Scalar Mesons as $\bar{q}^2 q^2$?
Insight from the Lattice

Abstract. I describe some insight obtained from a lattice calculation on the possibility that the light scalar mesons are $\bar{q}^2 q^2$ states rather than $\bar{q}q$. First I review some general features of $\bar{q}^2 q^2$ states in QCD inspired quark models. Then I describe a lattice QCD calculation of pseudoscalar meson scattering amplitudes, ignoring quark loops and quark annihilation, which finds indications that for sufficiently heavy quarks there is a stable four-quark bound state with $J^{PC} = 0^{++}$ and non-exotic flavor quantum numbers.

1 Talk presented by R. L. Jaffe at the Scalar Meson Workshop, May 2003, SUNYIT, Utica, NY
INTRODUCTION

We would like to call your attention to some work that we performed a few years ago, that bears on the interpretation of the scalar mesons. A complete description of our work can be found in Ref. [1].

The light scalar mesons have defied classification for decades [2, 3]. Some are narrow and have been firmly established since the 1960’s. Others are so broad that their very existence is controversial. Scalar mesons are predicted to be chiral partners of the pseudoscalars like the pion, but their role in chiral dynamics remains obscure. Naive quark models interpret them as orbitally excited $\bar{q}q$ states. Others have suggested that they are $\bar{q}q$ or “molecular” states,[5] strongly coupled to $\pi\pi$ and $\bar{K}K$ thresholds. Recently a consensus has emerged (at least in some quarters) that the light scalar mesons have important $\bar{q}q$ components at short distances and important meson-meson components at long distances.[6]

We propose a new way to shed some light on the nature of the scalar mesons using lattice QCD. Previously scalar mesons have been treated like other mesons: their masses have been extracted from the large Euclidean time falloff of $\bar{q}q$ correlation functions with the appropriate quantum numbers. Here we look for a $0^{++}\bar{q}q$ bound state. We construct $\bar{q}q$ sources, work in the quenched approximation, and discard $\bar{q}q$ annihilation diagrams so communication with $\bar{q}q$ and vacuum channels is forbidden. Also, we allow the quark masses to be large (hundreds of MeV), so the continuum threshold for the decay $\bar{q}q^2 \rightarrow (\bar{q}q)(\bar{q}q)$ is artificially elevated. We then study the large Euclidean time falloff of a $\bar{q}q^2$ correlator, looking for a falloff slower than $2m_{\bar{q}q}$, signalling a bound state. Such an object would have been missed by studies of $\bar{q}q$ correlators in the quenched approximation. We use shortcomings of lattice QCD to our advantage. By excluding processes that mix $\bar{q}q$ and $\bar{q}q^2$, we can unambiguously assign a quark content to a state. The heavy quark mass suppresses relativistic effects, which we believe complicate the interpretation of light quark states.

Our initial results are encouraging: within the limits of our computation we see signs of a bound state in the “non-exotic” $\bar{q}q^2$ channel, the one with quantum numbers that could also characterize a $\bar{q}q$ state ($I = 0$ for 2 flavors, the 1 and 8 for 3 flavors). In contrast, the “exotic” flavor $\bar{q}q^2$ channel ($I = 2$ for 2 flavors, the 27 for 3 flavors) shows no bound state. Instead it shows a negative scattering length, characteristic of a repulsive interaction. A definitive result will require larger lattices and more computer time, but this is well within the scope of existing facilities. There have been a couple of previous studies of $\bar{q}^2q^2$ sources on the lattice.[7, 8] Because these earlier works looked only at one (relatively small) lattice size they were unable to examine the possibility of a bound state.

