Genomic Survey of Salt Acclimation-Related Genes in the Halophilic Cyanobacterium Euhalothece sp. Z-M001

Hee Wook Yang1, Ji Young Song1, Sung Mi Cho1,3, Hak Cheol Kwon2, Cheol-Ho Pan2 & Youn-il Park1*

Like other halophilic cyanobacterial genomes, the de novo-assembled genome of Euhalothece sp. Z-M001 lacks genes encoding keto-carotenoid biosynthesis enzymes, despite the presence of genes encoding carotenoid-binding proteins (CBPs). Consistent with this, HPLC analysis of carotenoids identified β-carotene and zeaxanthin as the dominant carotenoids. CBPs coexpressed with the zeaxanthin biosynthesis gene increased the survival rates of Escherichia coli strains by preventing antibiotic-induced accumulation of reactive oxygen species (ROS). RNA-seq analysis of Euhalothece revealed that among various salt resistance-related genes, those encoding the Na+ transporting multiple resistance and pH adaptation (Mrp) systems, glycine betaine biosynthesis enzymes, exopolysaccharide metabolic enzymes, and CBPs were highly upregulated, suggesting their importance in hypersaline habitats. During the early phase of salt deprivation, the amounts of β-carotene and zeaxanthin showed a negative correlation with ROS content. Overall, we propose that in some halophilic cyanobacteria, β-carotene and zeaxanthin, rather than keto-carotenoids, serve as the major chromophores for CBPs, which in turn act as effective antioxidants.

Cyanobacteria are photosynthetic prokaryotes that exhibit diverse protective mechanisms to cope with harsh environmental conditions. One of the protective mechanisms involves the use of carotenoids1 and diverse carotenoid-binding proteins (CBPs)2, which play essential roles in protecting the photosynthetic apparatus from damage by both excess light energy and reactive oxygen species (ROS). Most cyanobacterial CBPs bind to β-carotene (β-Car) and its oxygenated derivatives, called xanthophylls (Xan), and are located in photosynthetic protein complexes such as photosystem I (PSI), PSII, and cytochrome b6f3. By contrast, water soluble CBPs bind non-covalently to cyanobacterial keto-carotenoids, such as echinenone (Ech) and canthaxanthin (Can), and to glycosylated-carotenoids such as myxoxanthophyll (Myx)4; CBPs then function as effective energy dissipaters by interacting with the light-harvesting antenna, phycobilisome (PBS)5. CBPs also bind to zeaxanthin (Zea), albeit with low affinity6.

The orange carotenoid protein (OCP) and its two paralogs, helical carotenoid protein (HCP) and C-terminal domain homolog (CTDH), are the only known soluble CBPs4. The OCP is composed of two globular domains (one each at the N- and C-terminal ends); a single carotenoid is embedded between the two domains via a hydrophobic interaction7. Blue light absorption by a keto-carotenoid results in a conformational change in the OCP, from the orange inactive form (OCP°) to the red active form (OCPR). Binding of OCPR to PBS quenches PBS fluorescence, which is prevented by fluorescence recovery protein (FRP)8. FRP prevents accumulation of the OCPR by interacting with the C-terminal domain of OCP9. The biological functions of HCPs, which are grouped into nine distinct clades9, are largely unknown. HCP4 isolated from the cyanobacterium Anabaena PCC 7120 binds to PBS and dissipates excess light as heat, whereas HCP2 and HCP3 quench O29. In Nostoc flagelliforme, these biochemical functions are related to dehydration resistance10. By contrast, CTDH transfers a single keto-carotenoid to a nearby HCP11.

1Department of Biological Sciences, Chungnam National University, Daejeon, 34134, Korea. 2Natural Product Informatics Research Center, KIST Gangneung Institute of Natural Products, Gangneung, 25451, Korea. 3Present address: Unit of Polar Genomics, Korea Polar Research Institute, Incheon, 21990, Korea. *email: yipark@cnu.ac.kr
Cyanobacteria are divided into two major groups, euryhaline and stenohaline, based on their salt tolerance levels12. *Synechocystis PCC6803* (hereafter referred to as *Synechocystis*) is a euryhaline cyanobacterium capable of adapting to a wide range of salinity, from fresh water to 1.2 M NaCl13. Stenohaline strains survive within a narrow range of salinity include the *Halothec* cluster from hypersaline environments14; however, many of their physiological traits and protective mechanisms that operate under low-salt stress remain unknown. Generally, salt stress negatively affects the growth rate of algae. To cope with salt stress, cyanobacteria prevent entry of Na⁺ ions into the cell using Na⁺/H⁺ antiporters and K⁺ transporters, or by accumulating various compatible solutes such as sucrose, trehalose, glucosylglycerol, proline, and glycine betaine15. Additionally, exopolysaccharides (EPSs) protect cyanobacteria against osmotic/salt stress16. Direct experimental evidence supporting the protective role of EPSs against various heavy metals17,18 is available for the freshwater unicellular cyanobacterium *Synechocystis*.

