ABSTRACT

Using spatially resolved H$\alpha$ emission line maps of star-forming galaxies, we study the evolution of gradients in galaxy assembly over a wide range in redshift ($0.5 \lesssim z \lesssim 1.7$). Our $z \sim 0.5$ measurements come from deep Hubble Space Telescope WFC3 G102 grism spectroscopy obtained as part of the CANDELS Lyman-$\alpha$ Emission at Reionization (CLEAR) Experiment. For star-forming galaxies with $\log(M_*/M_\odot) \geq 8.96$, the mean H$\alpha$ effective radius is $1.2 \pm 0.1$ times larger than that of the stellar continuum, implying inside-out growth via star formation. This measurement agrees within 1$\sigma$ with those measured at $z \sim 1$ and $z \sim 1.7$ from the 3D-HST and KMOS3D surveys respectively, implying no redshift evolution. However, we observe redshift evolution in the stellar mass surface density within 1 kiloparsec ($\Sigma_{1kpc}$). Star-forming galaxies at $z \sim 0.5$ with a stellar mass of $\log(M_*/M_\odot) = 9.5$ have a ratio of $\Sigma_{1kpc}$ in H$\alpha$ relative to their stellar continuum that is lower by $(19 \pm 2)\%$ compared to $z \sim 1$ galaxies. $\Sigma_{1kpc, H\alpha}/\Sigma_{1kpc, Cont}$ decreases towards higher stellar masses. The majority of the redshift evolution in $\Sigma_{1kpc, H\alpha}/\Sigma_{1kpc, Cont}$ versus stellar mass stems from the fact that $\log(\Sigma_{1kpc, H\alpha})$ declines twice as much as $\log(\Sigma_{1kpc, Cont})$ from $z \sim 1$ to 0.5 (at a fixed stellar mass of $\log(M_*/M_\odot) = 9.5$). By comparing our results to the TNG50 cosmological magneto-hydrodynamical simulation, we rule out dust as the driver of this evolution. Our results are consistent with inside-out quenching following in the wake of inside-out growth, the former of which drives the significant drop in $\Sigma_{1kpc, H\alpha}$ from $z \sim 1$ to $z \sim 0.5$.

1. INTRODUCTION

In a Lambda Cold Dark Matter (ΛCDM) Universe such as ours, the assembly of galaxies is thought to be controlled by the nature of the dark matter haloes within which galaxies reside. The mass of the dark matter halo dictates the rate of gas accretion from the cosmic web and its angular momentum distribution the radial distribution of stars (White & Rees 1978; Fall & Efstathiou 1980; Dalcanton et al. 1997; Van Den Bosch 2001; Dekel et al. 2013). In a simple model of galaxy formation, the sizes of galaxy disks are assumed proportional to the sizes of their dark matter haloes (Mo et al. 1998). As haloes grow in size with time, star formation in galaxies should progress at larger galactocentric radii. More recently however, sophisticated hydrodynamic cosmological simulations have revealed the assembly of galaxies is a delicate balance between multiple physical processes, complicating this simple picture (Kereš et al. 2005; Brooks et al. 2009; Sales et al. 2012; Übler et al. 2014; Genel et al. 2015; Minchev et al. 2015; Nelson et al. 2015; Fielding et al. 2017; Anglés-Alcázar et al. 2017; Sparre & Springel 2017; Beckmann et al. 2017; Mitchell et al. 2018; Correa et al. 2018; Dawoodbhoy et al. 2018; Peeples et al. 2019; Nelson et al. 2019; Kar Chandler et al. 2020; Nelson et al. 2020; Mitchell et al. 2020; Wright et al. 2020; Bennett & Sijacki 2020; Watts et al. 2020; Okalidis et al. 2021; Wright et al. 2021; Mitchell & Schaye 2022).

An important confirmation of this picture is evidence that galaxies grow from the “inside-out”. Observational studies on the integrated star formation in galaxies over a wide range in redshift (0 < z < 8) have revealed the rise (z ~ 8 to z ~ 2) and fall (z ~ 2 to z = 0) of the amount of star formation per unit solar mass per unit time per unit volume (Madau & Dickinson 2014 and references therein). Whilst able to provide indirect evidence for star formation and stellar mass build-up in galaxies, these studies are insufficient in helping us definitively answer how star formation proceeds in galaxies. Answering this question requires spatially resolved observations of galaxies that are able to show us where the star formation process starts and finishes in a galaxy.

Some of the first observational campaigns in pursuit of this were naturally confined to the local Universe where it is easier to spatially resolve galaxies. Narrow band imaging over wavelengths sensitive to ongoing star formation or different timescales were used (Hodge & Kennicutt, R. C. 1983; Athanassoula et al. 1993; Ryder & Dopita 1994; Kenney & Koopmann 1999; Koopmann & Kenney 2004a,b; Koopmann et al. 2006; Cortés et al. 2006; Crowl & Kenney 2006; Munoz-Mateos et al. 2007; Abramson et al. 2011; Vollmer et al. 2012; Gavazzi et al. 2013; Kenney et al. 2015; Abramson et al. 2016; Lee et al. 2017; Gavazzi et al. 2018; Cramer et al. 2019; Boselli et al. 2020). The presence of Hα emission in galaxy spectra indicates the presence of massive, young O and B stars that emit ultraviolet radiation (Kennicutt 1998). With lifetimes of approximately 10 Myr, Hα emission due to these stars allows us to trace star formation on very short timescales. By comparing the sizes and morphologies of galaxy images in Hα versus the rest-frame optical which is a tracer of predominantly older stars (the “stellar continuum”), we can compare where star formation in the galaxy has been taking place in the past 10 Myr versus where it had occurred in the distant past.

The first direct evidence for inside-out growth via star formation in galaxies at high redshift was provided at z ~ 1 as part of the 3D-HST Survey (van Dokkum et al. 2011; Brammer et al. 2012; Momcheva et al. 2016). Using spatially resolved space-based slitless spectroscopy with the Wide Field Camera 3 (WFC3) on-board the Hubble Space Telescope (HST), Nelson et al. (2012, 2016a) were able to show that ongoing star formation traced by Hα emission occurs in disks that are more extended than those occupied by existing stars in star-forming galaxies. Subsequently, a similar study was conducted at z ~ 1.7 using ground-based integral field spectroscopy with the K-band Multi-Object Spectrograph (KMOS) on the Very Large Telescope (VLT) as part of the KMOS3D survey (Wisnioski et al. 2015, 2019) confirming consistent, albeit marginally more extended star-forming disks as those observed at z ~ 1 (Wilman et al. 2020). In the local Universe (z = 0), there is some tentative evidence for inside-out growth (e.g. Munoz-Mateos et al. 2007) but the star-forming disk has been found to have the same spatial extent as the stellar disk (James et al. 2009; Fossati et al. 2013). These handful of results tentatively suggest inside-out growth via star formation slows down with the decline in cosmic star formation.

Understanding the evolution in the cosmic star formation history requires us to understand how star formation and the quenching of star formation operate both in the low and high redshift Universe. Tracking spatially resolved star formation during the epoch of cosmic star formation decline (0 < z < 2) could provide direct observational evidence for the dominant physical mechanism responsible for the quenching of star formation. Recently, Matharu et al. (2021) demonstrated how the same technique of using HST WFC3 space-based slitless spectroscopy in Nelson et al. (2016a) can be used to provide direct evidence for rapid outside-in quenching due to ram-pressure stripping in z ~ 1 galaxy clusters. Other similar measurements not using space-based slitless spectroscopy have been similarly successful in providing direct evidence of ram-pressure stripping in galaxy clusters at lower redshifts (Koopmann et al. 2020).
2. DATA

In this section, we describe the three data sets we use to probe Hα sizes and morphologies of star-forming galaxies over a wide range in stellar mass and redshift. This includes measurements from CLEAR (Section 2.1) at $0.22 \lesssim z \lesssim 0.75$, 3D-HST (Nelson et al. 2016a) at $0.7 < z < 1.5$ (Section 2.2) and KMOS$^{3D}$ (Wilman et al. 2020) at $0.7 \lesssim z \lesssim 2.7$ (Section 2.3).

2.1. The CLEAR Survey

The CANDELS Lyman-α Emission at Reionization (CLEAR) Experiment (GO-14227, PI: Papovich) is a deep Hubble Space Telescope (HST), Wide Field Camera 3 (WFC3) F105W/G102 direct imaging and grism spectroscopy survey, covering 12 pointings across the GOODS-S and GOODS-N deep CANDELS fields (Grogin et al. 2011; Koekemoer et al. 2011). The 6 pointings in GOODS-S have a maximum of 12 orbit depth, whilst the 6 pointings in GOODS-N have a maximum of 12 orbit depth, of which two orbits are obtained from GO-13420 (PI: Barro). Each pointing is observed with at least 3 orients separated by more than 10 degrees, allowing for a reduction in source confusion and improved mitigation of grism spectra contamination. There is also archival F105W/G102 observations covering some CLEAR pointings in GOODS-S from GO/DD-11359 (PI: O’Connell) and GO-13779 (PI: Malhotra), the latter of which is an additional 40 orbits on a CLEAR pointing covering the Hubble Ultra Deep Field (The Faint Infrared Grism Survey, Pirzkal et al. 2017). A full description of the CLEAR Survey will be discussed in an upcoming survey paper (Simons et al., in prep).