A reader who wishes to skip the details can look immediately at Fig. 3 where we plot the dependence on lattice size of the binding energy of the exotic and non-exotic $\bar{q}^2q^2$ channels. The exotic channel shows a negative binding energy with the $1/L^3$ dependence expected from analysis of the $(\bar{q}q)(\bar{q}q)$ continuum.[9] The coefficient of $1/L^3$ agrees roughly with Refs. [7, 8] and with the predictions of chiral perturbation theory. The non-exotic channel shows positive binding energy, but seems to depart from $1/L^3$, perhaps approaching a constant as $L \rightarrow \infty$, which would indicate the existence of a bound $\bar{q}^2q^2$ state. Confirmation of this result will require calculations on larger lattices.
OVERVIEW OF THE LIGHT SCALAR MESONS

In this section we give a very brief introduction to the phenomenology of the lightest $0^{++}$ mesons composed of light ($u$, $d$, and $s$) quarks and existing lattice calculations.

The known $0^{++}$ mesons divide into effects near and below 1 GeV, which are unusual, and effects in the 1.3–1.5 GeV region which may be more conventional. Here we focus on the states below 1 GeV. Altogether, the objects below 1 GeV form an $SU(3)_f$ nonet: two isosinglets, an isotriplet and two strange isodoublets. The isotriplet and one isosinglet are narrow and well confirmed. The isodoublets and the other isosinglet are very broad and still controversial.

The well established $0^{++}$ mesons are the isosinglet $f_0(980)$ and the isotriplet $a_0(980)$. Both are relatively narrow: $\Gamma[f_0] \sim 40$ MeV, $\Gamma[a_0] \sim 50$ MeV,† despite the presence of open channels ($\pi\pi$ for the $f_0$ and $\pi\eta$ for the $a_0$) for allowed s-wave decays. Both couple strongly to $\bar{K}K$ and lie so close to the $\bar{K}K$ threshold at 987 MeV that their shapes are strongly distorted by threshold effects. Interpretation of the $f_0$ and $a_0$ requires a coupled channel scattering analysis. The relevant channels are $\pi\pi$ and $\bar{K}K$ for the $f_0$ and $\pi\eta$ and $\bar{K}K$ for the $a_0$. In both cases the results favor an intrinsically broad state, strongly coupled to $\bar{K}K$ and weakly coupled to the other channel. The physical object appears narrow because the $\bar{K}K$ channel is closed over a significant portion of the object’s width. No summary this brief does justice to the wealth of work and opinion in this complex situation.

The other light scalar mesons are known as broad enhancements in very low energy s-wave meson-meson scattering. The enhancements are universally accepted, but their interpretation is more controversial. At the lowest energies only the $\pi\pi$ channel is open. The $\pi\pi$ s-wave can couple either to isospin zero or two. The $I = 2$ (e.g. $\pi^+\pi^+$) channel shows a weak repulsion in rough agreement with the predictions of chiral low energy theorems.[10] The $I = 0$ channel shows a strong attraction: the phase shift rises steadily from threshold to approximately $\pi/2$ by $\sim 800$ MeV before effects associated with the $f_0$ complicate the picture. This low mass enhancement in the $\pi\pi$ s-wave is the $\sigma$ meson of nuclear physics and chiral dynamics. Recent studies support the existence of an S-matrix pole associated with this state at a mass around 600 MeV, which we will refer to as the $\sigma(600)$.[3, 11] The $\pi K$ s-wave is very similar to $\pi\pi$. The exotic $I = 3/2$ (e.g. $\pi^+ K^+$) channel shows weak repulsion. The non-exotic $I = 1/2$ channel shows relatively strong attraction.

The conventional quark model assigns the $0^{++}$ mesons to the first orbitally excited multiplet of $\bar{q}q$ states. As in positronium, $0^{++}$ quantum numbers are made by coupling $L = 1$ to $S = 1$ to give total $J = 0$. The $0^{++}$ states should be very similar to the $1^{++}$ and $2^{++}$ $\bar{q}q$ states that lie in the same family. These are very well known and form conventional meson nonets (in $SU(3)_f$). Since they have a unit of excitation (orbital angular momentum), they are expected to be quite a bit heavier than the pseudoscalar and vector mesons. Most models put the $\bar{q}q$ $0^{++}$ mesons along with their $2^{++}$ and $1^{++}$ brethren around 1.2–1.5 GeV.