Interestingly, despite the presence of CBPs, some stenohaline cyanobacteria, including *Dactylococcopsis salina* PCC8305 and *Microcoleus* sp. IPPAS B-353, lack genes encoding keto-carotenoids. Moreover, cyanobacteria such as *Prochlorococcus* sp. lack not only genes encoding keto-carotenoids but also genes encoding CBPs (Supplementary Table S1). Based on publicly available genome information and de novo genomic data from *Euhalothece* sp. Z-M001 (hereafter referred to as *Euhalothece*), we found that some haloalkaliphilic cyanobacterial species, including *Euhalothece*, lack the gene encoding keto-carotenoids but harbor CBP-encoding genes. This finding raises an interesting question about the nature and physiological functions of chromophores of water soluble CBPs in cyanobacteria lacking the ketolase gene. Furthermore, the expression profiles of genes involved in salt resistance via extrusion of Na⁺ ions, biosynthesis of compatible compounds, production of EPSs, and transcription of heat shock proteins19,20 are largely unknown in this cyanobacterium.

*Euhalothece* is a single-celled, stenohaline cyanobacterium (Supplementary Table S1) requiring 7% NaCl for optimal growth. It exhibits considerable morphological variability depending on the pH, and on the concentrations of NaCl and carbonate20. Here, we investigated prevailing salt stress resistance strategies adopted by *Euhalothece*. Like *Dactylococcopsis salina* PCC8305, the genome of the *Euhalothece* (BioProject DB ID: PRJNA557890; http://168.188.109.191/cyanomain/) harbors genes encoding OCP, HCP, and CTDH, but lacks genes related to keto-carotenoid biosynthesis. Using transcriptomic approaches, we found that transcript levels of genes encoding EPS biosynthesis enzymes and soluble CBPs vary according to salt concentration. We then isolated genes encoding carotenoid biosynthesis proteins and CBPs. Functional characterization of these recombinant proteins suggests that CBPs function as antioxidants during salt deprivation.

Results and Discussion

Phylogenetic analysis and genome of *Euhalothece*. Phylogenetic analysis of 165 rRNA sequences derived from 59 cyanobacterial species, three eubacteria (used as outgroups)21,22, and three additional species (*Euhalothece* Z-M001, *Euhalothece* Z9404, and *Nostoc punctiforme* ATCC29133) revealed that *Euhalothece* is closely related to the stenohaline cyanobacterium *Dactylococcopsis salina* PCC8305 (supported by a perfect bootstrap value) (Supplementary Fig. S1; red color). This clade does not contain the *Microcoleus* and *Geitlerinema* taxa that form the basis of a monophyletic group comprising freshwater cyanobacteria subsections I and II. Current phylogeny reconstruction indicates that the halophilic cyanobacterium group is associated with diversification of freshwater cyanobacteria.

The complete circular genome of *Euhalothece* (GenBank ID: CP042326) is 3,317,848 bp in length (average GC content = 41.03%) and contains 3,354 coding sequences (CDSs), six rRNAs, 43 tRNAs, and three clustered regularly interspaced short palindromic repeat arrays (Supplementary Fig. S2). Genes responsible for carotenoid biosynthesis, including *crtR* (ezr1976) and *cruA* (ezr1782), and CBPs such as *ocp* (ezr1969), *hcp* (ezr2074), and *ctdh* (ezr2075), were distributed on both strands, and no strong GC skew or single DNA replication origin inflection point was detected. In addition to the main chromosome, four scaffolds (GenBank IDs: CP042327–CP042330) were assembled into plasmids. All plasmids were circular, varying in size (14,665–67,514 bp), G+C content (40.04–40.85%), and gene number (20–83). In plasmids, genes encoding mobile element proteins, ParAB, primase, DNA invertase, DNA integrase, transposase, and phage tail protein, were identified, but those encoding CBPs and proteins involved in carotenoid biosynthesis and EPS metabolism were absent. Overall, the four plasmids were different but contained a 1.6 kb long block of similar sequence; the remaining plasmid sequence shared no similarity.

Growth, photosynthetic pigments, and EPS content of *Euhalothece* acclimated to salt-depleted and -repleted conditions. In this study, salt deprivation retarded the growth of *Euhalothece* cells. Cells grown for 6 days on medium containing 3% NaCl grew faster (Fig. 1A), and contained more Chl a and phycocyanin (PC) than those grown under the salt-deprived conditions (Fig. 1B). By contrast, the total carotenoid and EPSs contents of cells under salt-depleted conditions increased significantly by a few-fold (Fig. 1C) and 2.1-fold (Fig. 1D), respectively. Thus, *Euhalothece* seems to adopt primarily EPS-based salt-out and carotenoid-based ROS scavenging strategies under varying external salt concentrations.

