textual entailment and summarization, we outperform the existing attention mechanisms based on softmax and sparsemax.

1 Introduction

Modern neural network architectures are commonly augmented with an attention mechanism, which tells the network where to look within the input in order to make the next prediction. Attention-augmented architectures have been successfully applied to machine translation [2, 27], speech recognition [9], image caption generation [41], textual entailment [35, 29], and sentence summarization [36], to name but a few examples. At the heart of attention mechanisms is a mapping function that converts real values to probabilities, encoding the relative importance of elements in the input. For the case of sequence-to-sequence prediction, at each time step of generating the output sequence, attention probabilities are produced, conditioned on the current state of a decoder network. They are then used to aggregate an input representation (a variable-length list of vectors) into a single vector, which is relevant for the current time step. That vector is finally fed into the decoder network to produce the next element in the output sequence. This process is repeated until the end-of-sequence symbol is generated. Importantly, such architectures can be trained end-to-end using backpropagation.

In parallel to these empirical successes, attention is playing an increasingly crucial role in bringing more interpretability to neural networks by helping explain how individual elements in an input contribute to the model’s decisions. However, the most commonly used attention mechanism, softmax, tends to produce dense outputs, meaning that all elements in the input always make at least a small contribution to the decision. To overcome this limitation, sparsemax was recently proposed [29], using the Euclidean projection onto the simplex as a sparse alternative to softmax. Compared to
A Regularized Framework for Sparse and Structured Neural Attention

Figure 1: Attention weights produced by the proposed fusedmax, compared to softmax and sparsemax, on sentence summarization. The input sentence to be summarized (taken from [36]) is along the \( x \)-axis. From top to bottom, each row shows where the attention is distributed when producing each word in the summary. All rows sum to 1, the grey background corresponds to exactly 0 (never achieved by softmax), and adjacent positions with exactly equal weight are not separated by borders. Fusedmax pays attention to contiguous segments of text with equal weight; such segments never occur with softmax and sparsemax. In addition to enhancing interpretability, we show in [4, 3] that fusedmax outperforms both softmax and sparsemax on this task in terms of ROUGE scores.

softmax, sparsemax outputs more interpretable attention weights, as illustrated in [29] on the task of textual entailment. The principle of parsimony, which states that simple explanations should be preferred over complex ones, is not, however, limited to sparsity. For instance, it remains open whether new attention mechanisms can be designed to benefit from more structural prior knowledge.

Our contributions. The success of sparsemax motivates us to explore new attention mechanisms that can both output sparse weights and take advantage of structural properties of the input through the use of modern sparsity-inducing penalties. To do so, we make the following contributions:

1) We propose a new general framework that builds upon a max operator, regularized with a strongly convex function. We show that this operator is differentiable, and that its gradient defines a mapping from real values to probabilities, suitable as an attention mechanism. Our framework includes the softmax and a slight generalization of sparsemax as special cases. (§2)

2) We show how to incorporate the fused lasso [39] in this framework, to derive a new attention mechanism, named fusedmax, which encourages the network to pay attention to contiguous segments of text when making a decision. This idea is illustrated in Figure 1 on sentence summarization. For cases when the contiguity assumption is too strict, we show how to incorporate an OSCAR penalty [6] to derive a new attention mechanism, named oscarmax, that encourages the network to pay equal attention to possibly non-contiguous groups of words. (§3)

3) In order to use attention mechanisms defined under our framework in an autodiff toolkit, two problems must be addressed: evaluating the attention itself and computing its Jacobian. However, our attention mechanisms require solving a convex optimization problem and do not generally enjoy a simple analytical expression, unlike softmax. Computing the Jacobian of the solution of an optimization problem is called argmin/argmax differentiation and is currently an area of active research (cf. [11] and references therein). One of our key algorithmic contributions is to show how to compute this Jacobian under our general framework, as well as for fused lasso and OSCAR. (§4)

4) To showcase the potential of our new attention mechanisms as a drop-in replacement for existing ones, we show empirically that our new attention mechanisms enhance interpretability while achieving comparable or better accuracy on three diverse and challenging tasks: textual entailment, machine translation, and sentence summarization. (§4)

Notation. We denote the set \( \{1, \ldots, d\} \) by \([d]\). We denote the \((d - 1)\)-dimensional probability simplex by \( \Delta_d := \{x \in \mathbb{R}^d : \|x\|_1 = 1, x \geq 0\} \) and the Euclidean projection onto it by \( P_{\Delta_d}(x) := \text{argmin}_{y \in \Delta_d} \|y - x\|^2 \). Given a function \( f : \mathbb{R}^d \to \mathbb{R} \cup \{\infty\} \), its convex conjugate is defined by \( f^*(x) := \sup_{y \in \text{dom} f} y^t x - f(y) \). Given a norm \( \|\cdot\| \), its dual is defined by \( \|x\|_* := \sup_{\|y\| \leq 1} y^t x \).
We denote the subdifferential of a function \( f \) at \( y \) by \( \partial f(y) \). Elements of the subdifferential are called subgradients and when \( f \) is differentiable, \( \partial f(y) \) contains a single element, the gradient of \( f \) at \( y \), denoted by \( \nabla f(y) \). We denote the Jacobian of a function \( g : \mathbb{R}^d \to \mathbb{R}^d \) at \( y \) by \( J_g(y) \in \mathbb{R}^{d \times d} \) and the Hessian of a function \( f : \mathbb{R}^d \to \mathbb{R} \) at \( y \) by \( H_f(y) \in \mathbb{R}^{d \times d} \).
We illustrate \( \max_{\Omega}(x) \) operator up to a constant (left) and the proposed \( \Pi_{\Omega}(x) \) mapping (right), illustrated with \( x = [t, 0] \) and \( \gamma = 1 \). In this case, \( \max_{\Omega}(x) \) is a ReLu-like function and \( \Pi_{\Omega}(x) \) is a sigmoid-like function. Our framework recovers softmax (negative entropy) and sparsemax (squared 2-norm) as special cases. We also introduce three new attention mechanisms: sq-pnorm-max (squared \( p \)-norm, here illustrated with \( p = 1.5 \)), fusedmax (squared 2-norm + fused lasso), and oscarmax (squared 2-norm + OSCAR; not pictured since it is equivalent to fusedmax in 2-d). Except for softmax, which never exactly reaches 0, all mappings shown on the right encourage sparse outputs.