† We use the observed peak width into $\pi\pi$ and $\pi\eta$ respectively, rather than some more model dependent method for extracting a width.
An idealized $\bar{q}q$ meson nonet has a characteristic pattern of masses and decay couplings. The vector mesons are best known, but the pattern is equally apparent in the $2^{++}$ or $1^{++}$ nonets. The isotriplet and the isosinglet composed of non-strange quarks are lightest and are roughly degenerate (e.g. the $\rho$ and the $\omega$). The strange isodoublets are heavier because they contain a single strange quark (e.g. the $K^*$). The final isosinglet is heaviest because it contains an $\bar{s}s$ pair (e.g. the $\phi$). Decay patterns show selection rules which follow from this quark content. In particular, the lone isosinglet does not couple to non-strange mesons ($\phi \not\to 3\pi$). The mass pattern, quark content and natural decay couplings of a $\bar{q}q$ nonet are summarized in Fig. 1a. These patterns seem to bear little resemblance to the masses and couplings of the light $0^{++}$ mesons, a fact which led earlier workers to explore other interpretations.

Four quarks ($\bar{q}^2q^2$) can couple to $0^{++}$ without a unit of orbital excitation. Furthermore, the color and spin dependent interactions, which arise from one gluon exchange, favor states in which quarks and antiquarks are separately antisymmetrized in flavor. For quarks in 3-flavor QCD the antisymmetric state is the flavor $\bar{3}$. Thus the energetically favored configuration for $\bar{q}^2q^2$ in flavor is $(\bar{q}q)^3(qq)^3$, a flavor nonet. The lightest multiplet has spin 0. Explicit studies in the MIT Bag Model indicated that the color-spin interaction could drive the $\bar{q}^2q^2$ $0^{++}$ nonet down to very low energies: 600 to 1000 MeV depending on the strangeness content.[4]

The most striking feature of a $\bar{q}^2q^2$ nonet in comparison with a $\bar{q}q$ nonet is an inverted mass spectrum (see Fig. 1b). The crucial ingredient is the presence of a hidden $\bar{s}s$ pair in several states. The flavor content of $(qq)^3$ is $\{[ud], [us], [ds]\}$, where the brackets denote antisymmetry. When combined with $(\bar{q}q)^3$, four of the resulting states contain a hidden $\bar{s}s$ pair: the isotriplet and one of the isosinglets have quark content $\{ud\bar{s}s, \frac{1}{\sqrt{2}}(u\bar{u} -
and \( \bar{d}s, \bar{s}d \) and \( \frac{1}{\sqrt{2}}(u\bar{u} + d\bar{d})s\bar{s} \), and therefore lie at the top of the multiplet. The other isosinglet, \( u\bar{d}d\bar{u} \) is the only state without strange quarks and therefore lies alone at the bottom of the multiplet. The strange isodoublets \( (usdd, etc.) \) should lie in between. In summary, one expects a degenerate isosinglet and isotriplet at the top of the multiplet and strongly coupled to \( KK \), an isosinglet at the bottom, strongly coupled to \( \pi\pi \), and a strange isodoublet coupled to \( K\pi \) in between (Fig. 1b). The resemblance to the observed structure of the light \( 0^{++} \) states is considerable.

These qualitative considerations motivate a careful look at the classification of the scalar mesons. Models of QCD are not sophisticated enough to settle the question. For example, the \( \bar{q}q^2 \) picture does not distinguish between one extreme where the four quarks sit in the lowest orbital of some mean field,[4] and the other, where the four quarks are correlated into two \( \bar{q}q \) mesons which attract one another in the flavor \( (\bar{q}q)^3(qq)^3 \) channel.[12, 5] For years, phenomenologists have attempted to analyse meson-meson scattering data in ways which might distinguish between \( \bar{q}q \) and \( \bar{q}^2q^2 \) assignments. A recent quantitative study favors the \( \bar{q}^2q^2 \) assignment.[3] However the \( \bar{q}q \) assignment has strong advocates. We hope that a suitably constrained lattice calculation can aid in the eventual classification of these states.