Salt acclimation genes associated with ion homeostasis, compatible solutes, EPS biosynthesis, and two component systems in *Euhalothece*. Monovalent cation transporters such as Na⁺/H⁺ antiporters (NhaS1–S6), multisubunit Na⁺/H⁺ antiporters (MrpA–G), K⁺ transporters (KtrA/B and KdpA–D), and K⁺ uptake protein (TrkA) are involved in salt acclimation15,19. The newly sequenced *de novo*-assembled genome of *Euhalothece* harbors genes encoding these cation transporters. The *Euhalothece* genome contains 12 genes encoding Na⁺ pumps, including six nhaS genes and six multiple resistance and pH adaptation (Mrp) system genes (mrpB/C/D/E/F/G) (Supplementary Table S2). The high-affinity ATP-dependent K⁺ transport system consists of KdpABC(D) subunits and is found in some cyanobacteria such as *Nostoc* 7120 and *Synechocystis*19. However, as in the majority of marine picoplanktonic strains, this Kdp system was not detected in the *Euhalothece* genome.
By contrast, the KtrAB(E) system, which is present in all known cyanobacterial genomes and presumably plays a key role in $K^+$ import\(^{19,23}\), was identified in the genome of *Euhalothece* (Supplementary Table S2). Among various transporter-encoding genes, the *mrp* gene clusters seem to play a major role in *Euhalothece*, since genes encoding these multisubunit Na\(^+\)/H\(^+\) antiporters were constitutively expressed under salt-deficient (0% NaCl) and -sufficient (3% NaCl) conditions, as revealed by RNA-seq profiling (Supplementary Table S2) and qRT-PCR analysis (Fig. 2).

Among compatible solutes such as sucrose, trehalose, glucosyglycerol, and glycine betaine, glucosyglycerate, and proline, genes encoding proteins involved in biosynthesis of sucrose (*spsA* and *spp*), trehalose (*treS* and *treY*), glucosyglycerol (*ggpP* and *ggpS*), glycine betaine (*gsmt* and *sdmt*), and proline (*proA/B/C*) were annotated; however, genes encoding glucosyglycerate biosynthesis proteins were absent from the *Euhalothece* genome.

Transcripts of genes encoding GSMT and SDMT were highly abundant compared with those of genes involved in biosynthesis of other solutes (Supplementary Table S2, Fig. 2). This suggests that glycine betaine acts a major compatible solute that protects against salt stress in *Euhalothece*, as in other hypersaline cyanobacteria\(^{24}\).

Figure 1. Growth, photosynthesis pigments, and exopolysaccharide (EPS, D) content in *Euhalothece* sp. Z-M001 maintained for 6 days on S growth medium containing 0% or 3% NaCl. (A–D) Growth (A), chlorophyll *a* (Chl) and phycocyanin (PC) content (B), carotenoid (Car) content (C), and exopolysaccharide (EPS) content (D) of *Euhalothece* cells. Cells grown in 3% NaCl-containing liquid S-medium (+Na) were transferred to 0% NaCl (−Na) medium under growth light conditions for 6 days. Data represent mean ± S.E. (n = 3–5). Significant differences are indicated with an asterisk (*p < 0.05; Student’s *t*-test).

Figure 2. Quantitative real-time PCR (qRT-PCR) analysis of representative salt resistance-related genes in *Euhalothece* Z-M001 maintained for 6 days on S growth medium containing 0% (−Na) or 3% NaCl (+Na). *nhaS5* (ezl1331; Na\(^+\)/H\(^+\) antiporter), *mrpD* (ezr1945; multisubunit Na\(^+\)/H\(^+\) antiporter), *trkA* (ezl0593; K\(^+\) uptake protein), *spmA* (ezl3057; sucrose phosphate synthase), *treS* (ezr3241; trehalose synthase), *gsmt* (ezr2095; glycine-sarcosine-N-methyltransferase), *ggpS* (ezr0090; glucosyglycerol-phosphate synthase), *rfbW* (EZL0736; mannosyl transferase), *cruA* (ezl1782; lycopene cyclase), *crtR* (ezr1976; β-carotene hydroxylase), *ocp* (ezr1969; orange carotenoid protein), *hcp* (ezr2074; helical carotenoid protein), and *ctdh* (ezr2075; C-terminal domain homolog). Data represent the mean ± S.E. (n = 3–5). Significant differences are indicated by an asterisk (*p < 0.05; Student’s *t*-test).
respectively, because β were designated as genes encoding lycopene cyclase (βEzr1976) in absence of NaCl (Supplementary Table S2, Fig. 2). However, as in several halotolerant and halophilic cyanobacteria, only one gene encoding glucosyl transferase fell (Supplementary Table S2 and Fig. 2). Thus, Synechocystis Ech was identified as a dominant carotenoid in PCC8305 (Supplementary Fig. S1).

crts and cbps in the Euhalothece genome. In addition to the above-mentioned genes involved in salt acclimation via regulation of intracellular water potential, carotenoids play protective roles against salt stress by promoting protein and membrane stabilization, and by scavenging ROS; this occurs, for example, in the mesophilic cyanobacterium Synechocystis. Thus, the carotenoid composition of Euhalothece was determined along with that of other halophilic cyanobacteria such as Euhalothece Z9404 and Microcoleus B353 (Fig. 3A). These three cyanobacterial species are halophilic and lack keto-carotenoid biosynthesis genes such as crtW and cto; this is also true for other halophilic cyanobacteria such as Halococcus PCC7418 and Dactylococcus salina PCC8305 (Supplementary Fig. S1).