## 2 Proposed regularized attention framework

### 2.1 The max operator and its subgradient mapping

To motivate our proposal, we first show in this section that the subgradients of the maximum operator define a mapping from \( \mathbb{R}^d \) to \( \Delta^d \), but that this mapping is highly unsuitable as an attention mechanism. The maximum operator is a function from \( \mathbb{R}^d \) to \( \mathbb{R} \) and can be defined by

\[
\max(x) := \max_i x_i = \sup_{y \in \Delta^d} y^T x.
\]

The equality on the r.h.s comes from the fact that the supremum of a linear form over the simplex is always achieved at one of the vertices, i.e., one of the standard basis vectors \( \{e_i\}_{i=1}^d \). Moreover, it is not hard to check that any solution \( y^* \) of that supremum is precisely a subgradient of \( \max(x) \):

\[
\partial \max(x) = \{e_i : i^* \in \arg\max_i \{x_i\} \}.
\]

We can see these subgradients as a mapping \( \Pi : \mathbb{R}^d \to \Delta^d \) that puts all the probability mass onto a single element: \( \Pi(x) = e_i \) for any \( e_i, e \in \partial \max(x) \).

However, this behavior is undesirable, as the resulting mapping is a discontinuous function (a Heaviside step function when \( x = [t, 0] \)), which is not amenable to optimization by gradient descent.

### 2.2 A regularized max operator and its gradient mapping

These shortcomings encourage us to consider a regularization of the maximum operator. Inspired by the seminal work of Nesterov [32], we apply a smoothing technique. The conjugate of \( \max(x) \) is

\[
\max^*(y) = \begin{cases} 0, & \text{if } y \in \Delta^d \\ \infty, & \text{o.w.} \end{cases}
\]

For a proof, see for instance [30, Appendix B]. We now add regularization to the conjugate

\[
\max_{\Omega}^*(y) := \begin{cases} \gamma \Omega(y), & \text{if } y \in \Delta^d \\ \infty, & \text{o.w.} \end{cases}
\]

where we assume that \( \Omega : \mathbb{R}^d \to \mathbb{R} \) is \( \beta \)-strongly convex w.r.t. some norm \( \| \cdot \| \) and \( \gamma > 0 \) controls the regularization strength. To define a regularized max operator, we take the conjugate once again

\[
\max_{\Omega}(x) = \max_{\Omega}^*(x) = \sup_{y \in \mathbb{R}^d} y^T x - \max_{\Omega}^*(y) = \sup_{y \in \Delta^d} y^T x - \gamma \Omega(y).
\]

Our main proposal is a mapping \( \Pi_{\Omega} : \mathbb{R}^d \to \Delta^d \), defined as the argument that achieves this supremum.

\[
\Pi_{\Omega}(x) := \arg\max_{y \in \Delta^d} y^T x - \gamma \Omega(y) = \nabla \max_{\Omega}(x)
\]

The r.h.s. holds by combining that i) \( \max_{\Omega}(x) = (y^*)^T x - \max_{\Omega}^*(y^*) \iff y^* \in \partial \max_{\Omega}(x) \) and ii) \( \partial \max_{\Omega}(x) = \{\nabla \max_{\Omega}(x)\} \), since \( \Omega \) has a unique solution. Therefore, \( \Pi_{\Omega} \) is a gradient mapping. We illustrate \( \max_{\Omega} \) and \( \Pi_{\Omega} \) for various choices of \( \Omega \) in Figure 2 (2-d) and in Appendix B.1 (3-d).
Importance of strong convexity. Our $\beta$-strong convexity assumption on $\Omega$ plays a crucial role and should not be underestimated. Recall that a function $f : \mathbb{R}^d \rightarrow \mathbb{R}$ is $\beta$-strongly convex w.r.t. a norm $\| \cdot \|$ if and only if its conjugate $f^*$ is $\frac{1}{\beta}$-smooth w.r.t. the dual norm $\| \cdot \|_*$. [42 Corollary 3.5.11] [20 Theorem 3]. This is sufficient to ensure that $\max_{x_{\Omega}}$ is $\frac{1}{\gamma \beta}$-smooth, or, in other words, that it is differentiable everywhere and its gradient, $\Pi_{\Omega}$, is $\frac{1}{\gamma \beta}$-Lipschitz continuous w.r.t. $\| \cdot \|$.

Training by backpropagation. In order to use $\Pi_{\Omega}$ in a neural network trained by backpropagation, two problems must be addressed for any regularizer $\Omega$. The first is the forward computation: how to evaluate $\Pi_{\Omega}(x)$, i.e., how to solve the optimization problem in (1). The second is the backward computation: how to evaluate the Jacobian of $\Pi_{\Omega}(x)$, or, equivalently, the Hessian of $\max_{x_{\Omega}}(x)$. One of our key contributions, presented in [33] is to show how to solve these two problems for general differentiable $\Omega$, as well as for two structured regularizers: fused lasso and OSCAR.

2.3 Recovering softmax and sparsemax as special cases

Before deriving new attention mechanisms using our framework, we now show how we can recover softmax and sparsemax, using a specific regularizer $\Omega$.