The CLEAR survey was primarily designed to measure the evolution in the strength of Lyman-α emission from galaxies at $6.5 \lesssim z \lesssim 8.2$ (Jung et al. 2021). By virtue of being a spectroscopic survey in the well-studied GOODS-S and GOODS-N fields, the CLEAR data has high utility, especially when combined with the wealth of ancillary photometry spanning from the ultraviolet to the near-infrared (Skelton et al. 2014) and WFC3/G141 grism spectroscopy from the 3D-HST survey (see Section 2.2). So far, it has allowed for studies on the ages, metallicities and star formation histories of high redshift massive quiescent galaxies (Estrada-Carpenter et al. 2019, 2020), the gas-phase metallicity gradients of star-forming galaxies between $0.6 < z < 2.6$ (Simons et al. 2020), emission line ratios at $z \sim 1.5$ (Backhaus et al. 2022), an exploration of Paschen-β as a star formation rate indicator in the local ($z \lesssim 0.3$) Universe (Cleri et al. 2022) and the ionization and chemical enrichment properties of star-forming galaxies at $1.1 \lesssim z \lesssim 2.3$ (Papovich et al. 2022).

The WFC3 F105W direct imaging in CLEAR provides high spatial resolution (FWHM~0.128″) rest-frame optical imaging of the stellar continuum for galaxies between $0.22 \lesssim z \lesssim 0.75$. The WFC3 G102 grism spectroscopy provides low spectral resolution ($R \sim 210$ at 10000 Å) but high spatial resolution (FWHM~0.128″) two-dimensional spectra in the wavelength range $8000 < \lambda / \AA < 11500$. G102 grism spectroscopy effectively provides an image of the galaxy at specific wavelengths in 24.5Å increments spanning the wave-
length range of the grism. An unresolved\(^1\) emission line in this two-dimensional spectrum manifests itself as an image of the galaxy in that line on top of the underlying stellar continuum. The combination of high spatial resolution of the WFC3 and low spectral resolution of the G102 grism allows for spatially-resolved emission line maps of galaxies. With the G102 grism, we can obtain spatially-resolved H\(\alpha\) emission line maps of galaxies between \(0.22 \lesssim z \lesssim 0.75\). For the study presented in this paper, we will use the H\(\alpha\) emission line maps obtained from the G102 grism observations in conjunction with the F105W direct imaging from CLEAR to study how star formation proceeds spatially in \(z \sim 0.5\) star-forming galaxies.

2.2. The 3D-HST Survey

The 3D-HST survey was a 248-orbit near-infrared spectroscopic program with HST. The survey covered three quarters of the CANDELS treasury survey area with WFC3 F140W/G141 direct imaging and grism spectroscopy to 2-orbit depth (van Dokkum et al. 2011; Brammer et al. 2012; Momcheva et al. 2016). The WFC3 F140W direct imaging in 3D-HST provides high spatial resolution (FWHM\(\sim 0.141''\)) rest-frame optical imaging of the stellar continuum for galaxies between \(0.7 < z < 1.5\). The WFC3 G141 grism spectroscopy provides low spectral resolution (\(R \sim 130\) at 14000 Å) but high spatial resolution (FWHM\(\sim 0.141''\)) two-dimensional spectra in the wavelength range \(10750 \leq \lambda / \AA \leq 17000\). G141 grism spectroscopy effectively provides an image of the galaxy at specific wavelengths in 46.5Å increments spanning the wavelength range of the grism. An unresolved emission line in this two-dimensional spectrum manifests itself as an image of the galaxy in that line on top of the underlying continuum.

The combination of high spatial resolution of the WFC3 and low spectral resolution of the G141 grism allows for spatially-resolved emission line maps of galaxies. With the G141 grism, we can obtain spatially-resolved H\(\alpha\) emission line maps of galaxies between \(0.7 < z < 1.5\). Nelson et al. (2016a) used the H\(\alpha\) emission line maps in conjunction with the F140W direct imaging from 3D-HST to study how star formation proceeds spatially in \(z \sim 1\) star-forming galaxies. We closely follow the methodology in Nelson et al. (2016a) – and in places expand upon it – for our analogous study at \(0.22 \lesssim z \lesssim 0.75\) with the CLEAR dataset (Section 2.1). We compare our results to those obtained by 3D-HST in Section 6.3.

2.3. The KMOS\(^3\)D Survey

The KMOS\(^3\)D survey (Wisnioski et al. 2015, 2019) was a near-infrared integral field spectroscopy survey with the K-band Multi-Object Spectrograph (KMOS) on the ESO Very Large Telescope (VLT). The survey targeted galaxies in the 3D-HST (Section 2.2) and CANDELS surveys that were accessible from Paranal Observatory. Target galaxies had a \(K\) magnitude $< 23$, a spectroscopic or grism redshift indicating the spectrum in the vicinity of the H\(\alpha\) line would be somewhat free of atmospheric OH lines and visible in the KMOS YJH or K-bands.

The survey led to a sample of 645 galaxies in the redshift range \(0.7 \lesssim z \lesssim 2.7\) with moderate spatial resolution (median FWHM\(\sim 0.456''\)) H\(\alpha\) emission line maps. Wilman et al. (2020) used these H\(\alpha\) emission line maps in conjunction with HST WFC3 F125W/F160W direct imaging from 3D-HST+CANDELS (Skelton et al. 2014) to study how star formation proceeds spatially in \(281 z \sim 1.7\) star-forming galaxies. We compare our results from the CLEAR dataset (Section 2.1) at \(z \sim 0.5\) to those obtained by KMOS\(^3\)D in Section 6.3.

3. DATA REDUCTION, SAMPLE SELECTION & STACKING

3.1. Grism Data Reduction

In this section we summarize the grism data reduction process for the CLEAR dataset (Section 2.1). For a detailed explanation of the full data reduction process, we refer the reader to Section 2 of Simons et al. (2020).

The newest version of the Grism redshift & line analysis software for space-based slitless spectroscopy (Grizli\(^2\), Brammer & Matharu 2021) is used to reduce the G102 data and create the H\(\alpha\) emission line maps. The reduction for the CLEAR dataset includes the reduction of overlapping F105W, G102 and G141 data from other archival programs when available. Grizli starts by querying the Mikulski Archive for Space Telescopes (MAST) for all available HST WFC3 observations on and in the vicinity of the CLEAR survey footprint. Grizli is designed to fully process HST imaging and grism spectroscopy datasets, from the retrieval and pre-processing of raw observations to the extraction of one-dimensional (1D) and two-dimensional (2D) spectra leading to the generation of emission line maps.

3.1.1. Pre-processing

Grizli processes the raw WFC3 data using the calwf3 pipeline, including corrections for variable sky backgrounds (Brammer 2016), identification of hot pixels and cosmic rays (S. Gonzaga, W. Hack, A. Fruchter 2012), flat-fielding, sky subtraction (Brammer et al. 2015), astrometric corrections and alignment.

\(^1\) Typical kinematic widths of star-forming galaxies are unresolved by the G102 and G141 grisms (\(\lesssim 800\) km s\(^{-1}\) and \(\lesssim 1000\) km s\(^{-1}\) per pixel, respectively (Outini & Copin 2020)).

\(^2\) https://grizli.readthedocs.io/en/master/
3.1.2. Source Extraction, Contamination Modeling and Subtraction

A contamination model for each HST pointing is created by forward-modelling the HST F105W full-field mosaic and it is this model that is used to subtract contaminating grism spectra for each grism spectrum. The contamination model is created in two steps. The first step is a flat model for every source with F105W magnitude < 25. Then third-order polynomial models are created for all sources with F105W magnitude < 24, subtracting the initial flat models.

All sources in the field of view with F105W magnitude < 25 have their grism spectra extracted with Grizli. The G102 exposure times for all extracted sources range from 2 – 30 hours, with median values of 2.5 and 7.7 hours for GOODS-N and GOODS-S respectively. 533 extracted sources only have G102 coverage and 470 of extracted sources have both G102 and G141 coverage.

3.1.3. Grism Redshift Determination

Grism redshifts are determined by fitting the grism spectra and available multiwavelength photometry simultaneously. A basis set of template Flexible Population Synthesis models (FSPS; Conroy et al. 2009; Conroy & Gunn 2010) are projected to the pixel grid of the 2D grism exposures using the spatial morphology from the HST F105W image. The 2D template spectra are then fit to the observed spectra with non-negative least squares. When performing a redshift fit, the user provides a trial redshift range. For the CLEAR extraction, \(0 < z < 12\) was used. The final grism redshift is taken to be where the \(\chi^2\) is minimized across the grid of trial redshifts.

3.1.4. Making H\(\alpha\) Maps

As part of the grism redshift determination process (Section 3.1.3), a combination of line complex and continuum templates are used. Included in the line complex templates are [O II] + [Ne III], [O III] + H\(\beta\) and H\(\alpha\) + [S II]. The line complexes help to break redshift degeneracies. The full grism redshift determination process (Section 3.1.3) leads to a full line + continuum model for each 2D grism spectrum. The user is then able to create drizzled\(^3\) continuum-subtracted narrow-band maps at any wavelength. The H\(\alpha\) emission line map is created by deliberately choosing the wavelength at which it is detected in the G102 grism from the grism redshift determination process. This extraction uses the full World Coordinate System (WCS) information for each individual grism exposure of the source.

Emission line maps are generated by subtracting the best-fit stellar continuum model under the assumption that the F105W direct image represents the morphology of the source in the stellar continuum. For this work, we made H\(\alpha\) emission line maps covering 189 \(\times\) 189 pixels with a pixel scale of 0.1”. These dimensions were chosen such that 2.5 times the elliptical Kron radius (as was done in van der Wel et al. 2012) in F105W of the largest galaxy in the sample could be encompassed.

Due to the low spectral resolution of the G102 grism (see Section 2.1), H\(\alpha\) and [N II] are blended. The presence of [N II] in our H\(\alpha\) emission line maps serves only to increase the overall flux by approximately one tenth of the H\(\alpha\) flux (e.g. Faisst et al. 2018 and see Section 3.3.2). Our study focuses only on shape and morphology measurements of the H\(\alpha\) emission. Therefore the results in our study are unlikely to be effected by this blending.