HPLC analysis detected trace amounts of Ech, but not Can, in these three stenohaline cyanobacteria, whereas Ech was identified as a dominant carotenoid in Synechocystis (Fig. 3A). In addition, Zea (5–6% of the total carotenoids) and β-Car (11–13% of the total carotenoids) were detected in Euhalothece and two other stenohaline cyanobacteria. A peak representing unknown compounds was detected in Euhalothece, the retention time of which was less than that of Can and Zea but more than that of Ech. This implies that the compound in the unknown peak is either more hydrophobic than both Can and Zea, but more hydrophilic than Ech, or a structurally different isoform (i.e., the cis-form) of the same carotenoid.

A search for homologs in the complete genome sequence of Euhalothece using the functionally confirmed carotenogenesis genes of both Synechocystis and Nostoc sp. PCC 7120 as query sequences revealed the presence of crtW, crtB, crtP, crtQ, cth, cruA, cruP, cruG, and cto genes in Euhalothece. Among these genes, Ez1782 and Ezr1976 were designated as genes encoding lycopene cyclase (cruA) and β-Car hydroxylase (cruR), respectively, because E. coli cells carrying these genes produced major peaks corresponding to β-Car and Zea, indicating that Ez1782 and Ezr1976 gene products are involved in lycopene cyclization and β-Car hydroxylation in Euhalothece (Fig. 3B). Both genes were expressed constitutively in the presence of 3% NaCl and in the absence of NaCl (Supplementary Table S2, Fig. 2). However, as in several halotolerant and halophilic cyanobacterial species including Microcoleus sp. B353 and Halococcus sp. PCC7418, no keto-carotenoid biosynthesis genes such as crtW and cto were detected. The failure of several Euhalothece crtW/O candidate genes to produce keto-carotenoids in β-Car-accumulating E. coli is consistent with this genomic survey. Based on this information, we propose the carotenoid biosynthesis pathway present in Euhalothece.

EuCBPs bind to β-car, Zea, and keto-carotenoids. Genes with a predicted amino acid sequence similar to that of crtW/O were not identified in Euhalothece, but genes encoding OCP and its paralogs HCP and CTDH were present. The Euhcp gene was adjacent to the Euthdh gene. A phylogenetic tree of OCP, HCP, and CTDH constructed using the maximum likelihood method revealed that EuOCP belongs to the OCP1 clade (Supplementary Fig. S3A), which includes the well-studied OCPs from Synechocystis (SyOCP) and Nostoc sp. PCC7120 (NoOCP). In general, the ocp1 gene co-exists with the fluorescence recovery protein (frp) gene in the genomes of most cyanobacteria. However, the frp gene was absent from the genome of Euhalothece. The phylogenetic tree for HCP revealed that EuHCP belonged to the HCP5 clade (Supplementary Fig. S3B). EuCTDH clustered with proteins in one of the major CTDH clades (CTDH1) and showed 91% identity to the amino acid sequences of these proteins (Supplementary Fig. S3C).

To test whether soluble EuCBPs bind to Zea, the Euocp, Euhcp, and Euthdh genes were expressed in Zea-producing E. coli. Syocp was also expressed in E. coli as a positive control. Recombinant SyOCP proteins bound to Zea but did not exhibit photoconversion activity upon blue light exposure (Fig. 4A). Consistent with this, recombinant EuOCP and EuHCP purified from Zea-producing E. coli failed to show a shift toward red light.
upon blue light illumination (Fig. 4B,C). Carotenoids were extracted from these holo-EuCBPs and analyzed by HPLC. Based on the retention times, carotenoids in the peaks were identified as Zea and \( \beta \)-Car respectively (Supplementary Fig. S4).

To test whether EuCBPs bind to keto-carotenoids, we expressed the \( \text{Euocp} \), \( \text{Euhcp} \), and \( \text{Euctdh} \) genes in \( \text{Can-producing E. coli} \). To verify that the EuCBPs expressed in Can-accumulating \( \text{E. coli} \) are photoactive, we measured the absorption spectra of purified holo-EuCBPs (Fig. 4E,F) and holo-SyOCP (Fig. 4D). A shift in the spectrum of the isolated EuOCP toward red light (active OCP) was detected upon exposure to blue light but, like SyOCP, active OCP reverted back to the inactive form in darkness. The maxima of the absorption spectra of both active and inactive EuOCP were slightly different from that of SyOCP. However, the time involved in the conversion from the active to inactive state, and the efficiency of chromophorylation (A472/A280 vs. A467/A280), were almost identical between EuOCP and SyOCP. This implies that the function of EuOCP is similar to that of SyOCP in the presence of keto-carotenoids. Recombinant EuHCP and EuCTDH had the color of orchids and violets, respectively. The maxima of the absorption spectrum of EuHCP and EuCTDH were 528 and 564 nm, respectively (Fig. 4F), similar to that of CTDH from \( \text{Thermosynechococcus elongatus} \)11.