Only a very few lattice calculations bear on the classification of the \( 0^{++} \) mesons. There have been lattice studies of both the spectrum of \( 0^{++} \) states and the mixing of \( \bar{q}q \) states with glueballs.

Unquenched spectroscopic calculations are just beginning to become available[13, 14]. In principle, these are of interest because they would couple to a \( \bar{q}^2q^2 \) configuration if it is energetically favorable. Both these studies find that the mass of the \( 0^{++} \) state is lower than that reported in quenched calculations. We return to this work briefly in our conclusions. Further insight from unquenched calculations will have to await more definitive studies.

Quenched calculations of the spectrum of \( \bar{q}q \) states find the \( 0^{++} \) states roughly degenerate with the other positive parity states. Their masses cluster around 1.3-1.5 times the \( \rho \) mass and are relatively constant as the ratio \( m_\pi/m_\rho \) is reduced toward the chiral limit. In short they behave like other \( \bar{q}q \) mesons. For more details the reader should consult Ref. [1].

In the past, lattice studies of four-quark states have been undertaken only in order to extract pseudoscalar-pseudoscalar \((P-P)\) scattering lengths for comparison with the predictions of chiral dynamics. It is known [9] that the energy shift \( \delta E \) of a two-particle state with quantum numbers \( \alpha \) in a cubic box of size \( L \) is related to the threshold scattering amplitude,

\[
\delta E_\alpha = E_\alpha - 2m_P = \frac{T_\alpha}{L^3} \left( 1 + 2.8373 \frac{mpT_\alpha}{4\pi L} + 6.3752 \left( \frac{mpT_\alpha}{4\pi L} \right)^2 + \cdots \right),
\]

where \( m_P \) is the mass of the scattering particles, and \( T_\alpha \) is the scattering amplitude at threshold in the channel labelled by \( \alpha \), which can be related to the scattering length,

\[
T_\alpha = -\frac{4\pi a_\alpha}{m_P}.
\]
FIGURE 2. The four types of quark line contraction that contribute to the pseudoscalar-pseudoscalar $(P-P)$ correlation function.

For a more detailed discussion, see Ref. [15]. In our case the channels of interest are exotic ($I = 2$, for two flavors) and non-exotic ($I = 0$, for two flavors). If the interaction is attractive enough to produce a bound state, then instead of eq. (1) one would find that $\delta E$ goes to a negative constant as $L \to \infty$.

In order to distinguish between a bound state and the continuum behavior described by eq. (1), it is necessary to perform calculations for several different lattice sizes. Calculations with $\bar{q}^2 q^2$ sources have been performed by Gupta et al.[7], who studied one lattice volume at one lattice spacing, and Fukugita et al.[8], who, for the heavy quark masses we are interested in, also studied only one lattice volume at one lattice spacing. Their results were therefore not sufficient to check the lattice-size dependence of the energy of the two-pseudoscalar state, and investigate the possibility of a bound state. Our method follows theirs, but we have studied a range of lattice sizes. Their results are plotted along with ours in Fig. 3. Where our calculations overlap, they agree.