Softmax. We choose $\Omega(y) = \sum_{i=1}^{d} y_i \log y_i$, the negative entropy. The conjugate of the negative entropy restricted to the simplex is the log-sum-exp [8 Example 3.25]. Moreover, if $f(x) = \gamma g(x/\gamma)$ for $\gamma > 0$, then $f^*(y) = \gamma g^*(y)$. We therefore get a closed-form expression: $\max_{x_{\Omega}}(x) = \gamma \log\text{sumexp}(x/\gamma) := \gamma \log \sum_{i=1}^{d} e^{x_i/\gamma}$. Since the negative entropy is 1-strongly convex w.r.t. $\| \cdot \|_1$, we get that $\max_{x_{\Omega}}$ is $\frac{1}{\gamma}$-smooth w.r.t. $\| \cdot \|_1$. We obtain the classical softmax, with temperature parameter $\gamma$, by taking the gradient of $\max_{x_{\Omega}}(x)$,

$$
\Pi_{\Omega}(x) = \frac{e^{x_\gamma}}{\sum_{i=1}^{d} e^{x_i/\gamma}}, \quad \text{(softmax)}
$$

where $e^{x_i/\gamma}$ is evaluated element-wise. Note that some authors also call $\max_{x_{\Omega}}$ a “soft max.” Although $\Pi_{\Omega}$ is really a soft argmax, we decide to follow the neural network terminology in this paper. When $x = [t, 0]$, it can be checked that $\max_{x_{\Omega}}(x)$ reduces to the softplus [14] and $\Pi_{\Omega}(x)$ to a sigmoid.

Sparsemax. We choose $\Omega(y) = \frac{1}{2} \| y \|_2^2$, also known as Moreau-Yosida regularization in proximal operator theory [32, 33]. Since $\frac{1}{2} \| y \|_2^2$ is 1-strongly convex w.r.t. $\| \cdot \|_2$, we get that $\max_{x_{\Omega}}$ is $\frac{1}{\gamma}$-smooth w.r.t. $\| \cdot \|_2$. In addition, it is easy to verify that

$$
\Pi_{\Omega}(x) = P_{\Delta^\gamma} (x/\gamma). \quad \text{(sparsemax)}
$$

This mapping was introduced as $\text{is}$ in [29] with $\gamma = 1$ and was named sparsemax, due to the fact that it is a sparse alternative to softmax. Our derivation thus gives us a slight generalization, where $\gamma$ controls the sparsity (the smaller, the sparser) and could be tuned; in our experiments, however, we follow the literature and set $\gamma = 1$. The Euclidean projection onto the simplex, $P_{\Delta^\gamma}$, can be computed exactly in worst-case $O(d \log d)$ time [31, 13]. Following [29], the Jacobian of $\Pi_{\Omega}$ is

$$
J_{\Pi_{\Omega}}(x) = \frac{1}{\gamma} J_{P_{\Delta^\gamma}} (x/\gamma) = \frac{1}{\gamma} \left( \text{diag}(s) - ss^T/\|s\|_1 \right),
$$

where $s \in \{0, 1\}^d$ indicates the support of $\Pi_{\Omega}(x)$. Since $\Pi_{\Omega}$ is Lipschitz continuous, Rademacher’s theorem implies that $\Pi_{\Omega}$ is differentiable almost everywhere. For points where $\Pi_{\Omega}$ is not differentiable (where $\max_{x_{\Omega}}$ is not twice differentiable), we can take an arbitrary matrix in the set of Clarke’s generalized Jacobians [10], the convex hull of Jacobians of the form $\lim_{x_{\Omega} \rightarrow x} J_{\Pi_{\Omega}}(x_{\Omega})$ [29].

3 Deriving new sparse and structured attention mechanisms

3.1 Differentiable regularizer $\Omega$

Before tackling more structured regularizers, we address in this section the case of general differentiable regularizer $\Omega$. Because $\Pi_{\Omega}(x)$ involves maximizing (1), a concave function over the simplex, it can be computed globally using any off-the-shelf projected gradient solver. Therefore, the main challenge is how to compute the Jacobian of $\Pi_{\Omega}$. This is what we address in the next proposition.
Proposition 1  Jacobian of $\Pi_\Omega$ for any differentiable $\Omega$ (backward computation)

Assume that $\Omega$ is differentiable over $\Delta^d$ and that $\Pi_\Omega(\mathbf{x}) = \arg\max_{\mathbf{y} \in \Delta^d} \mathbf{y}^T \mathbf{x} - \gamma \Omega(\mathbf{y}) = \mathbf{y}^*$ has been computed. Then the Jacobian of $\Pi_\Omega$ at $\mathbf{x}$, denoted $J_{\Pi_\Omega}$, can be obtained by solving the system

$$(I + A(B - I)) J_{\Pi_\Omega} = A,$$

where we defined the shorthands $A := J_{P_{\Delta^d}}(\mathbf{y}^* - \gamma \nabla \Omega(\mathbf{y}^*) + \mathbf{x})$ and $B := \gamma H_{\Omega}(\mathbf{y}^*)$.

The proof is given in Appendix A.1. Note that argmin differentiation has recently been tackled by applying matrix differential calculus to the Karush–Kuhn–Tucker (KKT) conditions [1]. Our proof is very different and relies on differentiating the fixed point iteration $\mathbf{y}^* = P_{\Delta^d}(\mathbf{y}^* - \gamma \nabla f(\mathbf{y}^*))$.

To compute the product $J_{\Pi_\Omega} \mathbf{v}$, with an arbitrary vector $\mathbf{v} \in \mathbb{R}^d$, as is usually needed in a practical implementation of backpropagation, all we need is to solve the system $(I + A(B - I)) (J_{\Pi_\Omega} \mathbf{v}) = A \mathbf{v}$.

Squared $p$-norms. As a useful example of differentiable function over the simplex, consider squared $p$-norms: $\Omega(\mathbf{y}) = \frac{1}{2} \|\mathbf{y}\|^2_p = \left(\sum_{i=1}^d y_i^p\right)^{2/p}$, where $\mathbf{y} \in \Delta^d$ and $p \in (1, 2]$. For this choice of $p$, it is known that the squared $p$-norm is strongly convex w.r.t. $\|\cdot\|_p$ [3]. This implies that $\max_{\Omega}$ is $\frac{1}{2(p-1)}$ smooth w.r.t. $\|\cdot\|_q$, where $\frac{1}{p} + \frac{1}{q} = 1$. We call the induced mapping function $sq$-norm-max:

$$\Pi_{\Omega}(\mathbf{x}) = \arg\min_{\mathbf{y} \in \Delta^d} \frac{\gamma}{2} \|\mathbf{y}\|^2_p - \mathbf{y}^T \mathbf{x}. \quad \text{(sq-norm-max)}$$