These \( \text{Eucbps} \) were expressed constitutively in \( \text{Euhalothece} \) cells containing 0% or 3% NaCl (Supplementary Table S2). Interestingly, qRT-PCR analysis revealed that transcript levels of \( \text{crisA}, \text{hcp}, \) and \( \text{ctdh} \) genes increased upon salt deprivation (Fig. 2), suggesting that carotenoid biosynthesis and CBPs play important roles in \( \text{Euhalothece} \) under conditions of salt deprivation stress.
Zea and EuCBPs function as antioxidants. FRP, which facilitates conversion of red OCP to orange OCP, is absent from the \textit{Euhalothece} genome. Furthermore, Zea-bound OCP is unable to induce fluorescence quenching, although it absorbs blue–green light in \textit{crtO}-deficient \textit{Synechocystis} 6. Thus, EuCBPs are most likely inefficient dissipaters of excess light energy. The Zea-binding ability of recombinant EuOCP and EuHCP proteins (Fig. 4A–C) implies that EuCBPs function as ROS scavengers instead of excitation energy quenchers in \textit{Euhalothece} cells. Like other carotenoids, Zea and β-Car are strong ROS scavengers 38,39, and OCP and HCP exhibit antioxidant properties 9,39. Thus, we hypothesized that \textit{E. coli} producing both carotenoids and CBPs would show better survival under ROS stress than wild-type cells. In the present study, ROS production was induced by cefatoxime and gentamycin, which kill bacteria by inducing ROS production 40. Inhibitory effects of antibiotics on \textit{E. coli} growth were observed; however, the intensity of these effects was low in the presence of Zea alone or Zea-bound OCPs and HCPs. Under antibiotic-induced ROS stress, all three \textit{E. coli} strains containing SyOCP, EuOCP, and EuHCP showed higher survival rates than \textit{E. coli} cells containing only Zea (Fig. 5A). To identify whether the survival rate is related to the ROS scavenging effect of Zea and holo-EuCBPs, we compared the relative ROS content of \textit{E. coli} cells using the fluorescence dye DCFH-DA. Higher ROS content was detected in all \textit{E. coli} cells treated with antibiotics, although \textit{E. coli} cells treated with gentamycin produced more ROS than those treated with cefatoxime. This result explains the lower survival rate of gentamycin-treated \textit{E. coli} cells. After treatment with both antibiotics, ROS content in all three \textit{E. coli} strains containing CBPs was lower than that in \textit{E. coli} cells containing only Zea (Fig. 5B). We did not include CTDH for this \textit{in vitro} assay because CTDH did not bind to Zea (Supplementary Fig. S4) 11. These results strongly imply that EuCBPs are effective ROS scavengers. Indeed, the absence of ketolase and \textit{cbp} genes is one of the main factors responsible for the sensitivity of \textit{Prochlorococcus} species to high irradiance, and their inability to degrade ROS 41,42.

Figure 4. Absorption spectra of OCP and its paralogs, HCP and CTDH, purified from zeaxanthin (Zea)- and cantaxanthin (Can)-producing \textit{E. coli}. (A–F) Absorption spectra of proteins purified from Zea-producing \textit{E. coli} (A–C) and Can-producing \textit{E. coli} (D–F). SyOCP, \textit{Synechocystis} OCP (Slr0088); EuOCP, \textit{Euhalothece} OCP (Ezr1969); EuHCP, \textit{Euhalothece} HCP (Ezr2074); EuCTDH, \textit{Euhalothece} CTDH (Ezr2075). Orange and red lines (A–E) represent absorption spectra of OCP and HCPs before (OCP°, OCP* and HCP°) and after exposure to light (OCP, OCP* and HCP*). Both EuHCP and EuCTDH bound to Can were non-responsive to illumination (F).