A $\bar{Q}^2Q^2$ EXERCISE ON THE LATTICE

For our purposes the salient categorization of $\bar{q}^2 q^2$ correlators is into “exotic” channels (flavor states that are only possible for a $\bar{q}^2 q^2$ state, $I = 2$ for two flavors, the 27 for three flavors) and non-exotic channels (flavor states that could be $\bar{q}^2 q^2$ or $\bar{q}q$, $I = 0$ for two flavors, the 8 and 1 for three flavors). In the absence of quark annihilation diagrams, the 8 and 1 are identical. When annihilation is included, the 1, like the $I = 0$ for two flavors, can mix with pure glue. As shown in Fig. 2, the $\bar{q}^2 q^2$ $0^{++}$ correlation functions can be expressed in terms of a basis determined by the four ways of contracting the quark propagators[15]: direct (D), crossed (C), single annihilation (A), complete annihilation into glue (G). Since we are interested in $\bar{q}^2 q^2$ states, we only study the D and
C contributions. We will assume that all quarks are degenerate, so there is only one quark mass, and as far as color and spinor indices are concerned all quark propagators are the same. In our lattice calculation we will therefore build our $q^2\bar{q}^2$ correlators from color and spinor traces of contractions of four identical quark propagators, putting in the flavor properties by hand when we choose the relative weights of the different contractions.

In the case of two flavors, there are two possible channels for a spatially symmetric source: $I = 2$ (exotic) and $I = 0$ (non-exotic). Evaluation of the flavor dependence of the quark line contractions shows that the $I = 2$ channel is $D - C$, and $I = 0$ is $D + \frac{1}{2} C$ [15].

For three flavors, the possible channels are the symmetric parts of $3 \times 3 \times \bar{3} \times \bar{3}$, namely $1 + 8$ (non-exotic) and $27$ (exotic). As in the two-flavor case, the exotic channel is $D - C$. At sufficiently large Euclidean time separation, each contraction will behave as a sum of exponentials, corresponding to the states it overlaps with. Generically, all linear combinations will be dominated by the same state: the lightest. Only with correctly chosen relative weightings will the leading exponential cancel out, yielding a faster-dropping exponential corresponding to a more massive state. The exotic $(D - C)$ channel is the one where such a cancellation occurs, yielding a repulsive interaction between the pseudoscalars. For any other linear combination of $D$ and $C$ the correlator is therefore dominated by the lightest, attractive state. Without loss of generality, we can therefore study the following linear combinations:

\begin{align*}
\text{Exotic:} & \quad J_E = D - C & \text{2 flavor: } I = 2 & \text{3 flavor: } 27 \\
\text{Non-exotic:} & \quad J_N = D + \frac{1}{2} C & \text{2 flavor: } I = 0 & \text{3 flavor: } 1, 8
\end{align*}

We conclude that if, as our results suggest, there is a bound $\bar{q}q^2$ state in the non-exotic channel, then this means that with two flavors, the $I = 0$ channel is bound, and with three flavors both the $1$ and $8$ are bound. Once quark loops and annihilation diagrams are included, the $1$ and $8$ will split apart. Unquenched lattice calculations will be needed to see if they remain bound.

In our lattice calculations, we work in the quenched (valence) approximation, and use Symanzik-improved glue and quark actions. This means that irrelevant terms ($O(a), O(a^2)$, where $a$ is the lattice spacing) have been added to the lattice action to compensate for discretization errors. Improved actions are crucial to our ability to explore a range of physical volumes using limited computer resources. Because most of the finite-lattice-spacing errors have been removed, we can use coarse lattices, which have fewer sites and hence require much less computational effort: note that the number of floating-point-operations required even for a quenched lattice QCD calculation rises faster than $a^{-4}$.

Improved actions have been studied extensively [16, 17, 18, 19, 20], and it has been found that even on fairly coarse lattices ($a$ up to 0.4 fm) good results can be obtained for hadron masses by estimating the coefficients of the improvement terms using tadpole-improved perturbation theory. For the energy differences that we measure, we find that the improved action works very well. There are no signs of lattice-spacing dependence at $a$ up to 0.4 fm, so as well as greatly reducing the computer resources required, it enables us to dispense with the extrapolation in $a$ that is usually needed to obtain continuum results.
We work at a quark mass close to the physical strange quark: the pseudoscalar-to-vector meson mass ratio \( m_P/m_V \) is 0.76. We emphasize that this is not entirely unwelcome, since it makes our results easier to interpret.