The gradient and Hessian needed for Proposition 1 can be computed by $\nabla \Omega(\mathbf{y}) = \frac{\mathbf{y}^{p-1}}{\|\mathbf{y}\|^{p-2}_p}$ and

$$H_{\Omega}(\mathbf{y}) = \text{diag}(d) + uu^T,$$

where $d = (p-1)\|\mathbf{y}\|^{-p+2}_p \text{diag}(\mathbf{y}^{p-2})$ and $u = \sqrt{(2-p)\|\mathbf{y}\|^{-2p+2}_p} \mathbf{y}^{p-1}$, with the exponentiation performed element-wise. $sq$-norm-max recovers sparsemax with $p = 2$, as is usually needed in a practical implementation of backpropagation, all we need is to solve the system $(I + A(B - I)) (J_{\Pi_\Omega} \mathbf{v}) = A \mathbf{v}$.

3.2 Structured regularizers: fused lasso and OSCAR

Fusedmax. For cases when the input is sequential and the order is meaningful, as is the case for many natural languages, we propose fusedmax, an attention mechanism based on fused lasso [39], also known as 1-d total variation (TV). Fusedmax encourages paying attention to contiguous segments, with equal weights within each one. It is expressed under our framework by choosing

$$\Omega(\mathbf{y}) = \frac{1}{2} \|\mathbf{y}\|_2^2 + \lambda \sum_{i=1}^{d-1} |y_{i+1} - y_i|, \text{ i.e., the sum of a strongly convex term and of a 1-d TV penalty.}$$

It is easy to verify that this choice yields the mapping

$$\Pi_{\Omega}(\mathbf{x}) = \arg\min_{\mathbf{y} \in \Delta^d} \frac{1}{2} \|\mathbf{y} - \mathbf{x}/\gamma\|^2_2 + \lambda \sum_{i=1}^{d-1} |y_{i+1} - y_i|. \quad \text{(fusedmax)}$$

Oscarmax. For situations where the contiguity assumption may be too strict, we propose oscarmax, based on the OSCAR penalty [6], to encourage attention weights to merge into clusters with the same value, regardless of position in the sequence. This is accomplished by replacing the 1-d TV penalty in fusedmax with an $\infty$-norm penalty on each pair of attention weights, i.e., $\Omega(\mathbf{y}) = \frac{1}{2} \|\mathbf{y}\|_2^2 + \lambda \sum_{i=1}^{d-1} \max(|y_i|, |y_j|)$. This results in the mapping

$$\Pi_{\Omega}(\mathbf{x}) = \arg\min_{\mathbf{y} \in \Delta^d} \frac{1}{2} \|\mathbf{y} - \mathbf{x}/\gamma\|^2_2 + \lambda \sum_{i<j} \max(|y_i|, |y_j|). \quad \text{(oscarmax)}$$

Forward computation. Due to the $\mathbf{y} \in \Delta^d$ constraint, computing fusedmax/oscarmax does not seem trivial on first sight. The next proposition shows how to do so, without any iterative method.

Proposition 2 Computing fusedmax and oscarmax (forward computation)

$$\text{fusedmax: } \Pi_{\Omega}(\mathbf{x}) = P_{\Delta^d} (P_{TV}(\mathbf{x}/\gamma)), \quad P_{TV}(\mathbf{x}) := \arg\min_{\mathbf{y} \in \mathbb{R}^d} \frac{1}{2} \|\mathbf{y} - \mathbf{x}\|^2_2 + \lambda \sum_{i=1}^{d-1} |y_{i+1} - y_i|.$$

$$\text{oscarmax: } \Pi_{\Omega}(\mathbf{x}) = P_{\Delta^d} (P_{OSC}(\mathbf{x}/\gamma)), \quad P_{OSC}(\mathbf{x}) := \arg\min_{\mathbf{y} \in \mathbb{R}^d} \frac{1}{2} \|\mathbf{y} - \mathbf{x}\|^2_2 + \lambda \sum_{i<j} \max(|y_i|, |y_j|).$$
Here, $P_{TV}$ and $P_{OSC}$ indicate the proximal operators of 1-d TV and OSCAR, and can be computed exactly by [11] and [44], respectively. To remind the reader, $P_{\Delta \delta}$ denotes the Euclidean projection onto the simplex and can be computed exactly using [31]. Proposition 2 shows that we can compute fusedmax and oscarmax using the composition of two functions, for which exact non-iterative algorithms exist. This is a surprising result, since the proximal operator of the sum of two functions is not, in general, the composition of the proximal operators of each function. The proof follows by showing that the indicator function of $\Delta \delta$ satisfies the conditions of [42, Corollaries 4,5].

Groups induced by $P_{TV}$ and $P_{OSC}$. Let $z^*$ be the optimal solution of $P_{TV}(x)$ or $P_{OSC}(x)$. For $P_{TV}$, we denote the group of adjacent elements with the same value as $z^*_i$ by $G^*_i$, $\forall i \in [d]$. Formally, $G^*_i = [a, b] \cap \mathbb{N}$ with $a \leq i \leq b$ where $a$ and $b$ are the minimal and maximal indices such that $z^*_i = z^*_j$ for all $j \in G^*_i$. For $P_{OSC}$, we define $G^*_i$ as the indices of elements with the same absolute value as $z^*_i$, more formally $G^*_i = \{ j \in [d]: |z^*_i| = |z^*_j| \}$. Because $P_{\Delta \delta}(z^*) = \max(z^* - \theta, 0)$ for some $\theta \in \mathbb{R}$, fusedmax/oscarmax either shift a group’s common value or set all its elements to zero.

$\lambda$ controls the trade-off between no fusion (sparsemax) and all elements fused into a single trivial group. While tuning $\lambda$ may improve performance, we observe that $\lambda = 0.1$ (fusedmax) and $\lambda = 0.01$ (oscarmax) are sensible defaults that work well across all tasks and report all our results using them.