3.2. Sample Selection

In this section we describe the sample selection for our study. A summary of the sample selection in the order it is applied can be viewed in Table 1. A selection of some galaxies in the final sample with their corresponding H\(\alpha\) emission line maps are shown in Figures 1 and 2 to illustrate the nature of our data.

Our sample is first selected to have F105W magnitude < 25 as the limiting magnitude of the Grizli data reduction process (Section 3.1.2). Within the sample of extracted grism spectra with Grizli, we find all the galaxies in the CLEAR fields with a H\(\alpha\) flux > 0 ergs s\(^{-1}\) cm\(^{-2}\) as detected by Grizli in their G102 spectrum. Then, given the rest-frame wavelength Grizli uses for the H\(\alpha\) line (6564.61Å), we ensure that the H\(\alpha\) line has been detected within the high-throughput wavelength range of the G102 grism (8000 < \(\lambda\) / Å < 11500, see Section 2.1), given the grism redshift determined for each galaxy (Section 3.1.3). This gives a sample of 613 galaxies in GOODS-N and 305 in GOODS-S.

3.2.1. Selecting Star-forming Galaxies

We then use the UVJ color separation from Williams et al. (2009) to select star-forming galaxies for the appropriate redshift range of our sample. We do this by interpolating between

---

\(^3\) Raw images from HST are distorted, and are therefore “drizzled” to some tangent point to create an undistorted image.

**Table 1. Summary of Sample Selection in order**

| Sample Selection Criteria |          |
|---------------------------|----------|
| F105W magnitude < 25      |          |
| H\(\alpha\) flux > 0 ergs s\(^{-1}\) cm\(^{-2}\) |          |
| 0.22 \(\leq\) z \(\leq\) 0.75 |          |
| Star-forming galaxies: \((U - V)_{\text{rest}} < 0.88 (V - J)_{\text{rest}} + 0.64\) |          |
| AGN detected from X-ray removed |          |
| Log(M\(\ast\)/M\(_{\odot}\)) \(\geq\) 8.96 |          |
| H\(\alpha\) stack SNR > 48 |          |
| All fields and GS4 sample separation (see Section 3.2.5) |          |
Figure 1. Zoomed-in regions (89 × 89 pixels, pixel scale = 0.1") of individual stellar continuum and Hα thumbnails for select galaxies in the CLEAR sample ordered by descending stellar mass. Original thumbnails are 189 × 189 pixels (see Section 3.1.4 for reasoning). Hα emission line maps are multiplied by 50 for visibility. The 3D-HST source ID for each galaxy is marked in the top right corner of each Hα thumbnail. GS = GOODS-S, GN = GOODS-N and see Section 3.2.5 for GS4 explanation. The stellar mass and grism redshift is stated in the bottom left corner of each F105W thumbnail.
Figure 2. Figure 1 continued
Figure 3. $UVJ$ color separation (solid black line) applied to our sample to select star-forming galaxies during the sample selection process. See Section 3.2.1 for details. Background contours show the full photometrically selected sample between $0.22 \lesssim z \lesssim 0.75$ and $\log(M_*/M_{\odot}) \geq 8.96$. Markers show all galaxies in CLEAR that pass the first 3 steps of sample selection (see Table 1) with stellar masses $\log(M_*/M_{\odot}) \geq 8.96$.

Figure 4. Grism redshift (left panel) and stellar mass (right panel) distributions for galaxies in the CLEAR sample used in this study. Full sample shows the galaxies that go into the stacks. Individual fits show the distributions for those galaxies that obtained good quality individual fits.
the $0.0 < z < 0.5$ and $0.5 < z < 1.0$ UVJ color separations provided in their Equation 4. The UVJ color separation we use to select star-forming galaxies is stated in the fourth row of Table 1 and is shown applied to our sample in Figure 3. This gives us a sample of 524 star-forming galaxies in GOODS-N and 258 in GOODS-S.

### 3.2.2. Quality check

We then quality check all 782 G102 grism spectra and the quality of the grism redshift fits by eye. This is done to ensure:

1. Successful subtraction of contamination from the grism data reduction process (Section 3.1.2) allowing for usable Hα emission line maps.
2. The grism redshift fit is not driven by poorly subtracted contamination, leading to the false identification of a Hα line.

After the quality check is applied, we are left with 399 star-forming galaxies in GOODS-N and 192 in GOODS-S with good quality Hα emission line maps (a contamination rate of 24%).

### 3.2.3. Removal of Active Galactic Nuclei (AGN)

Active Galactic Nuclei (AGN) detected from X-ray data (Luo et al. 2016; Xue et al. 2016) are then removed from the sample. 7 are removed from GOODS-N and 2 from GOODS-S. This leaves us a sample of 392 star-forming galaxies in GOODS-N and 190 in GOODS-S. A total of 582 star-forming galaxies.

### 3.2.4. Mass Completeness + Hα Signal-to-Noise Ratio (SNR) cut

For our sample of 582 star-forming galaxies, we perform both individual size determination fits and stacking analysis (Section 3.3). There is however an increasing trend in the Hα signal-to-noise ratio (SNR) with stellar mass. Therefore, the size determination process is more challenging for low-mass galaxies.

The median stellar mass of our sample is $\log(M_\ast/M_\odot) = 8.96$. Measurements from both individual fits and stacking analysis were the most unreliable for galaxies below this stellar mass. Therefore, the analysis in this paper focuses on star-forming galaxies with $\log(M_\ast/M_\odot) \geq 8.96$ that lead to Hα stacks of integrated SNR $> 48$. This amounts to a total of 279 star-forming galaxies and is referred to as the “full sample”. The distribution of this sample in grism redshifts and stellar mass can be seen in Figure 4. We will also show the size measurements for all our reliable individual fits with $\log(M_\ast/M_\odot) \geq 8.96$. The distribution for this sample is also shown in Figure 4. It can be seen that the stellar mass distribution for the individual fits is much flatter than the stellar mass distribution for the full sample owing to the challenge of fitting low mass galaxies.

### 3.2.5. All fields and GS4 Sample Separation

In preparation for the stacking analysis (see Section 3.3), the full sample (Figure 4) is separated into two groups. The first group, which we refer to as “all fields” contains galaxies in the full sample that have F105W imaging of similar depth. This includes all galaxies in GOODS-N and all but one CLEAR pointing in GOODS-S. The excluded GOODS-S pointing—which we will refer to as “GS4”– has much deeper F105W imaging due to its overlap with the Hubble Ultra Deep Field (HUDF) and therefore many archival programs which include F105W imaging. Because we weight galaxies by their inverse variance when stacking, galaxies in GS4 completely dominate the F105W stacks. Consequently, any measurements on the F105W stacks are not representative of the full sample, but of GS4 galaxies alone which represent only 1/12 of the full sample. We therefore group GS4 galaxies separately, but conduct identical analysis on both groups.

### 3.3. Stacking

Despite many of the CLEAR Hα emission line maps having deep, 12 orbit depth observations (Section 2.1) allowing for individual size measurements, the main analysis in this paper focuses on results obtained from a stacking analysis.

#### 3.3.1. Motivation for Stacking Analysis

Reliable individual size measurements cannot be obtained for all galaxies in the full sample. This is because some of these galaxies do not lie in the maximum depth region of the CLEAR footprint given the survey design (Section 2.1) and so have shallow Hα emission line maps. Furthermore, only high SNR Hα emission line maps would lead to reliable size measurements and these would naturally bias towards high mass galaxies due to the star formation rate – stellar mass relation (e.g. Whitaker et al. 2012). This likely leads to the Hα SNR relation with stellar mass in the sample (Section 3.2.4), which also leads to a bias towards high mass galaxies. This introduces strong biases on conclusions made from reliable individual measurements alone and are not representative conclusions for the full sample. Furthermore, as will be explained in Section 4, we assume a single component Sérsic profile in our size determination process. For very deep Hα emission line maps, this simple model can become inappropriate due to the clumpy nature of Hα morphologies. Therefore, it leads to unreliable size measurements.

By performing a stacking analysis, all galaxies in the full sample, regardless of their observational depth, stellar mass or...
Hα SNR are included. Additionally, stacking averages over the sample, smoothing out irregularities in Hα morphologies prominent in individual maps, allowing us to focus on where most of the Hα emission resides in typical star-forming galaxies. Thus, the Hα morphologies of the stacks are simplified, making the single component Sérsic profile an appropriate assumption.

Stacking also boosts SNR, allowing us to trace the Hα distribution out to larger radii than would be possible from individual measurements.

### 3.3.2. Stacking Procedure

Our stacking method closely follows that of 3D-HST (Section 2.2) presented in Nelson et al. (2016a), but is more streamlined due to the sophistication of Grizli. Drizzled F105W direct image thumbnails and Hα emission line maps of galaxies generated by Grizli in the grism data reduction process (Section 3.1) are stacked in bins of stellar mass. Stellar masses for all galaxies in the CLEAR survey (Section 2.1) are calculated using Eazy-py (EAZY; Brammer et al. 2008) from the wealth of ancillary multiwavelength photometry available. The “fsps_QSF_12_v3” Spectral Energy Distribution (SED) template created with FSPS (see Section 3.1.3) is used, assuming a Chabrier (2003) Initial Mass Function (IMF). Stellar mass bins in the “all fields” and GS4 samples are chosen to include approximately an equal number of galaxies.

Before stacking the F105W direct image thumbnails, we convert their units from counts s$^{-1}$ to $\times 10^{-17}$ ergs s$^{-1}$ cm$^{-2}$, which are the units the Hα emission line maps are in. This is done using the pivot wavelength of the F105W filter. Bad pixels are then masked in each F105W and Hα emission line map. Neighbouring sources to the galaxy of interest in the F105W thumbnails are masked using the Grizli-generated segmentation thumbnail from the SExtractor (Bertin & Arnouts 1996) segmentation map. The same mask is used on the corresponding Hα emission line map. We do not use the asymmetric double pacman mask devised in Nelson et al. (2016a) to mask [S II] emission and poorly subtracted stellar continuum in our analysis since Grizli provides an improved solution. More specifically, the flux of the [S II]$\lambda\lambda 6717, 6731$ doublet$^5$ as well as the flux for all other emission lines are determined directly from the grism spectrum and the 2D emission line models. The models are created with the assumption that the emission line maps have the same spatial morphology as the galaxy does in F105W.