To obtain the binding energy \( \delta E_N \) in the \( I = 0 \) channel, and the binding energy \( \delta E_E \) in the \( I = 2 \) channel, we construct ratios of correlators and fit them to an exponential

\[
R_N(t) = \frac{J_N(t)}{\langle P(t) \rangle^2} \sim A \exp(-\delta E_N t),
\]
\[
R_E(t) = \frac{J_E(t)}{\langle P(t) \rangle^2} \sim B \exp(-\delta E_E t).
\]

Here \( J_N \) and \( J_E \) are the \( D + \frac{1}{2}C \) (non-exotic) and \( D - C \) (exotic) correlators respectively, and \( P \) is the pseudoscalar correlator. \( t \) is the Euclidean lattice time. The ratios of correlators are expected to take the single exponential form only at large \( t \), after contributions from excited states have died away. We followed the usual procedure of looking for a plateau and found no difficulty in identifying the plateau and extracting \( \delta E_N \) or \( \delta E_E \).

Since this is not a lattice workshop I will spare you further details. However the reader can find a discussion of the sources we used and our fitting methods in Ref. [1].

**RESULTS AND DISCUSSION**

We measured \( \delta E_N \) and \( \delta E_E \) for several different lattice spacings and sizes. Our results are shown in Fig. 3 along with previous results from Refs. [7, 8]. The exotic and non-exotic channels appear to scale differently as a function of \( L \). The exotic channel falls like \( 1/L^3 \), which is the expected form for a scattering state, eq. (1). A fit is shown in the figure. The non-exotic channel appears to depart from \( 1/L^3 \) falloff. To be complete, however, we have fitted the non-exotic data also to the form expected for a scattering state.

Our results are consistent with those of Refs. [7, 8], even though we use much coarser lattices. This supports our use of Symanzik-improved glue and quark actions with tadpole-improved coefficients. As a further check on the validity of the improved actions, we note that at \( L = 2 \) fm, where we performed a calculation at two different lattice spacings for the same lattice volume, the results for the two lattice spacings agree very well. There is no evidence of any discretization errors.

For the exotic \( \bar{q}^2q^2 \) system, the fit to eq. (1) is quite good, and the fitted scattering amplitude is remarkably similar to the result expected in the chiral limit, \( 4f_P^2T = 1 \).** We conclude that there are no surprises in the exotic channel – the interaction near threshold appears repulsive and the strength is close to that predicted by chiral perturbation theory.

The non-exotic \( \bar{q}^2q^2 \) system, however, does not fit the expected scaling law at large \( L \). The fit to eq. (1) has a very large \( \chi^2 \), and is so poor that the extracted amplitude \( T \) is meaningless. Instead \( \delta E_N \) appears to be approaching a negative constant at large

** Since we did not calculate \( f_P \) at our quark masses, we have used the value \( f_P = 148 \) MeV, derived from Ref. [7], Table 1.
FIGURE 3. $P\bar{P}$ binding energy in non-exotic (N) and exotic (E) channels. The data at $a = 0.08$ fm are from [7]; the data at $a = 0.16$ fm are from [8]. The $a = 0.25$ fm and $a = 0.4$ fm points at $L = 2$ fm have been displaced slightly to either side in order to distinguish them. The lines are fits to eq. (1).

$L$. Instead of a scattering state, we appear to be seeing a bound state in the non-exotic channel. Although our data are suggestive, they are not conclusive. It would be very interesting to gather more data at $L \sim 4$ fm, as well as at a range of quark masses, in order to verify the existence of this new state in the quenched hadron spectrum.