Backward computation. We already know that the Jacobian of $P_{\Delta \delta}$ is the same as that of sparsemax with $\gamma = 1$. Then, by Proposition 2, if we know how to compute the Jacobians of $P_{TV}$ and $P_{OSC}$, we can obtain the Jacobsians of fusedmax and oscarmax by straightforward application of the chain rule. However, although $P_{TV}$ and $P_{OSC}$ can be computed exactly, they lack analytical expressions. We next show that we can nonetheless compute their Jacobians efficiently, without needing to solve a system.

Proposition 3 Jacobians of $P_{TV}$ and $P_{OSC}$ (backward computation)

Assume $z^* = P_{TV}(x)$ or $P_{OSC}(x)$ has been computed. Define the groups derived from $z^*$ as above.

\[
\text{Then, } [J_{P_{TV}}(x)]_{i,j} = \begin{cases} \frac{1}{|G^*_i|} & \text{if } j \in G^*_i, \\ 0 & \text{o.w.} \end{cases} \quad \text{and} \quad [J_{P_{OSC}}(x)]_{i,j} = \begin{cases} \frac{1}{|G^*_i|} & \text{if } j \in G^*_i \text{ and } z^*_i \neq 0, \\ 0 & \text{o.w.} \end{cases}
\]

The proof is in Appendix A.2. Clearly, the structure of these Jacobians permits efficient Jacobian-vector products. Note that $P_{TV}$ and $P_{OSC}$ are differentiable everywhere except at points where groups change. For these points, the same remark as for sparsemax applies, and we can use Clarke’s Jacobian.

4 Experimental results

We showcase the performance of our attention mechanisms on three challenging tasks in natural language processing: textual entailment, machine translation, and sentence summarization.

4.1 Textual entailment (a.k.a. natural language inference) experiments

Textual entailment is the task of deciding, given a text $T$ and an hypothesis $H$, whether a human reading $T$ is likely to infer that $H$ is true [12]. We use the Stanford Natural Language Inference (SNLI) dataset [7], a collection of 570,000 English sentence pairs. Each pair consists of a sentence and an hypothesis, manually labeled with one of the labels ENTAILMENT, CONTRADICTION, or NEUTRAL.

We use a variant of the neural attention–based classifier proposed for this dataset by [35] and follow the same methodology as [29] in terms of implementation, hyperparameters, and grid search. We employ the CPU implementation provided in [29] and simply replace sparsemax/oscarmax with fusedmax/oscarmax; we observe that training time per epoch is essentially the same for each of the four attention mechanisms (timings and more experimental details in Appendix B.2).

Table 1 shows that, for this task, fusedmax reaches the highest accuracy, and oscarmax slightly outperforms softmax. Furthermore, fusedmax results in the most interpretable feature groupings: Figure 3 shows the weights of the neural network’s attention to the text, when considering the hypothesis “No one is dancing.” In this case, all four models correctly predicted that the text “A band is playing on stage at a concert and the attendants are dancing to the music.”

|                | accuracy |
|----------------|----------|
| softmax        | 81.66    |
| sparsemax      | 82.39    |
| fusedmax       | 82.41    |
| oscarmax       | 81.76    |
denoted along the $x$-axis, **contradicts** the hypothesis, although the attention weights differ. Notably, fusedmax selects the meaningful segment “band is playing” as a group.

### 4.2 Machine translation experiments

Neural Machine Translation (NMT) based on sequence-to-sequence models has recently gained popularity [2][27]. In such models, neural attention can be seen as an alignment mechanism between source and target words. To demonstrate the potential of our new attention mechanisms as a drop-in replacement for softmax, we ran experiments on 10 language pairs. Our experiments also include sparsemax, which, to our knowledge, had never been explored for NMT before. We used the Python version of OpenNMT [22], based on PyTorch [34]. We used the default settings for all flags and hyperparameters (detailed in Appendix B.3). The only change needed in OpenNMT was to replace softmax with our proposed mapping functions, $\Pi_{\Omega}$, which we implemented as PyTorch functions.

OpenNMT with softmax attention is optimized for the GPU. Since sparsemax, fusedmax, and oscarmax rely on sorting operations, we implement their computations on the CPU for simplicity, keeping the rest of the pipeline on the GPU. However, we observe that, even with this context switching, the number of tokens processed per second was within $\frac{3}{4}$ of the softmax pipeline. For sq-pnorm-max, we observe that the projected gradient solver used in the forward pass, unlike the linear system solver used in the backward pass, could become a computational bottleneck. To mitigate this effect, we set the tolerance of the solver’s stopping criterion to $10^{-2}$.

Quantitatively, we find that all compared attention mechanisms are always within 1 BLEU score point of the best mechanism (for detailed results, cf. Appendix B.3). This suggests that structured sparsity does not restrict accuracy. However, as illustrated in Figure 4 fusedmax and oscarmax often lead to more interpretable attention alignments, as well as to qualitatively different translations.

![Figure 4: Attention weights for French to English translation, using the conventions of Figure 1.](image)

Within a row, weights grouped by oscarmax under the same cluster are denoted by “•”. Here, oscarmax finds a slightly more natural English translation. More visualizations are given in Appendix B.3.

### 4.3 Sentence summarization experiments

Attention mechanisms were recently explored for sentence summarization in [36]. To generate sentence-summary pairs at low cost, the authors proposed to use the title of a news article as a noisy summary of the article’s leading sentence. They collected 4 million such pairs from the Gigaword dataset and showed that this seemingly simplistic approach leads to models that generalize...
surprisingly well. We follow their experimental setup and are able to reproduce comparable results to theirs with OpenNMT when using softmax attention. The models we use are the same as in §4.2.

Our evaluation follows [36]: we use the standard DUC 2004 dataset (500 news articles each paired with 4 different human-generated summaries) and a randomly held-out subset of Gigaword, released by [36]. We report results on ROUGE-1, ROUGE-2, and ROUGE-L. Our results, in Table 2, indicate that fusedmax is the best under nearly all metrics, always outperforming softmax. In addition to Figure 1, we exemplify our enhanced interpretability and provide more detailed results in Appendix B.4.