---

$^5$ It is assumed these lines have a 1:1 line ratio.
Therefore the [S II] emission line map is subtracted before drizzling the Hα emission line map.

We do not correct the Hα flux to account for the effect of blending of Hα and [N II] as was done in Nelson et al. (2016a). This is due to the fact that the majority of our galaxies have low stellar masses (Median Log(M*/M☉) = 9.47), where [N II]/Hα is expected to be very small – specifically ~0.1 – at z ~ 0.5 (e.g. Faisst et al. 2018). Regardless, this re-scaling reduces the overall brightness of the Hα stack by some fixed value and so does not alter the shape of the Hα distribution. Consequently, it does not affect structural measurements tracing morphology and size, which are the focus of our study.

Grizli generates inverse variance maps for both F105W and emission line map thumbnails. These provide an estimate of the errors per pixel. We use these maps to weight each pixel and then add a further weighting by F105W flux density\(^6\) for each map. This second weighting ensures no single bright galaxy dominates a stack (Nelson et al. 2016a). The F105W direct image thumbnails and Hα emission line maps for each stack are summed and then exposure-corrected by dividing them by their corresponding summed weight stacks. For each stack, variance maps are therefore \(\sigma^2_{ij} = 1/\sum w_{ij}\), where \(w_{ij}\) is the weight map for each galaxy in the stack.

Analogous work to ours as part of the 3D-HST survey (Section 2.2) demonstrated that rotating and aligning the thumbnails along the measured semi-major axis of the galaxy before stacking did not change their results (Nelson et al. 2016a). Therefore, we do not rotate and align our thumbnails along the measured semi-major axis before stacking.

Our resulting stacks and associated fits from the size determination process (see Section 4.2) can be seen in Figure 5. The first column entry for each stack states (in order) the sub-sample the galaxies belong to (Section 3.2.5), the mean grism redshift of the stack, the stellar mass range of galaxies in the stack and the number of galaxies in the stack. As is apparent, residuals are negligible and a clear trend of increasing size with stellar mass can be seen by eye. For the first three stacks with the largest number statistics, we can see that both the stellar continuum and Hα emission have circular profiles. It is therefore most apparent when comparing their stacks and model fits by eye that the Hα emission is indeed more extended than the stellar continuum. We quantitatively confirm this in Section 6.2.

4. SIZE DETERMINATION

As briefly mentioned in Sections 3.2.4 and 3.3.1, size measurements are conducted on both individual thumbnails and stacks for both F105W and Hα. The analysis in this paper focuses on the measurements made from the stacking analysis, since these include all the galaxies in our full sample (Figure 4). Nevertheless, we show and discuss our size measurements for both individual thumbnails and stacks in Section 6.1. In this section, we will describe the size determination process for our individual measurements (Section 4.1) and our stacks (Section 4.2).

Both size determination processes use the two-GALFIT-run approach developed and used in Matharu et al. (2019). This approach uses GALFIT (Peng et al. 2002, 2010a) to fit 2D single-component Sérsic profiles to the thumbnails/stacks in two iterations and leads to a high level of agreement (see Figure 12 for level of agreement on individual F105W measurements in CLEAR and Matharu et al. 2019) with published size measurements for the stellar continuum from van der Wel et al. (2012). The Sérsic profile is defined as:

\[
I(r) = I(R_{\text{eff}}) \exp\left\{-\kappa \left(\frac{r}{R_{\text{eff}}}\right)^{1/n} - 1\right\}
\]  

where \(R_{\text{eff}}\) is the effective radius. This is the radius within which half of the galaxy’s total flux resides. \(n\) is the Sérsic index and \(\kappa\) is an \(n\)-dependent parameter to ensure that half of the total intensity is contained with \(R_{\text{eff}}\). \(I(R_{\text{eff}})\) is the intensity at the effective radius.

The first iteration of the two-GALFIT-run approach keeps all parameters free and obtains refined values for the shape parameters \((x, y\) coordinates, axis ratio and position angle) of the galaxy/stack. The second iteration fixes the values obtained for the shape parameters in the first iteration, keeping only \(R_{\text{eff}}, n\) and magnitude free. In this work, there are variations on how the two-GALFIT-run approach is implemented depending on if fitting is being conducted on direct image thumbnails or the fainter Hα emission line maps.

4.1. Size Determination for Individual fits

We run our size determination process on the F105W direct image thumbnails first, since the shape parameters determined provide more reliable initial values for the Hα emission line map size determination process.

4.1.1. Source Detection and Initial Parameter values

We use the SExtractor (Bertin & Arnouts 1996) F105W source detection results from the F105W GOODS-S and GOODS-N mosaics to obtain our initial values for F105W magnitude, axis ratio, position angle (PA) and \(R_{\text{eff}}\). Since Grizli centers all thumbnails according to their SExtractor determined centers in F105W, our initial \(x, y\) coordinates for each galaxy are pixel coordinates for the center of each thumbnail. For the Sérsic index, \(n\), we use an initial value of 2.5.

4.1.2. Point Spread Function (PSF)

The resolution limit of the WFC3 leads to image smearing. A PSF image can be included in every GALFIT fit to account

---

\(^6\) These are the F105W fluxes of the best-fit Grizli template.
for this. We use the Grizli generated drizzled F105W PSFs for each galaxy. These are generated using the Anderson (2016) WFC3/IR empirical PSF library. This library provides PSFs sampled on a 3 \times 3 grid at various positions across the WFC3 detector. Four sub-pixel center positions are available at each of these grid points. The relevant empirical PSF is placed at the exact location of the galaxy in the detector frame. This is done for each individual exposure the galaxy is detected in. The PSF model is then drizzled to the same pixel grid as the H\alpha emission line maps (Mowla et al. 2018).

4.1.3. Noise Image

To account for the noise at each pixel, a noise image – or $\sigma$ image in GALFIT nomenclature – can be included in every GALFIT fit. We use the Grizli generated drizzled F105W and H\alpha weight maps for each galaxy to create $\sigma$ images, where $\sigma = 1/\sqrt{\text{weight}}$.

4.1.4. Bad pixel mask

The drizzling process can sometimes lead to bad pixels with indefinite values. Not accounting for these pixels can prohibit GALFIT from converging to a solution other than the initial parameters provided. We account for these pixels by providing GALFIT with a bad pixel mask for each GALFIT fit.

4.1.5. Size measurements with GALFIT

We run GALFIT on the F105W direct image thumbnails keeping all the parameters free, including fitting for the sky background. We separate the resulting fits to those that are “successful” and those that are “asterisked”. Successful fits are those for which all the parameters converge to a solution. Asterisked fits are those for which there is a problem in the fitting of at least one parameter. The majority of the asterisked fits are due to problems in the fitting of the axis ratio. For this subset of problematic fits, we refit them keeping their $x$, $y$ and PA fixed, with all other parameters free. Those fits that converge in this run with no asterisks are added to the final sample of successful F105W fits.

For all the first-stage successful fits, we proceed with a second GALFIT run. This iteration takes the shape parameter $(x, y, \text{axis ratio} \text{ and PA})$ values determined in the first GALFIT run and keeps them fixed. The parameters left free are $R_{\text{eff}}$, $n$, magnitude and sky background. Those fits that converge in this run with no asterisks are added to the final sample of successful F105W fits.

All successful F105W fits are quality checked by eye, by the criteria listed below:

- Over-subtraction due to the GALFIT model being too extended.
- An obvious shape mismatch in the PA of the GALFIT model to the galaxy.

- An obvious shape mismatch (axis ratio, axis ratio + PA) of the GALFIT model to the galaxy.

All three of the above criteria lead to poor residuals. However, minor problems in one or two can allow for a usable fit. No problems in all three criteria define good quality fits. Unusable fits are those where there are significant problems in all three criteria. For our sample of 582 star-forming galaxies before mass completeness and H\alpha SNR cuts are applied, 497 have good quality F105W individual fits and 37 have usable F105W individual fits.

For the 534 galaxies with good quality and usable F105W individual size measurements, we proceed to make individual measurements on their corresponding H\alpha emission line maps. This size determination process is more challenging due to the low SNR of H\alpha emission relative to F105W. To mitigate this challenge, we make reasonable assumptions that allow us to reduce the number of parameters required to be fit for. We assume that the centroid and PA of the H\alpha spatial distribution is the same as the centroid and PA of the F105W spatial distribution. Support for this assumption can be seen in the KMOS3D survey (Section 2.3), where only 24\% of galaxies have H\alpha spatial distributions mis-aligned from their stellar continuum spatial distributions by more than 30\% (Wisnioski et al. 2019).

The initial GALFIT run on the H\alpha emission line maps therefore keeps $x$, $y$ and PA fixed to values determined from the F105W size determination process. Magnitude, axis ratio, $R_{\text{eff}}$ and $n$ are set to the same initial values used for the first GALFIT run on the F105W thumbnails (Section 4.1.1). Resulting fits are separated into “successful” and “asterisked” categories just like in the first iteration of the F105W size determination process. H\alpha emission line maps that make the successful fits category then undergo a second GALFIT run which fixes the axis ratio to the value determined in the first GALFIT run. Those fits that converge with no asterisks make the final sample of successful H\alpha fits. These successful fits are then quality checked by eye using the same criteria listed above that was used on the individual F105W measurements. 164 galaxies obtained good quality H\alpha individual fits and 86 obtained usable H\alpha individual fits. In total, there are 152 galaxies with both good quality F105W and H\alpha fits and 250 with both good quality and usable F105W and H\alpha fits. Applying the mass completeness and H\alpha stack SNR cuts (Section 3.2.4) to the good quality fits alone gives 97 galaxies with reliable F105W and H\alpha individual fits.