Apparently we have evidence for a $\bar{q}^2q^2$ bound state just below threshold in the non-exotic pseudoscalar-pseudoscalar $s$-wave. In 2-flavor QCD the bound state would correspond to an isosinglet meson coupling to $\pi\pi$. In 3-flavor QCD the non-exotic channel corresponds to an entire nonet including two non-strange isosinglets and an isotriplet, and two strange isodoublets (see Fig. 1b). We work with a large quark mass so our results are not directly applicable to $\pi\pi$ scattering, but they do resemble physical
The known isosinglet $f_0(980)$ and isotriplet $a_0(980)$ mesons are obvious candidates to identify with the non-exotic $q^2q^2$ bound states we seem to have found on the lattice.

We believe the quark mass dependence of the non-exotic $q^2q^2$ state is quite different from a standard $qq$ lattice state. In the quenched approximation the masses of $0^{++}qq$ states have been found to be roughly independent of $m_P$. At large quark mass the $\bar{q}q$ $0^{++}$ mass is below $2m_P$, but as $m_P$ is decreased the $\bar{q}q$ $0^{++}$ mass crosses threshold, $2m_P$. It appears to be smooth as it crosses the threshold. In contrast, we believe that the $q^2q^2$ state we may have identified is strongly correlated with the $PP$ threshold when the quark mass is large, and departs from it in a characteristic way as the quark mass is reduced. (Indirect support for this comes from Gupta et al.’s finding that their binding energy is independent of the pseudoscalar mass.) In particular, we believe that the bound state will move off into the meson-meson continuum as $m_P$ is reduced toward the physical pion mass.

To explore the $m_P$ dependence of our results, we have made a toy model based on a relativistic generalization of potential scattering. We write a Klein-Gordon equation for the $s$-wave relative meson-meson wavefunction, $\phi(r)$,

$$-\phi''(r) + (2m_P - U(r))^2\phi(r) = E^2\phi(r),$$

with the boundary condition that $\phi(0) = 0$. For $U(r) = 0$ the spectrum is a continuum beginning at $E = 2m_P$ as required. In the non-relativistic limit $m_P \ll |U|$, eq. (5) reduces to the Schrödinger equation with an attractive potential $-U(r)$ (for $U(r) > 0$). For sufficient depth and range, this potential will have a bound state. However, as $m_P \to 0$, $\hat{K}\hat{K}$ scattering.$^\dagger$ Although we work in the $SU(3)_l$ limit where all quark masses are equal.
the potential term in eq. (5) turns repulsive and the bound state disappears. Thus, if one keeps the depth and range of $U$ fixed as one decreases $m_P$, the bound state moves out into the continuum and disappears. To be quantitative, we have taken a square well, $U(r) = U_0$, for $r \leq b$, and $U(r) = 0$ for $r > b$. We chose a range $b = 1/m_\pi \approx 1.4$ fm, and adjusted $U_0$ such that the bound state has binding energy of 10 MeV when $m_P \sim 800$ MeV. The bound state does indeed move off into the continuum (first as a virtual state) when $m_P$ goes below 330 MeV. The behavior of the bound state in this toy model is shown in Fig. 4. Note this toy model is not meant to be definitive but it illustrates the expected behavior of a $P-P$ bound state: tracking $2m_P$ with roughly constant binding energy as $m_P$ falls, then unbinding at some critical $m_P$.

On the basis of our lattice computation and the $m_P$ dependence suggested by our toy model, we believe it is possible that all the phenomena associated with the light scalar mesons are linked to $q^2\tilde{q}^2$ states. The narrow $0^{++}$ isosinglet $f_0(980)$ and isotriplet $a_0(980)$ mesons near $K\bar{K}$ threshold can be directly identified with $q^2\tilde{q}^2$ lattice bound states (top line of Fig. 1b). The broad $\kappa(900)$ and $\sigma(600)$ (middle and bottom lines of Fig. 1b) couple to low mass ($\pi\pi$ or $\pi K$) channels. We speculate that they are to be identified as the continuum relics of the same objects which appear as bound states of heavy quarks.