5 Related work

Smoothed max operators. Replacing the max operator by a differentiable approximation based on the log-sum-exp has been exploited in numerous works. Regularizing the max operator with a squared 2-norm is less frequent, but has been used to obtain a smoothed multiclass hinge loss [38] or smoothed linear programming relaxations for maximum a-posteriori inference [30]. Our work differs from these in mainly two aspects. First, we are less interested in the max operator than in its gradient, which we use as a mapping from $\mathbb{R}^d$ to $\Delta^d$. Second, since we plug this mapping in a neural network trained with backpropagation, we need to compute its Jacobian, contrary to previous works.

Interpretability, structure and sparsity in neural networks. Providing interpretations alongside predictions is important for accountability, error analysis and exploratory analysis, among other reasons. Toward this goal, several recent works have been relying on visualizing hidden layer activations [18, 25] and the potential for interpretability provided by attention mechanisms has been noted in multiple works [2, 35, 36]. Our work fulfills this potential by providing a unified, regularized framework upon which new attention mechanisms can be designed. Selecting contiguous text segments for model interpretations is explored in [24], where an explanation generator network is proposed for justifying predictions using a fused lasso penalty. However, this network is not an attention mechanism and has its own parameters to be learned. Furthermore, [24] sidesteps the need to backpropagate through the fused lasso, unlike our work, by using a stochastic training approach. In contrast, our attention mechanisms are deterministic and drop-in replacements for existing ones.

A different approach to incorporating structure into attention uses the marginal probabilities from a conditional random field as attention weights [21]. While this approach takes into account structural correlations, the marginal probabilities are generally dense and different from each other. Our proposed mechanisms produce sparse and clustered attention weights, a visible benefit in interpretability. Finally, sparsity-inducing penalties have been used to obtain convex relaxations [4] or to compress models [26, 40, 37]. These works differ from ours, in that sparsity is applied w.r.t. network weights, while our goal is to produce sparse and structured attention outputs.

6 Conclusion and future directions

We proposed in this paper a unified regularized framework upon which new attention mechanisms can be designed. To enable such mechanisms to be used in a neural network trained by backpropagation, we demonstrated how to carry out forward and backward computations for general differentiable regularizers. We further developed two new structured attention mechanisms, fusedmax and oscarmax, and demonstrated that they enhance interpretability while achieving comparable or better accuracy on three diverse and challenging tasks: textual entailment, machine translation, and summarization.

The usefulness of a differentiable mapping from real values to the simplex or to $[0, 1]$, possibly with sparse or structured outputs, goes beyond attention mechanisms. We expect that our framework will be useful to sample from categorical distributions using the Gumbel trick [19, 28] and for conditional computation [8] or differentiable neural computers [16, 17]. We plan to explore these in future work.
A Regularized Framework for Sparse and Structured Neural Attention

Appendix

A Proofs

A.1 Proof of Proposition \[1\]

Recall that

\[ \Pi_{\Omega}(x) = \arg\min_{y \in \Delta^d} f(y), \quad \text{where} \quad f(y) := \gamma \Omega(y) - y^T x. \]

At an optimal solution, we have the fixed point iteration \[23\] §4.2]

\[ y^* = P_{\Delta^d}(y^* - \nabla f(y^*)). \] (2)

Seeing \( y^* \) as a function of \( x \), and \( P_{\Delta^d} \) and \( \nabla f \) as functions of their inputs, we can apply the chain rule to \[4\] to obtain

\[ J_{\Pi_{\Omega}}(x) = J_{P_{\Delta^d}}(y^* - \nabla f(y^*)) \left( J_{\Pi_{\Omega}}(x) - J_{\nabla f y^*}(x) \right). \] (3)

Applying the chain rule once again to \( \nabla f(y^*) = \gamma \nabla \Omega(y^*) - x \), we obtain

\[ J_{\nabla f y^*}(x) = \gamma J_{\nabla \Omega}(y^*) J_{\Pi_{\Omega}}(x) - I = \gamma H_{\Omega}(y^*) J_{\Pi_{\Omega}}(x) - I. \]

Plugging this into (3) and re-arranging, we obtain

\[ (I + A(B - I)) J_{\Pi_{\Omega}} = A, \]

where we defined the shorthands

\[ J_{\Pi_{\Omega}} := J_{\Pi_{\Omega}}(x), \quad A := J_{P_{\Delta^d}}(y^* - \gamma \nabla \Omega(y^*) + x) \quad \text{and} \quad B := \gamma H_{\Omega}(y^*). \]

A.2 Proof of Proposition \[3\]

Let \( z^* = P_{TV}(x) \) or \( P_{OSC}(x) \). The outline of the proof is: we use the optimality conditions of \( P_{TV} \) and \( P_{OSC} \) (separately) in order to express \( z^* \) as an explicit function of \( x \). Then, obtaining the Jacobians of \( P_{TV}(x) \) and \( P_{OSC}(x) \) follows by application of the chain rule to the two expressions.

Jacobian of \( P_{TV} \).

Lemma 1 Let \( z^* = P_{TV}(x) \in \mathbb{R}^d \) and \( G^*_i \) be the set of indices around \( i \) with the same value at the optimum, as defined in §3.2. Then, we have

\[ z^*_i = \sum_{j \in G^*_i} x_j + \lambda (s_{a_i} - s_{b_i}), \] (4)

where \( a_i = \min G^*_i, b_i = \max G^*_i \) are the boundaries of segment \( G^*_i \), and

\[ s_{a_i} = \begin{cases} 0 & \text{if } a = 1, \\ \text{sign}(z^*_{a_i-1} - z^*_i) & \text{if } a > 1 \end{cases}, \quad \text{and} \quad s_{b_i} = \begin{cases} 0 & \text{if } b = d, \\ \text{sign}(z^*_j - z^*_i) & \text{if } b < d \end{cases}. \]