Using the angular diameter distance to each galaxy calculated using its grim redshift, we convert the determined GALFIT $R_{\text{eff}}$ from pixels to kiloparsecs. These individual measurements are shown as small red circular (F105W) and blue star (H\alpha) markers in the top row of Figure 6. These results are discussed further in Section 6.1.
4.2. Size determination for the Stacks

After we complete the stacking process for the full sample (Section 3.3), we generate the relevant files that will allow us to conduct our size determination process on the stacks directly. In this section, we describe the generation of these files and the size determination process specific to the stacking analysis.

4.2.1. PSF construction

To create PSFs for each stack, we use the Grizli generated drizzled F105W PSFs for each galaxy in the stack that are explained in Section 4.1.2. A mask is created for each PSF indicating which pixels have non-zero, finite values. The PSFs for each stack are summed and then divided by the sum of the masks for that stack. The F105W PSF stack is used on both the F105W and Hα stack for each stellar mass bin.

Note that our method for generating a PSF for each stack improves upon the method used by 3D-HST. In Nelson et al. (2016a), a single PSF modelled using the TinyTim software (Krist 1995) was used in the size determination process. As explained in Section 4.1.2, the PSFs we use account for variations in the PSF across the detector frame. Stacking these PSFs for each galaxy better captures the true PSF for that particular stack.

4.2.2. Noise estimation

During the stacking procedure (Section 3.3.2), weight maps are also stacked and used to weight the pixels in each stack. These weight maps are inverse variance maps, and so can be used to generate a σ image for each stack. We simply take the summed weight maps for each F105W and Hα stack, and calculate the σ image for the stacks, where
\[ \sigma_{\text{stack}} = \frac{1}{\sqrt{\text{weight}_{\text{stack}}}}. \]

4.2.3. Initial Parameter values

As was the case for the individual fits (Section 4.1.1), initial values for magnitude, axis ratio, \( R_{\text{eff}} \) and PA for each stack are obtained from the SExtractor GOODS-S and GOODS-N F105W source detection results. For each F105W stack and its corresponding Hα stack, we use the mean value calculated from the individual values for each galaxy in F105W. The initial value for \( n \) is set to 2.5 and the sky background is kept free throughout the fitting process, as was the case for the individual fits.

4.2.4. Size measurements with GALFIT

As was the case in the individual fits, we run GALFIT on the F105W stacks first, keeping all the parameters free (Section 4.1.5). The purpose of this run is to obtain refined shape parameters (\( x, y, \) axis ratio and PA), some of which can be used as initial values on the corresponding fainter, lower SNR Hα stacks. We quality check all fits by eye. For those that fail the same quality check criteria described in Section 4.1.5, did not converge to a solution, or had problems with the fitting of a parameter, we rerun the fit keeping \( R_{\text{eff}} \) and \( n \) fixed to their initial values (Section 4.2.3). Fixing parameters which we are unconcerned about in the fit is a recommended strategy when GALFIT is struggling to converge.

After the refined shape parameters are determined from the first GALFIT run, we set up a second GALFIT run that fixes the shape parameters (\( x, y, \) axis ratio and PA) to those determined in the first GALFIT iteration. All these fits converge to a solution that also pass the quality check criteria described in Section 4.1.5. The F105W stacks and their final GALFIT fits can be seen in Figure 5.

As in the size determination process for individual fits (Section 4.1.5), we take the values determined for \( x, y, \) and PA for the F105W stacks and use them as initial fixed values for the corresponding Hα stack (see Section 4.1.5 for reasoning). All our fits converge to solutions and pass the quality check criteria outlined in Section 4.1.5. The second GALFIT run on the Hα stacks takes the axis ratio determined in the first run and keeps it fixed, leaving \( R_{\text{eff}}, n, \) magnitude and the sky background free parameters to be determined. All fits converge to sensible solutions and pass the quality check criteria described in Section 4.1.5. The Hα stacks and their final GALFIT fits can be seen in Figure 5.

5. MORPHOLOGY PARAMETERS

Part of our analysis explores different morphology parameters for the stellar continuum and Hα spatial distributions. In this section, we describe how these parameters are calculated.

All parameters calculate the stellar mass surface density within a particular radius, assuming that the mass profile follows the light profile of the galaxy and that the light profile follows a Sérsic profile (Equation 1).

5.1. The Stellar Mass Surface Density within the Effective Radius, \( \Sigma_{\text{eff}} \)

\( \Sigma_{\text{eff}} \) is the stellar mass surface density within the effective radius, \( R_{\text{eff}} \) (Barro et al. 2017). \( R_{\text{eff}} \) is defined in Section 4.

\[ \Sigma_{\text{eff}} = \frac{0.5 M_\ast}{\pi R_{\text{eff}}^2} \]

where \( M_\ast \) is the stellar mass.

5.2. The Stellar Mass Surface Density within 1 kpc, \( \Sigma_{1\text{kpc}} \)

\( \Sigma_{1\text{kpc}} \) is the stellar mass surface density within a radius of one kiloparsec (Cheung et al. 2012; Barro et al. 2017).

\[ \Sigma_{1\text{kpc}} = \frac{M_\ast \gamma (2n, b_n R_{\text{eff}}^{-1/n})}{\pi} \]

where \( M_\ast \) is the stellar mass, \( n \) is the Sérsic index, \( b_n \) satisfies the inverse to the lower incomplete gamma function,
The regularized lower incomplete gamma function \( \gamma(2n, b_n) \) is given by:

\[
\gamma(2n, 0.5) = \frac{1}{\Gamma(2n)} \int_0^{0.5} t^{2n-1} e^{-t} dt
\]

where \( \Gamma \) is the Gamma function. \( \gamma(2n, b_n R_{\text{eff}}^{1/n}) \) therefore takes the same form as Equation 4.

5.3. The Stellar Mass Surface Density within radius \( r \), \( \Sigma_r \)

The stellar mass surface density can also be calculated within an arbitrary radius, \( r \). First we define \( x = b_n (r/R_{\text{eff}})^{1/n} \) where \( b_n \) is defined in Section 5.2 and \( n \) is the Sérsic index. Then the stellar mass surface density within an arbitrary radius, \( \Sigma_r \), is:

\[
\Sigma_r = \frac{M_\ast \gamma(2n,x)}{\pi}
\]

where \( \gamma \) is the regularized lower incomplete gamma function, the form of which is given in Equation 4.

6. RESULTS

In this section we discuss the results from our size measurements of the CLEAR dataset (Sections 6.1 and 6.2) and compare them to analogous results obtained from the 3D-HST and KMOS3D surveys at \( z \sim 1 \) and \( z \sim 1.7 \) (Section 6.3). In Section 6.4, we discuss the advantages of using \( \Sigma_{1kpc} \) (Section 5.2) over other morphology parameters.

6.1. The H\( \alpha \) vs. Stellar Continuum Mass–Size Relation at \( z \sim 0.5 \)

The top row of Figure 6 shows the stellar continuum (F105W) and H\( \alpha \) stellar mass–size relations for CLEAR. Red circles show stellar continuum measurements and blue stars show H\( \alpha \) measurements. Large markers show measurements from stacks (Section 4.2) whilst small markers show individual measurements (Section 4.1). The grey shaded regions in the background delineate the stellar mass bins for each stack. The numbers at the bottom of each region state how many galaxies are in each stack, with the numbers in brackets stating the numbers of individual measurements in that stellar mass bin.

The \( z = 0.25 \) and \( z = 0.75 \) stellar mass–size relations for late-type galaxies at a rest-frame wavelength of 5000Å from van der Wel et al. (2014) are shown as red lines with the area between them shaded red. In general, our measurements agree well with the mass–size relations derived from individual measurements in van der Wel et al. (2014) for the appropriate redshift of the CLEAR dataset. Because the measurements in van der Wel et al. (2014) are made at a rest-frame wavelength of 5000Å, we show the agreement between our F105W individual measurements and those of van der Wel et al. (2012) for the same galaxies in Figure 12 of the Appendix. No significant systematic offset between the two size determination methods exists: the mean value of our size measurements are smaller than those of van der Wel et al. (2012) by 0.4%.

From the measurements on the stacks it can already be seen by eye that the H\( \alpha \) effective radii are on average larger than those of the stellar continuum at fixed stellar mass. This is most apparent in the stacks for the “All fields (excluding GS4)” sample (left panel in Figure 6). The bottom row of Figure 6 shows this trend more explicitly in both individual and stack measurements, where the ratio of the effective radius in H\( \alpha \) and the continuum is shown. Error bars on the stack measurements are calculated by jackknife re-sampling the stacks and conducting the stack size determination process (Section 4.2) on the jackknife re-sampled stacks.

On average, the H\( \alpha \) effective radius is a factor \( 1.2 \pm 0.1 \) larger than the stellar continuum effective radius for the full sample. This could be construed as evidence that star-forming galaxies at \( z \sim 0.5 \) are growing in an inside-out fashion via star formation, where the short-lived O- and B-type stars tend to reside at larger galactocentric radii than the longer-lived later-type stars (we discuss this further in Section 7). However, this result is driven by the Log(\( M_\ast / M_\odot \)) \( \sim 9.5 \) stack measurement, which is higher than at any other mass albeit similar to a few measurements of individual systems. In Section 6.2, we explore whether this measurement is driven by peculiarities in the morphology of Log(\( M_\ast / M_\odot \)) \( \sim 9.5 \) star-forming galaxies at \( z \sim 0.5 \) compared to star-forming galaxies of other stellar masses.