β-Car and Zea content, ROS content, and levels of \textit{crt} and \textit{cbp} gene transcripts at the early phase of salt deprivation. The involvement of carotenoids β-Car and Zea, and the corresponding EuCBPs, in ROS scavenging can be inferred from the inverse relationship between carotenoid and ROS content. To verify this inference, \textit{Euhalothece} cells grown in 3% NaCl were transferred to salt-deficient growth medium (0% NaCl) for 1 h. Cells acclimated to salt deficiency for 6 days showed a 4.5-fold increase in total carotenoid content (Fig. 1C); in addition, short-term exposure to salt deprivation increased the content of β-Car and Zea by 1.2–1.3-fold, but decreased that of ROS by 30% (Fig. 6A and B). This inverse relationship implies that carotenoid-dependent ROS scavenging is crucial for responses to salt deprivation. Transcript levels of \textit{hcp} and \textit{ctdh} increased several-fold (Fig. 6C) and remained higher even after acclimation to salt-deficient conditions (Fig. 2); by contrast, those of \textit{ocp} remained unchanged in response to altered salt concentrations (Figs. 2 and 6C). However, expression of \textit{crtR} and \textit{cruA} increased transiently upon salt deprivation (Figs. 2 and 6D). The different responses of carotenoid biosynthesis and CBP genes to salt stress suggests that CBP-dependent ROS scavenging in \textit{Euhalothece} is regulated at both the transcriptional and post-transcriptional level.
In conclusion, among multiple salt acclimation strategies, maintenance of low internal water potential within *Euhalothece* cells is achieved by the MRP system pumping out intracellular Na\(^+\) ions, a compatible solute glycine betaine and exogenous Na\(^+\)-chelating EPSs. Additionally, *Euhalothece* cells are equipped with β-Car- and Figure 5. *Euhalothece* carotenoid-binding proteins EuOCP and EuHCP act as ROS scavengers. (A,B) Survival rate (A) and ROS content (B) of *E. coli* BL21 cells grown in media containing antibiotics, such as cefatoxime (Cef) and gentamycin (Gen), or DMSO (control; Con). *E. coli* strains produced Zea alone or Zea and CBPs (OCP and HCP) from *Synechocystis* sp. PCC 6803 (SyOCP) and *Euhalothece* Z-M001 (EuOCP and EuHCP). Mock represents *E. coli* cells carrying no plasmid. Data represent mean ± S.E. (n = 3–4). \(^*\)p < 0.05 for the comparison between mock treatment and Zea or Zea + CBP. \(^{**}\)p < 0.05 for the comparison between Zea and Zea + CBP.

Figure 6. Carotenoid and ROS contents, and transcript levels of genes for carotenogenesis and CBPs in *Euhalothece* Z-M001 during the early phase of salt deficiency. (A–D) Changes in carotenoid (β-Car and Zea) content (A), cellular ROS content (B), and expression levels of *ocp*, *hcp* and *cdth* (C), and zeaxanthin (*crtR*), and β-carotene (*cruA*) biosynthesis genes (D). Cells grown in 3% NaCl (+Na)-containing liquid S-medium were transferred to no-salt (0% NaCl, −Na) medium under growth light conditions for 1 h. Data represent mean ± S.E. (n = 3–4). \(^*\)p < 0.01.

In conclusion, among multiple salt acclimation strategies, maintenance of low internal water potential within *Euhalothece* cells is achieved by the MRP system pumping out intracellular Na\(^+\) ions, a compatible solute glycine betaine and exogenous Na\(^+\)-chelating EPSs. Additionally, *Euhalothece* cells are equipped with β-Car- and
Zea-dependent ROS scavenging systems against salt stress, whereas Zea either acts freely or is bound to CBPs. Thus, in the absence of frp, CBPs seem to act as effective ROS scavengers. The role of EPSs in cell-to-cell aggregation, biofilm formation, biomineralization, and abiotic stress tolerance needs to be explored further in *Euhalothece*.

**Methods**

**Strain and cultivation conditions.** The natronophilic cyanobacterium *Euhalothece* sp. Z-M001, originally isolated from Lake Magadi (Eastern African Rift Valley, Kenya; 1°52′0″S, 36°16′0″E), was obtained from the Culture Collection of the Department of Biology, Moscow State University. The strain was grown on S-solid media (for 1 L, 1 g KCl, 16.8 g NaHCO₃, 0.5 g K₂HPO₄, 2.5 g NaNO₃, 1 g K₂SO₄, 30 g NaCl, 0.1 g MgSO₄, 0.04 g CaCl₂, 0.01 g FeSO₄, 0.08 g EDTA, 1 mL of trace metal mix stock, and 1% agar [pH 9.5]) or S-liquid medium at 28°C under continuous white light at an intensity of 10 μmol m⁻²s⁻¹. To determine the survival rate of *Escherichia coli* cells producing Zea alone or in combination with CBPs such as SyOCP, EuOCP1, and EuHCP, *E. coli* cultures with an optical density of 0.1 at 600 nm (O.D.600) were treated with cefatoxime (50 μg/mL) or gentamycin (60 μg/mL) and grown in a 6-well plate at 37°C for 2 h.