To prove Lemma \[1\] we make use of the optimality conditions of the fused lasso proximity operator \[15\] Equation 27], which state that \( z^* \) satisfies

\[ z^*_i - x_j + \lambda (t_j - t_{j+1}) = 0, \quad \text{where} \quad t_j \in \begin{cases} \{0\} & \text{if } i \in \{1, d\}, \\ \{\text{sign}(z^*_j - z^*_{j-1})\} & \text{if } z^*_j \neq z^*_{j-1}, \\ [-1, 1] & \text{o.w.} \end{cases}. \] (5)

The optimality conditions \[5\] form a system with unknowns \( z^*_i, t_j \) for \( j \in [d] \). To express \( z^* \) as a function of \( x \), we shall now proceed to eliminate the unknowns \( t_j \).
Let us focus on a particular segment $G_i^*$. For readability, we drop the segment index $i$ and use the shorthands $z := z_i^*$, $a := a_i$, and $b := b_i$. By definition, $a$ and $b$ satisfy
\[ z_j^* = z \forall a \leq j \leq b, \quad z_{a-1}^* \neq z \text{ if } a > 1, \quad z_{b+1}^* \neq z \text{ if } b < d. \]

It immediately follows from the definition of $t_j$ in (5) that
\[ t_a = \begin{cases} 0 & \text{if } a = 1, \\ \text{sign}(z - z_{a-1}^*) & \text{if } a > 1 \end{cases} \quad \text{and} \quad t_{b+1} = \begin{cases} 0 & \text{if } b = d, \\ \text{sign}(z_{b+1}^* - z) & \text{if } b < d \end{cases}. \]

In other words, the unknowns $t_a$ and $t_b$ are already solved for. To emphasize that their value is determined, we introduce $s_a := t_a$ and $s_b := t_{b+1}$, leaving $t_j$ only unknown for $a < j \leq b$.

By rearranging the optimality conditions (6) we obtain the recursion
\[ \lambda t_j = x_j - z + \lambda t_{j+1} \quad \forall a \leq j \leq b. \]

We start with the first equation in the segment (at $j = a$), and unroll the recursion until reaching the stopping condition $j = b$.
\[
\begin{align*}
\lambda s_a &= x_a - z + \lambda t_{a+1} \\
&= x_a - z + x_{a+1} - z + \cdots + x_b - z + \lambda s_b \\
&= \sum_{k=a}^{b} x_k - (b - a + 1)z + \lambda s_b
\end{align*}
\]

Rearranging the terms, we obtain the expression
\[ z = \sum_{k=a}^{b} x_k + \lambda (s_b - s_a) - \frac{b - a + 1}{2}. \]

Applying this calculation to each segment in $z^*$ yields the desired result. \qed

The proof of Proposition 2 follows by applying the chain rule to (4), noting that the groups $G_i^*$ are constant within a neighborhood of $x$ (observation also used for OSCAR in [4]). Therefore, for $P_{TV}$,
\[
\frac{\partial z_i^*}{\partial x_j} = \frac{1}{|G_i^*|} \left( \sum_{k \in G_i^*} \frac{\partial x_k}{\partial x_j} + \lambda \left( \frac{\partial s_b}{\partial x_j} - \frac{\partial s_a}{\partial x_j} \right) \right).
\]

Since $s_b$ and $s_a$ are either constant or sign functions w.r.t. $x$, their partial derivatives are 0, and thus
\[ \frac{\partial z_i^*}{\partial x_j} = \begin{cases} \frac{1}{|G_i^*|} & \text{if } j \in G_i^*, \\ 0 & \text{o.w.} \end{cases}. \]

Jacobian of $P_{\text{Osc}}$.

**Lemma 2 (44 Theorem 1).** Let $z^* = P_{\text{Osc}}(x) \in \mathbb{R}^d$ and $G_i^*$ be the set of indices around $i$ with the same value at the optimum: $G_i^* = \{ j \in [d] : |z_i^*| = |z_j^*| \}$. Then, we have
\[ z_i^* = \max \left( \frac{\sum_{j \in G_i^*} x_j}{|G_i^*|} - w_i, 0 \right), \tag{6} \]
where $w_i = \lambda \left( d - \frac{u_i + v_i}{2} \right)$, $u_i = \left\{ \{ j \in [d] : |z_j^*| < |z_i^*| \} \right\}$, $v_i = u_i + |G_i^*|$. \hfill \(\blacksquare\)

Lemma 2 is a simple reformulation of Theorem 1, part ii from [44]. With the same observation that the induced groups do not change within a neighborhood of $x$, we may differentiate (6) to obtain
\[ \frac{\partial z_i^*}{\partial x_j} = \begin{cases} 0 & \text{if } z_i^* = 0, \\ \frac{1}{|G_i^*|} \sum_{k \in G_i^*} \frac{\partial x_k}{\partial x_j} + \frac{\partial w_i}{\partial x_j} & \text{o.w.} \end{cases}. \]

Since $w_i$ is derived only from group indices, $\frac{\partial w_i}{\partial x_j} = 0$. We therefore obtain
\[ \frac{\partial z_i^*}{\partial x_j} = \begin{cases} \frac{1}{|G_i^*|} & \text{if } j \in G_i^* \text{ and } z_i^* \neq 0, \\ 0 & \text{o.w.} \end{cases}. \]
B Additional experimental results

B.1 Visualizing attention mappings in 3-d

Figure 5: 3-d visualization of $\Pi_\Omega([t_1, t_2, 0])_2$ for several proposed and existing mappings $\Pi_\Omega$. sq-pnorm-max with $p = 1.5$ resembles sparsemax but with smoother transitions. The proposed structured attention mechanisms, fusedmax and oscarmax, exhibit plateaus and ridges in areas where weights become fused together. We set $\gamma = 1$ and $\lambda = 0.2$.

B.2 Textual entailment results

Experimental setup. We build upon the implementation from [29], which is a slight variation of the attention model from [35], using GRUs instead of LSTMs. The GRUs encoding the premise and hypothesis have separate parameters, but the hypothesis GRU is initialized with the last state of the premise GRU. We use the same settings and methodology as [29]: we use fixed 300-dimensional GloVe vectors, we train for 200 epochs using ADAM with learning rate $3 \cdot 10^{-4}$, we use a drop-out probability of 0.1, and we choose an $l_2$ regularization coefficient from $\{0, 10^{-4}, 3 \cdot 10^{-4}, 10^{-3}\}$. Experiments are performed on machines with 2×Xeon X5675 3.06GHz CPUs and 96GB RAM.