6.2. The Morphologies of the CLEAR H\( \alpha \) and Stellar Continuum Stacks

To analyse the shape of the stellar continuum and H\( \alpha \) spatial distributions for CLEAR, we measure the surface brightness profiles of the stacks and their GALFIT models. We use the Python package MAGPIE\(^7\) to calculate all surface brightness profiles. This software has the advantages of taking into account the surface area of each pixel included within each concentric circular aperture (i.e. including fractional pixels near the edge of each aperture) and allows us to incorporate our \( \sigma \) images (Section 4.2.2) to appropriately calculate errors on the surface brightness profiles.

Figure 7 shows the normalized surface brightness profiles for the stellar continuum (red circles) and H\( \alpha \) (blue stars) stacks. The thick solid red and blue lines show the normalized surface brightness profiles of the associated GALFIT models. 2D profiles of these can be seen in Figure 5. The grey line shows the surface brightness profile of the PSF (Section 4.2.1). The Sérsic index and Log(\( \Sigma_{1kpc} \)) of each GALFIT model is stated in the top right-hand corner of each panel. The effective

\(^7\) https://github.com/knaido029/magpie/
radii for both the stellar continuum and Hα measured by GAlFIT are marked with short vertical lines.

Out to approximately 10 kiloparsecs (1.5″ at z = 0.57), the shapes of the surface brightness profiles for both the stellar continuum and Hα stacks are captured well by GAlFIT. The good agreement between model and data in all panels indicates that the size measurements are reliable for all mass bins. Furthermore, all surface brightness profiles are spatially resolved, since the PSF surface brightness profiles represent the resolution limit. By eye, it can be seen that the stellar continuum profiles are always steeper and therefore more compact than the Hα profiles. This supports the more extended Hα effective radii we measure and discuss in Section 6.1.

Sérsic index, $n$, is often used as a proxy for morphology (e.g. Ravindranath et al. 2004; Bell 2008; Blanton & Moustakas 2009; Bell et al. 2012; Papovich et al. 2015). However, it is somewhat unreliable due to its degeneracy with the effective radius. This degeneracy means Sérsic index and effective radius are highly covariant (e.g. Ji et al. 2020, 2021). We see an example of this issue in the second panel of Figure 7. For all other stellar mass bins, the Sérsic index for the Hα profiles is smaller than for the stellar continuum profiles ($n(\text{H}\alpha) < n(\text{Cont})$), supporting the case for more extended Hα reflected sizes.
by the larger Hα effective radii measurements discussed in Section 6.1. This trend breaks down for the stellar mass bin within which we see particularly large Hα effective radii measurements. \( n(Hα) > n(\text{Cont}) \), even though we can see by eye that overall the Hα surface brightness profile is more extended than the stellar continuum surface brightness profile.

One way to remove the degeneracy between \( n \) and \( R_{\text{eff}} \) is to combine them into one morphology parameter. An example of such a parameter is the stellar mass surface density within 1 kiloparsec, \( \Sigma_{1\text{kpc}} \), described in Section 5.2 (Cheung et al. 2012; Barro et al. 2017; Estrada-Carpenter et al. 2020). When \( \Sigma_{1\text{kpc}} \) is calculated at a particular wavelength, it indicates what the stellar mass surface density within 1 kpc would be if the stellar mass were traced by the flux at that wavelength. Comparing \( \Sigma_{1\text{kpc}} \) calculated at two different wavelengths is equivalent to comparing the fraction of total light emitted within 1 kpc at those two wavelengths. We calculate \( \Sigma_{1\text{kpc}} \) for all our stacks and state the values for \( \log(\Sigma_{1\text{kpc}}) \) under those of the Sérsic indices in each panel of Figure 7. Larger values of \( \Sigma_{1\text{kpc}} \) indicate a higher degree of compactness within a radius of 1 kpc. We can see that the Hα and stellar continuum trends in \( \log(\Sigma_{1\text{kpc}}) \) better reflect the relative shape of the Hα and stellar continuum surface brightness profiles. In every case, the stellar continuum is more compact than Hα within 1 kpc. This result quantitatively confirms the initial impression from Figure 5 that the Hα emission is more extended than the stellar continuum. In Section 6.4, we discuss the advantages of \( \Sigma_{1\text{kpc}} \) as a morphology parameter and advocate for its use in similar future studies.

In the next Section, we will compare our measurements with CLEAR at \( z \sim 0.5 \) to those of 3D-HST at \( z \sim 1 \) and KMOS\textsuperscript{3D} at \( z \sim 1.7 \) to study the evolution of spatially resolved star formation in star-forming galaxies over a wide range in redshift.

### 6.3. The Evolution of Spatially Resolved Star Formation in Star-forming Galaxies between 0.5 < \( z \) < 1.7

Including CLEAR, there are now a few studies on spatially resolved star formation of \( z > 0 \) star-forming galaxies using Hα emission line maps (Nelson et al. 2016a; Tacchella et al. 2015a; Wilman et al. 2020). The redshift ranges of these studies make it possible to study the evolution of spatially resolved star formation in star-forming galaxies over a wide range in redshift for the first time.

Figure 8 compares the results from CLEAR (\( z \sim 0.5 \), this work) to the results of 3D-HST (\( z \sim 1 \), Nelson et al. 2016a) and KMOS\textsuperscript{3D} (\( z \sim 1.7 \), Wilman et al. 2020). For each of these studies, we compare the effective radii \( (R_{\text{eff}}) \), stellar mass surface densities within the effective radius \( (\Sigma_{\text{eff}}, \text{Section 5.1}) \) and within 1 kpc \( (\Sigma_{1\text{kpc}}, \text{Section 5.2}) \) derived for the Hα emission line maps and the stellar continuum.

| Hα/Continuum ratio | CLEAR | 3D-HST | KMOS\textsuperscript{3D} |
|--------------------|-------|--------|--------------------------|
| \( z \sim 0.5 \)    | 1.18 ± 0.08 | 1.16 ± 0.12 | 1.29\textsuperscript{0.92}\textsuperscript{0.29} |
| \( z \sim 1 \)      | 0.81 ± 0.15 | 0.79 ± 0.13 | 1.00\textsuperscript{0.89}\textsuperscript{0.03} |
| \( z \sim 1.7 \)    | 0.77 ± 0.14 | 0.80 ± 0.17 | 0.84\textsuperscript{1.80}\textsuperscript{0.69} |
It is worth comparing the properties of the galaxy samples and data quality between CLEAR, 3D-HST, and KMOS\textsuperscript{3D}. CLEAR (Section 2.1) and 3D-HST (Section 2.2) are the most similar in terms of the type of dataset and methodology. Both use data from the same telescope (HST) and instrument (WFC3) and use the same technique of grism spectroscopy. The only difference is the wavelength range and depth of the imaging (F105W vs F140W) and spectroscopy (G102 vs G141). The CLEAR work follows the same methodology as 3D-HST, but deviates in places where \textsc{Grizli} provides improved solutions. The stellar mass distribution of the galaxies in both samples is similar (Top panel of Figure 8).

KMOS\textsuperscript{3D} (Section 2.3) on the other hand uses H\alpha emission line maps obtained from ground-based IFU observations with KMOS on the VLT. These have coarser spatial resolution compared to emission line maps obtained from ground-based IFU observations with KMOS on the VLT. These have coarser spatial resolution (see Section 2.3) compared to emission line maps obtained from ground-based IFU observations with KMOS on the VLT. The only difference is the wavelength range and depth of the imaging (F105W vs F140W) and spectroscopy (G102 vs G141). The CLEAR work follows the same methodology as 3D-HST, but deviates in places where \textsc{Grizli} provides improved solutions. The stellar mass distribution of the galaxies in both samples is similar (Top panel of Figure 8). KMOS\textsuperscript{3D} is not used for the size determination process and it is assumed that the H\alpha emission follows a pure exponential profile ($n = 1$). Nevertheless, Wilman et al. (2020) demonstrate the high level of agreement between their size determination method and that of van der Wel et al. (2014) for the same set of galaxies in their stellar continuum (HST WFC3 F160W). Furthermore, CLEAR and 3D-HST use the stacking technique in bins of stellar mass where as the KMOS\textsuperscript{3D} measurements are made on individual galaxies. The stellar mass distribution of the KMOS\textsuperscript{3D} sample is the most different to that of CLEAR and 3D-HST, as it is skewed to higher stellar masses (Top panel of Figure 8). The median stellar masses in Log($M_*/M_\odot$) for the CLEAR, 3D-HST and KMOS\textsuperscript{3D} samples are 9.47, 9.62 and 10.22 respectively.

### 6.3.1. Results using the Effective Radius, \(R_{\text{eff}}\)

In the second panel of Figure 8, we show the ratio of the H\alpha $R_{\text{eff}}$ to that of the stellar continuum $R_{\text{eff}}$ for all three datasets. We see that especially for 3D-HST, there is a trend that the H\alpha sizes are larger than the stellar continuum sizes for galaxies at higher mass. This trend is apparent, but weaker for CLEAR. More quantitatively, the linear fit to the CLEAR measurements also indicates a positive trend but with a lower level of significance than the linear fit to the 3D-HST measurements. This can be seen explicitly in Table 3. The KMOS\textsuperscript{3D} measurements however do not exhibit this trend. On average, all three data sets agree within 1\sigma of each other. This is shown explicitly in the first row of Table 2, where we state the mean $R_{\text{eff,H}\alpha/R_{\text{eff,Cont}}}$ for each data set and their errors.