Of course, a thorough examination of this question would require implementing flavor $SU(3)$ violation by giving the strange quark a larger mass. This would mix and split the isoscalars, shift the other multiplets (see Fig. 1b), and dramatically alter thresholds. For example, the $I = 1$ $q^2\tilde{q}^2$ state couples both to $K\bar{K}$ and $\pi\eta$ (through the $\bar{s}s$ component of the $\eta$) in the quenched approximation. The fact that the physical $K\bar{K}$ and $\pi\eta$ thresholds are significantly different would certainly affect the manifestation of bound states such as those we have been discussing in the $SU(3)$-flavor-symmetric limit.

In summary we have presented evidence for previously unknown pseudoscalar meson bound states in lattice QCD. Our results need confirmation. Calculations on larger lattices are needed, and variation with quark mass, lattice spacing, and discretization scheme should be explored.

In the real world a $0^{++}$ $q^2\tilde{q}^2$ state may, depending on its flavor quantum numbers, mix with $0^{++}$ $\bar{q}q$ and glueball states. It seems natural to expect that for sufficiently heavy quarks a bound state will remain, but only full, unquenched lattice calculations can confirm this.

It is possible that unquenched studies of $0^{++}$ $\bar{q}q$ operators may show some corroboration of our results [13, 14]. These studies use $\bar{q}q$ sources with dynamical fermions, but there is nothing to stop their $\bar{q}q$ source from mixing with $q^2\tilde{q}^2$, and allowing them to see the $q^2\tilde{q}^2$ bound state we have identified. It is therefore quite interesting that they report that the $0^{++}$ state is significantly lighter in unquenched calculations than in quenched ones. However, the calculations are still far from the continuum and chiral limits, and it is hard to tell whether their $f_0$ will become light compared to typical $\bar{q}q$ singlet states as the pion mass drops.

---

§ We could have chosen a different relativistic generalization of the Schrödinger equation which would have preserved the bound state as $m_P \to 0$. For example, we could have replaced $(2m_P - U)^2$ by $2m_P^2 - 2m_P U_1 - U_2^2$, and fine-tuned $U_1$ and $U_2$ to provide binding at arbitrarily low $m_P$. 

If light $\bar{q}q^2$ states are, in fact, a universal phenomenon, and if the $\sigma(600)$ is predominantly a $\bar{q}q^2$ object, then the chiral transformation properties of the $\sigma$ have to be re-examined. The $\pi$ and the $\sigma(600)$ are usually viewed as members of a (broken) chiral multiplet. In the naive $\bar{q}q$ model both $\pi$ and $\sigma$ are in the $(\frac{1}{2}, \frac{1}{2}) \oplus (\frac{1}{2}, \frac{1}{2})$ representation of $SU(2)_L \otimes SU(2)_R$ before symmetry breaking. In a $\bar{q}q^2$ model, as in the real world, the chiral transformation properties of the $\sigma$ are not clear.

If the phenomena that we have discussed survive the introduction of differing quark masses, then they will also have implications for heavy quark physics. For example, there could be a $0^{++}$ bound state just below the decay threshold for two $D$ mesons in the charmonium spectrum.

Finally, we note that calculations similar to ours could be undertaken in the meson-baryon sector and in other $J^{PC}$ meson channels. It has long been speculated that the $\Lambda(1405)$ is some sort of $KN$ bound state[24] and $\bar{q}q^2$ states have been postulated in other meson-meson partial waves.

ACKNOWLEDGMENTS

This work is supported in part by funds provided by the U.S. Department of Energy (D.O.E.) under cooperative research agreement #DF-FC02-94ER40818. The lattice QCD calculations were performed on the SP-2 at the Cornell Theory Center, which receives funding from Cornell University, New York State, federal agencies, and corporate partners. The code was written by P. Lepage, T. Klassen, and M. Alford.