Dataset and preprocessing. We use the SNLI v1 dataset [7]. We apply the minimal preprocessing from [29], skipping sentence pairs with missing labels and using the provided tokenization. This results in a training set of 549,367 sentence pairs, a development set of 9,842 sentence pairs and a test set of 9,824 sentence pairs. We report timing measurements in Table 3 and visualizations of the produced attention weights in Figure 6.

|                  | attention | time per epoch |
|------------------|-----------|----------------|
| softmax          |           | 1h 26m 40s ± 51s |
| sparsemax        |           | 1h 24m 21s ± 54s |
| fusedmax         |           | 1h 23m 58s ± 50s |
| oscarmax         |           | 1h 23m 19s ± 50s |

Table 3: Timing results for training textual entailment on SNLI, using the implementation and experimental setup from [29]. With this C++ CPU implementation, fusedmax and oscarmax are as fast as sparsemax, and all three sparse attention mechanisms are slightly faster than softmax.

B.3 Machine translation results

Experimental setup. Because our goal is to demonstrate that our attention mechanisms can be drop-in replacements for existing ones, we focus on OpenNMT-py with default settings for all of our sequence-to-sequence experiments. These defaults are: an unidirectional LSTM, 500 dimensions for the word vectors and for the LSTM hidden representations, drop-out probability of 0.3, global attention, and input-feeding [27]. Following the default, we train our models for 13 epochs with
stochastic gradient updates (batches of size 64 and initial learning rate of 1, halved every epoch after the 8th). Weights (including word embeddings) are initialized uniformly over [−0.1, 0.1], and gradients are normalized to have norm 5 if their norm exceeds this value. For test scores and visualizations, we use the model snapshot at the epoch with the highest validation set accuracy. All of the experiments in this section are performed on machines equipped with Xeon E5 CPUs and Nvidia Tesla K80 GPUs.

Datasets. We employ training and test datasets from multiple sources.

- **BENCHMARK**: Training, validation, and test data from the NMT-Benchmark project (http://scorer.nmt-benchmark.net/). All languages have ~1M training sentence pairs, and equal validation and test sets of size 1K (French) and 2K (Italian, Dutch and Swedish).
- **BENCHMARK+**: Training and validation data as above, but testing on all available newstest data. For Italian we use the 2009 data (~2.5K sentence pairs), and for French we concatenate 2009–2014 (~11K sentence pairs).
- **WMT16, WMT17**: Translation tasks at the first and second ACL Conferences for Machine Translation, available at http://www.statmt.org/wmt16/translation-task.html and http://www.statmt.org/wmt17/translation-task.html. Training, validation, and test sizes are, approximately, for Romanian 400K/2K/2K, for German 5.8M/6K/3K, for Finnish 2.6M/2K/2K, for Latvian 4.5M/2K/2K, and for Turkish 207K/1K/3K.

We use the preprocessing scripts from Moses [23] for tokenization, and, where needed, SGML parsing. We limit source and target vocabulary sizes to 50K lower-cased tokens and prune sentences longer than 50 tokens at training time and 100 tokens at test time. We do not perform recasing.

We report BLEU scores in Table 4 and showcase the enhanced interpretability induced by our proposed attention mechanisms in Figure 7. Timing measurements can be found in Table 5.

**Table 4: Neural machine translation results: tokenized BLEU scores on test data.**

|          | BENCHMARK     | BENCHMARK+    | WMT16       | WMT17       |

**Table 5: Timing results for French-to-English translation using OpenNMT-py (all standard errors are under 2 minutes). For simplicity, all attention mechanisms, except softmax, are implemented on the CPU, thus incurring memory copies in both directions. (The rest of the pipeline runs on the GPU.) Even without special optimization, sparsemax, fusedmax, and oscarmax are practical, taking within 1.75x the training time of a softmax model on the GPU.**
A Regularized Framework for Sparse and Structured Neural Attention

Figure 6: Attention weights on several examples also used in [35, 29]. The hypotheses considered are “Two mimes sit in complete silence.” (top), “A boy is riding an animal.” (left), and “Two dogs swim in the lake.” (right). All attention mechanisms result in correct classifications (top: contradiction; left: entailment; right: contradiction). As can be seen, fusedmax prefers contiguous support segments even when not all weights are tied.
| fusedmax | oscarmax | sq-pnorm-max | softmax | sparsemax |
|----------|----------|--------------|---------|-----------|

Figure 7: Attention alignment examples for French-to-English translation, following the conventions of Figure [1] “@@” denotes a hyphen not separated by spaces. When oscarmax induces multiple clusters, we denote them using different bullets (e.g., •, ▲, ■). Fusedmax often selects meaningful grammatical segments, such as “est consacré,” as well as determiner-noun constructions.
D’unepart, les prix doivent être réglementés.

La coalition pour l’aide internationale devrait le lire avec attention.

Khrouchtchev ne connaissait rien d’autre que le communisme.
B.4 Sentence summarization results

Experimental setup and data. We use the exact same experimental setup and preprocessing as for machine translation, described in Appendix B.3. We use the preprocessed Gigaword sentence summarization dataset, made available by the authors of [36] at https://github.com/harvardnlp/sent-summary. Since, unlike [36], we do not perform any tuning on DUC-2003, we can report results on this dataset, as well. We observe that the simple sequence-to-sequence model is able to keep summaries short without any explicit constraints, informed only through training data statistics; therefore, in this section, we also report results without output truncation at 75 bytes (Table 6). We also provide precision and recall scores for ROUGE-L in Table 7. Finally, we provide attention weights plots for all studied attention mechanisms and a number of validation set examples in Figure 8.

Table 6: Sentence summarization $F_1$ scores for several ROUGE variations.

|         | Truncated |                   | Not truncated |                   |
|---------|-----------|-------------------|---------------|-------------------|