#### 6.3.2. Results using the Surface Density within the Effective Radius, \(\Sigma_{\text{eff}}\)

The third panel of Figure 8 shows the ratio of the H\alpha $\Sigma_{\text{eff}}$ (Section 5.1) to that of the stellar continuum $\Sigma_{\text{eff}}$ for all three datasets. As was the case for the trends in $R_{\text{eff}}$ (Section 6.3.1), high mass galaxies are more extended in H\alpha than their stellar continuum in both CLEAR and 3D-HST. The trend is stronger over the stellar mass range of 3D-HST. Once again we provide the linear fits shown for both datasets in Table 3. The KMOS\textsuperscript{3D} measurements however do not exhibit a significant trend, having a $\Sigma_{\text{eff,H}\alpha/\Sigma_{\text{eff,Cont}}}$ that is consistent with unity over the stellar mass range probed (see also Table 2), especially in the region where the stellar mass distribution is well sampled.

#### 6.3.3. Results using the Surface Density within 1 kpc, \(\Sigma_{1\text{kpc}}\)

In Section 6.2, we explained how the effective radius is degenerate with the Sérsic index. This contributes to the scatter between stellar mass versus the effective radius and $\Sigma_{\text{eff}}$ in the second and third panels of Figure 8. $\Sigma_{1\text{kpc}}$ however does not suffer from this degeneracy because it combines the two degenerate morphology parameters into a single one (see Section 5.2). We therefore present our measurements for $\Sigma_{1\text{kpc}}$ for all three datasets and compare them to our $R_{\text{eff}}$ and $\Sigma_{\text{eff}}$ measurements in Figure 8.

In the bottom panel of Figure 8, we show the ratio of the H\alpha $\Sigma_{1\text{kpc}}$ to that of the stellar continuum $\Sigma_{1\text{kpc}}$ for all three datasets (CLEAR, 3D-HST, and KMOS\textsuperscript{3D}). Using this morphology parameter we see a clear (pun not intended) negative trend in all three datasets. More massive galaxies at all redshifts have lower H\alpha surface densities compared to their stellar continuum. We discuss this result along with its physical implications in more detail in Section 7. More importantly, the linear trends found for both the CLEAR and 3D-HST measurements are much tighter than those calculated for $R_{\text{eff}}$ and $\Sigma_{\text{eff}}$. This can be seen in the high significance of the gradient and intercepts determined in Table 3. The high significance of the $\Sigma_{1\text{kpc,H}\alpha/\Sigma_{1\text{kpc,Cont}}}$–stellar mass relations at $z \sim 0.5$ and $z \sim 1$ as well as the apparent non-evolving slope unveil a
Figure 8. Evolution of Hα to stellar continuum morphologies for star-forming galaxies between 0.5 \( \lesssim z \lesssim 1.7 \). Top panel: Stellar mass distributions for the different datasets. Ratio of the Hα to stellar continuum effective radius \( R_{\text{eff}, \text{H}} \) (second panel), surface density within the effective radius \( \Sigma_{\text{eff}} \) (third panel) and surface density within 1 kiloparsec \( \Sigma_{1kpc} \) (bottom panel) for CLEAR \((z \sim 0.5)\), 3D-HST \((z \sim 1)\) and KMOS\(^{3D}\) \((z \sim 1.7)\) star-forming galaxies. KMOS\(^{3D}\) results are plotted as running means from individual measurements. Over the stellar mass range shown, the Hα to stellar continuum \( R_{\text{eff}} \), \( \Sigma_{\text{eff}} \) and \( \Sigma_{1kpc} \) are on average the same between \( 0.5 \lesssim z \lesssim 1.7 \) within 1\( \sigma \) (see Table 2). Trends of larger/more extended Hα than stellar continuum for higher mass galaxies at fixed redshift and larger/more extended Hα for \( z \sim 0.5 \) galaxies at fixed stellar mass are apparent for all three morphology parameters, but are stronger in \( \Sigma_{1kpc} \). Between \( 0.5 \lesssim z \lesssim 1 \), the slope of the \( \Sigma_{1kpc, \text{H}}/\Sigma_{1kpc, \text{Cont}} \)--stellar mass relation is constant, but the intercept increases by a factor of 1.07 (see Table 3) between \( z \sim 0.5 \) and \( z \sim 1 \) (bottom panel). At \( \log(M_*/M_\odot) = 9.5 \), star-forming galaxies at \( z \sim 0.5 \) have a \((19 \pm 2)\% \) lower surface density in Hα compared to the stellar continuum than \( z \sim 1 \) star-forming galaxies within a galactocentric radius of 1 kiloparsec.

6.4. The Advantages of \( \Sigma_{1kpc} \) as a Morphology Parameter

In general, the stellar mass surface density within some arbitrary radius, \( \Sigma_r \) — whether that radius be one kiloparsec or not — is a more reliable morphology parameter to use than \( n, R_{\text{eff}} \) or even \( \Sigma_{\text{eff}} \). This is because it breaks the parameter degeneracy between \( n \) and \( R_{\text{eff}} \) discussed in Section 6.2. \( n, R_{\text{eff}} \) and any parameter that is calculated using either \( n \) or \( R_{\text{eff}} \) (such as \( \Sigma_{\text{eff}} \)), is effected by this degeneracy. This parameter degeneracy increases scatter in \( n \) and \( R_{\text{eff}} \) measurements, rendering some measurements unreliable. An example of this issue can be seen in Figure 8, where the particularly large Hα \( R_{\text{eff}} \) measurements at \( \log(M_*/M_\odot) \sim 9.5 \) in CLEAR (Figure 6) can be seen in both \( R_{\text{eff}} \) and \( \Sigma_{\text{eff}} \) measurements, but not in \( \Sigma_{1kpc} \) measurements. It can also be seen that the level of scatter at fixed stellar mass in \( \Sigma_{1kpc} \) is far lower than in \( R_{\text{eff}} \) and \( \Sigma_{\text{eff}} \) (see also Cheung et al. 2012; Fang et al. 2013; van Dokkum et al. 2014; Tacchella et al. 2015b; Woo et al. 2015; Whitaker et al. 2017; Barro et al. 2017). The least-squares linear fits for CLEAR and 3D-HST go through all the points and more quantitatively, the derived gradient and intercept values have higher significance (Table 3) than the trends measured from \( R_{\text{eff}} \) and \( \Sigma_{\text{eff}} \) measurements.

Because \( \Sigma_r \) mitigates the \( n-R_{\text{eff}} \) parameter degeneracy, there is no apparent reason as to why \( r = 1kpc \) should be preferred to any other radius. In Figure 9, we explore this using \( \Sigma_r \) measured at different radii, \( r = 1.0 \) to 5.0 kpc (where 5 kpc is approximately the maximum value of the effective radii measured for the galaxies in all three datasets). The strongest trends in \( \Sigma_r \) with stellar mass are apparent for lower values of \( r \), with \( \Sigma_{1kpc} \) exhibiting the strongest trend.

Interestingly, in all three datasets, \( \Sigma_r \) behaves somewhat differently at \( \log(M_*/M_\odot) = 9.5 \). \( \Sigma_{1kpc} \) has the highest or higher Hα surface density compared to \( \Sigma_{r > 1kpc} \). This may be indicative of central starburst activity, which is prevalent for star-forming galaxies toward low stellar masses (Fumagalli et al. 2012; Khostovan et al. 2021). \( \Sigma_r \) towards larger \( r \) asymptotes towards the trends we see in \( \Sigma_{\text{eff}} \) (third panel, Figure 8). There are a few reasons that can explain this, which we discuss in the sections that follow.
Regarding $\Sigma_r$, there are two effects that act at larger radii and render $\Sigma_r$ less reliable for studies like that in this work. The first is that the stellar continuum and H\textalpha light profiles are more uncertain at larger radii. This can be seen in Figure 7, where the error bars on surface brightness of the H\textalpha emission in the stacked sample increase substantially at larger radii. As we calculate $\Sigma_r$ for $r$ at larger radii, we are increasingly including low SNR regions of the light profile, introducing more uncertainty in our $\Sigma_r$ measurement. Any $\Sigma_r$ trends with stellar mass become increasingly washed out towards larger radii. Tilvi et al. (2013) showed that the SNR within an aperture reaches a maximum at approximately 0.69×FWHM. The CLEAR, 3D-HST and KMOS$^3$D data have spatial resolutions with FWHMs $\sim$ 0.128″, 0.141″ and 0.456″ respectively (see Sections 2.1, 2.2 & 2.3). The aperture within which the SNR is maximum for sources in these surveys are then 0.09″, 0.1″ and 0.3″. At the respective redshifts of these surveys, this is equal to 0.6 kpc, 0.8 kpc and 2.6 kpc. It is therefore unsurprising that $\Sigma_{1\text{kpc}}$ which encompasses or is measured well within these radii exhibits the strongest trends with stellar mass in Figure 9.

The second effect is that the ratio of the H\textalpha to stellar continuum stellar mass surface density within various galactocentric radii, $\Sigma_r$, $r = 5$ kpc represents the approximate maximum effective radius measured in the three datasets. $\Sigma_{1\text{kpc}}$ (dark purple lines) exhibits the strongest trend with stellar mass for all three datasets. $\Sigma_r$ at smaller galactocentric radii are more reliable since they probe the highest signal-to-noise-ratio and therefore most well-determined parts of the stellar continuum and H\textalpha light profiles (see Figure 7 and Section 6.4 for more details).

## 6.4.1. Unreliability of $\Sigma_r$ at large radii

Both effects discussed above advocate for choosing a smaller value of $r$ when using $\Sigma_r$. This improves the ability of this quantity to reveal trends that are otherwise washed out at large radii.