**Genomic DNA isolation and purity assessment.** Genomic DNA was isolated as described previously. To assess the purity of the extracted genomic DNA, a 16S rRNA gene was amplified by PCR in a 25 μL volume containing 2 mM of each universal 16S rRNA primer (27F and 1492R), 200 μM dNTPs, 1× master mix, and 1 U DNA polymerase (Apex Taq; Genesee Scientific Corp.). PCR was performed using the following protocol: initial denaturation at 95°C for 10 min, followed by 30 cycles of denaturation at 90°C for 30 s, annealing at 50°C for 30 s, and extension at 72°C for 2 min, and a final extension at 72°C for 5 min. The PCR products were precipitated with ethanol and resuspended in 15 μL nuclease-free water. The 16S rRNA gene amplicon (20–50 ng μL⁻¹) was sequenced using commercially available universal primers 27F and 1492R (Supplementary Table S3).

**Whole genome sequencing, assembly, and annotation.** Genomic DNA was fragmented and sheared using a g-TUBE (Covaris Inc., Woburn, MA, USA) and then purified using AMPure PB magnetic beads (Beckman Coulter Inc. Bread, CA, USA). A 10 μL library was prepared using the PacBio DNA template Prep Kit 1.0 (for 3–10 kb). SMRTbell templates were annealed using PacBio DNA/Polymerase Binding Kit P6. Libraries were sequenced on PacBio SMRT Cell using the PacBio Sequel (Pacific Biosciences) sequencing platform (Macrogen; Seoul, Korea), yielding 490,426 reads (average read length, 9,180; N50 value, 16,358; total read length, 4,502,067 bp). Some reads that were fully contained in other reads provide no extra information with respect to constructing the genome; these were filtered out. After quality control, 81,788 reads were recovered (average length, 5,709; N50 value, 9,479; total read length, 466,969,904 bp). The filtered reads were used to assemble the genome using HGAPl4 v4.0, with default options. The genome sequence was circularized using the Circulator algorithm and annotated using the RAST server or the NCBI Prokaryotic Genome Annotation Pipeline (PGAP). The *Circos* program was used to draw the chromosome map. Secondary metabolites were predicted using antiSMASH. CRISPR loci were detected using CRISPRFinder. The genome sequence was deposited in the NCBI BioProject under accession number PRJNA557809.

**RNA isolation and quantitative real-time PCR (qRT-PCR).** Total RNA was isolated from *Euhalothece*, as described previously, with some modifications. The extracted total RNA was treated with DNaseI (Takara) and then cleaned using the NucleoSpin RNA Cleanup Kit (Macherey-Nagel). First-strand cDNA was synthesized using the iScript cDNA Synthesis Kit (Bio-Rad), and qRT-PCR was carried out on the CFX96 Real Time System (Bio-Rad) using SYBR Green Supermix (Bio-Rad) and gene-specific primers (Supplementary Table S3). The 16S rRNA gene was used as the control in each trial of qRT-PCR.

**RNA sequencing and data analysis.** Construction of the cDNA libraries, RNA sequencing, and data analysis were carried out as described previously. The Ribo-Zero rRNA Removal Kit (Epigentre, USA) was used to deplete RNA from 2 μg total RNA. The cDNA libraries were quantified using Bioanalyzer 2100 (Agilent, USA) and sequenced on the Hi-seq 2500 (Illumina, USA) platform to generate 100 bp paired-end reads. The reads were mapped to transcripts using bowtie2 v2.1.0 (mismatch ≤ 2) and then normalized using the DESeq v1.22.1 library in R46,47. Statistical analysis was performed, and genes showing a 2-fold change between compared samples with an adjusted p-value < 0.01 in a binomial test were identified as differentially expressed. Dendrograms and heatmaps of differentially expressed genes were generated using the R program (Bioconductor, R v3.0.3 library in R48,49. Dendrograms and heatmaps of differentially expressed genes were generated using the R package gplots. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program. Dendrograms and heatmaps of differentially expressed genes were generated using the R program.
Production of carotenoids with or without CBPs in E. coli. 

*E. coli* cells transformed with PAC-ZEAX and PACtrcp-TPR6673 plasmids encoding various carotenoids were grown at 28 °C for 20 h, and Zea or Can production was induced by the addition of 0.2 mM IPTG. Then, Zea- or Can-binding holo-CBPs were produced by the transformation of pBAD-CBP plasmids into Zea- or Can-producing *E. coli* strains. The transformed cells were grown at 37 °C for 20 h. Then, 0.02% arabinose was added to the cultures, and the cells were grown at 28 °C for 20 h. The induced cells were harvested by centrifugation at 3,500 rpm at 4 °C for 10 min, and the cell pellets were stored at −70 °C until needed. LB and RM media were used for BL21 and LMG194 cell cultures, respectively. Chloramphenicol (35 μg/ml) and ampicillin (100 μg/ml) were used for selecting and maintaining the transformed cells.

**Pigment levels.** Chlorophyll (Chl) *a*, phycocyanin (PC), and carotenoid (Car) levels in cells grown for 3 days on S-liquid media were estimated using whole-cell spectra or 100% N,N-dimethylformamide extracts.

**Carotenoid extraction and HPLC analysis.** Carotenoids from lyophilized cyanobacterial cells (15 mg dry cell weight) were extracted using HPLC-grade methanol by sonication for 1 h, followed by centrifugation at 12,000 rpm at 4 °C for 20 min. The supernatants were collected, and the centrifugation was repeated two more times. The supernatants from each centrifugation were pooled, evaporated, concentrated under nitrogen gas, and dissolved in HPLC-grade acetonitrile. The dissolved residues were filtered before HPLC analysis. To extract carotenoids from *E. coli* cell cultures, cold hexane:acetone (1:1, v/v) solution was used.

**Isolation of holo-CBPs.** Holo-CBPs were isolated from *E. coli* cells in the dark, as described previously, with some modifications. Frozen pellets of *E. coli* cells were resuspended in the lysis buffer containing 50 mM Tris–HCl (pH 8), 100 mM NaCl, 0.1% IGEPA, and 10% glycerol, and the mixtures were sonicated for 1–1.5 h. After sonication, the samples were centrifuged at 13,000 rpm for 10 min at 4 °C. The supernatant was transferred to a tube containing Ni-NTA resin, previously resuspended with 300 mM NaCl and 20 mM imidazole at 4 °C for 2 h. After incubation, the Ni-NTA resin was transferred to a column and then washed with 50 mM Tris–HCl buffer (pH 8.0) containing 300 mM NaCl, 0.1% IGEPA, 10% glycerol, and 20 mM imidazole. CBPs were then eluted using 50 mM Tris–HCl buffer (pH 8.0) containing 300 mM NaCl and 250 mM imidazole. The eluted proteins were stored at −70 °C until needed for further analysis.

**Antibiotic treatment of E. coli.** *E. coli* BL21 cells carrying the PAC-ZEAX plasmid alone or together with pBAD-CBP plasmids were grown at 37 °C in LB media containing chloramphenicol (35 μg/ml) or both chloramphenicol (35 μg/ml) and ampicillin (200 μg/ml), respectively. After 6 h, the cultures were transferred to 28 °C and then grown for another 12 h. Six hours after the transfer to 28 °C, 0.02% arabinose was added to BL21 cells containing both PAC-ZEAX and pBAD-CBP plasmids, and the cultures were grown for another 6 h. Then, fresh LB media was added to the overnight cultures to dilute them to an O.D. 600 of 0.1. The cultures were grown further to an O.D. 600 of 0.4–0.6; BL21 cells without plasmids were grown at 37 °C, while BL21 cells containing PAC-ZEAX alone or both PAC-ZEAX and pBAD-CBP plasmids were grown at 28 °C. The cells were diluted again using 5 mL LB in a 6-well plate (O.D. 600 = 0.1), and cefatoxime (50 μg/ml) or gentamycin (60 μg/ml) was added to the culture. The culture was grown at 37 °C and 130 rpm, and O.D. 600 was measured after 2 h. All cultures were grown in the dark.

**ROS detection.** Overnight cultures of *E. coli* were diluted to an O.D. 600 of 0.1 using fresh LB media containing 5 μM 2′,7′-dichlorodihydrofluorescein diacetate (DCFH-DA). *Euhalothece* cells grown in the presence of 3% NaCl or 1.5 h after transfer to salt-deficient S-media were suspended in 1 mL 1X phosphate-buffered saline containing 5 μM DCFH-DA (O.D. 580 = 0.2). Emission spectra were measured using a fluorescence spectrometer (LS-55, Perkin Elmer, Waltham, USA) at an excitation wavelength of 480 nm. Fluorescence emission at 520 nm was used to determine the ROS production.

**Extraction and quantification of exopolysaccharides.** Cells grown for 7 days in S-solid medium were in inoculated in S-liquid medium containing 3% NaCl or 0% NaCl (O.D. 750 = 0.7). The cultures were grown for 9 days at 28 °C under continuous white light at an intensity of 10 μmol m−2s−1. Samples (2 ml) were taken from the cultures and centrifuged at 12,000 rpm for 10 min. After washing twice with 1 mL ultra-pure water, the pellets were resuspended in 1 mL ultra-pure water and boiled for 15 min at 100 °C. After cooling and centrifugation at 13,000 rpm for 15 min, supernatants were taken to measure the concentration of total carbohydrate contents of EPSs using the phenol-sulfuric acid method.

**Phylogenetic analysis.** Sequences of the 16S rRNA genes of 58 cyanobacteria, whose taxa were already verified, were retrieved from GenBank. The 16S rRNA gene sequences of four additional species (*Euhalothece* Z-M001, *Euhalothece* Z9404, *Microcoleus* IPPAS B-353, and *Nostoc punctiforme* ATCC29133) were confirmed by sequencing and added to the retrieved sequences. Multiple alignments were made using Mafft ver.7 with the L-INS-i parameter. "The maximum likelihood (ML)" tree was constructed using PhyML and the best-fitting substitution model was selected as GTR + G + I using Akaiken information Criterion (AIC)69–71.