### 7. DISCUSSION

The main result of this paper is that star-forming galaxies at lower redshifts have lower H\textalpha-to-stellar continuum surface densities within 1 kpc, but similar H\textalpha-to-stellar continuum effective radii to their high redshift counterparts. This is an intriguing result, for which there are multiple physical explanations. To help rule out some of these physical explanations, we perform a comparison of our observational results to similar, albeit not identical, measurements made to galaxies in the cosmological hydrodynamical simulation TNG50 (Pillepich et al. 2019; Nelson et al. 2019), of the IlustrisTNG project. Pillepich et al. (2019) studied the stellar and H\textalpha disks of thousands of star-forming galaxies in the TNG50 simulation between 0 $\lesssim z \lesssim$ 6. Their measurements provide us with the opportunity to attempt a direct comparison between observational and simulated data.

#### 7.1. Sizes and comparable galaxy samples from TNG50

To ensure as direct a comparison as possible with simulations, it is imperative that we ensure both observables and sample selection are as unbiased as possible.

In the case of observables, we use stellar mass and star formation rate (SFR) measurements from the TNG50 results that

Table 4. Least-Squares linear fits to the Log($R_{\text{eff}}$)- and Log($\Sigma_{1\text{kpc}}$)- stellar mass relations for the stellar continuum and Hα shown in Figure 10.

|                | CLEAR          | 3D-HST         |
|----------------|----------------|----------------|
|                | 0.22 $\lesssim$ $z$ $\lesssim$ 0.75 | 0.7 $< z < 1.5$ | |
|                | Median Log($M_*/M_\odot$) = 9.47 | Median Log($M_*/M_\odot$) = 9.62 | |
| Log($R_{\text{eff}}$) | Gradient | Intercept | Gradient | Intercept |
| Cont            | 0.19186 $\pm$ 0.00005 | $-1.4272 \pm 0.0004$ | 0.1936 $\pm$ 0.0001 | $-1.538 \pm 0.001$ |
| Hα              | 0.32 $\pm$ 0.02 | $-2.6 \pm 0.2$ | 0.233 $\pm$ 0.006 | $-1.89 \pm 0.06$ |
| Log($\Sigma_{1\text{kpc}}$) | Cont | Gradient | Intercept | Gradient | Intercept |
| Hα              | 0.7966 $\pm$ 0.0001 | 0.726 $\pm$ 0.009 | 0.7824 $\pm$ 0.0002 | 0.98 $\pm$ 0.02 |
are comparable to the analogous quantities measured from our observations. However, we do not undertake a true forward modeling of the observational quantities. Instead, following Pillepich et al. (2019), we use the stellar mass within 30 kiloparsecs from the galaxy centre as our comparable stellar mass. From our observations, we derive SFRs from our grism Hα emission line measurements, corrected for dust and [N II] contribution. Hα emission traces young stars with lifetimes of approximately 10 Myr (Kennicutt, Jr. 1998). Therefore in TNG50, we choose to compare to the SFR averaged over the last 10 Myr measured within 30 kiloparsecs from the galaxy centre. We compare our stellar continuum effective radii to the half-light radii in the V band measurements made on face-on 2D projections of TNG50 galaxies. Our Hα effective radii are compared to the half-light radii measurements made on face-on 2D projections of Hα emission for the same TNG50 galaxies. The size estimates from TNG50 are all circularized; moreover, they represent the intrinsic extents of the simulated galaxies, as the effects of dust are not accounted for.

Next, to ensure our samples of TNG50 galaxies are as directly comparable to our observational samples as possible, we select samples of TNG50 star-forming galaxies at z = 0.5 and z = 1 that have the same stellar mass and SFR distributions as the star-forming galaxies in our CLEAR and 3D-HST samples respectively. We do this by performing two-dimensional kernel density estimation, assigning probabilities to TNG50 star-forming galaxies based on how well they follow the observed stellar mass and SFR distributions for their respective redshifts. We draw 1000 samples each containing 100 galaxies that match the stellar mass and SFR distributions of our CLEAR sample from the z = 0.5 TNG50 snapshot and do the same for the z = 1 snapshot with respect to the 3D-HST stellar mass and SFR distributions.

7.2. Results on the comparison to Simulations

Figure 10 shows our observational and TNG50 measurements separated by stellar continuum and Hα in the left panel to help disentangle where most of the redshift evolution occurs. The TNG50 results are binned using the same bins as those used for the observations. Means are calculated for each bin, as we posit that the mean is the statistic most closely related to what the observational stack measurements represent. The shaded regions show these means and 1σ standard deviation from measurements made for the 1000 samples (see Section 7.1). The thick solid lines in the first and third rows of the left panel are least-squares fits to the observational measurements, details for which are given in Table 4. Second and fourth rows show Log(R_{eff,CLEAR}) - Log(R_{eff,3D-HST}) and Log(Σ_{1kpc,CLEAR}) - Log(Σ_{1kpc,3D-HST}) in green over the same stellar mass range using the linear fits respectively. The solid line shows the stellar mass range over which there are measurements from both surveys and the dashed lines extrapolations. The blue line is the same, but for TNG50. The numbers stated in these plots are the least-squares measured slopes of the solid lines.

The most striking result when looking at the observational results by eye is that the majority of the redshift evolution is in Hα, not the stellar continuum. This is seen in the larger y-separation between the CLEAR and 3D-HST linear fits in the first and third row of the second column compared to the first column. We can see this more quantitatively in the corresponding difference plots in the second and fourth rows. At a fixed stellar mass of Log(M_*/M_☉) = 9.5, the difference between the CLEAR and 3D-HST Log(R_{eff}) measurements is 2 times larger in Hα than in the stellar continuum. The same level of evolution is seen for Log(Σ_{1kpc}). This larger evolution in Hα is also seen in TNG50 Log(R_{eff}) measurements, with a factor 1.4 times larger difference in Hα compared to the stellar continuum. It is also evident that this difference rises towards higher stellar masses in the observations, due to the positive slopes in the Log(R_{eff}) and Log(Σ_{1kpc}) Hα differences. This is not true in the simulation, where the stellar continuum and Hα Log(R_{eff}) differences have the same slope.

Another important takeaway from this comparison is that the TNG50 R_{eff} measurements in both the stellar continuum and Hα follow the observational results remarkably well. Even though here the operational definition of sizes is not identical between observed and simulated galaxies (circularized vs. major axis, effective radii measured directly versus GALFIT-based Sérsic profile fitting). A similarly good level of agreement between TNG50 and observational results at z ~ 1 has been noticed before in Nelson et al. (2021), for the locus of the star-forming main sequence and SFR profiles. Here we show that in R_{eff} for both stellar continuum and Hα, this encouraging level of agreement continues down to z ~ 0.5.

In the next Section, we discuss how the agreement in stellar continuum and Hα R_{eff} measurements between the observations and TNG50 can help us constrain the physical explanation responsible for the more extended Hα profiles in low redshift star-forming galaxies.

7.3. Why low redshift Star-forming Galaxies have lower Hα Central Surface Densities at fixed stellar mass

7.3.1. Dust

The first possible physical explanation for the lower Hα central surface densities in star-forming galaxies towards low
redshifts is higher dust obscuration in the central regions of these galaxies preferentially attenuating Hα emission from young stars. A natural consequence of inside-out growth via star formation is that the central regions of galaxies are older than their outer regions. Therefore, the star formation history of the inner region is longer than that of the outer region. Consequently, inner regions of galaxies have a higher degree of stellar mass loss, leading to more efficient enrichment of the interstellar medium (ISM). The central regions of galaxies therefore build up a thicker metal column, leading to increased obscuration of light caused by dust (Wuyts et al. 2012). Higher levels of dust at the centers of galaxies with respect to the outskirts leads to preferential dust attenuation of light in the central regions of galaxies. In the context of a galaxy’s light profile (e.g. Figure 7), this will have the effect of flattening out and extending the light profile in the central regions of galaxies (e.g. Nelson et al. 2016b), and in the context of our study, increase $R_{eff}$ and decrease $\Sigma_{1kpc}$ measurements.

However, the stellar continuum and Hα emission for our galaxies both in CLEAR and 3D-HST are measured within the same wavelength range, meaning the level of dust attenuation for both the stellar continuum and Hα emission should be the same and should therefore cancel out in any Hα-to-stellar continuum ratio measured. The only way the relatively more extended Hα profiles to the stellar continuum profiles at low redshift can be explained by dust is if there is excess attenuation of Hα emission relative to the stellar continuum. Many works in the literature have found results for (Calzetti et al. 2000; Förster Schreiber et al. 2009; Yoshikawa et al. 2010; Mancini et al. 2011; Wuyts et al. 2011, 2013; Kashino et al. 2013; Kreckel et al. 2013; Price et al. 2014; Bassett et al. 2017; Theios et al. 2019; Koyama et al. 2019; Greener et al. 2020; Wilman et al. 2020; Rodríguez-Muñoz et al. 2021) and against (Erb et al. 2006; Reddy et al. 2010) higher dust attenuation of Hα relative to the stellar continuum. This is thought to be driven by the fact that Hα traces emission from young stars which can still be enshrouded in stellar birth clouds. The stellar continuum, which is dominated by older stars does not suffer significantly from this additional contribution. Regardless of this excess attenuation of Hα, if the relative dust attenuation of Hα versus the stellar continuum is independent of redshift, we should not see a difference in the intercept of the $\Sigma_{1kpc,H\alpha}/\Sigma_{1kpc,Cont} \rightarrow$ stellar mass relation with redshift.

A handle on the amount of dust attenuation towards star-forming regions can be directly probed using the Balmer decrement, the ratio of the Hα to Hβ line flux (Calzetti 1997). At $z \sim 1.4$, Nelson et al. (2016b) measured spatially resolved Balmer decrements from HST WFC3 G141 grism spectroscopy as part of the 3-D-HST survey (Section 2.2). They found that galaxies with a mean stellar mass of $\log(M_{\star}/M_\odot) = 9.2$ – which is close to the mean stellar mass of both our CLEAR and 3-D-HST samples ($\log(M_{\star}/M_\odot) \sim 9.5$) – exhibit little dust attenuation at all galactocentric radii. Similarly, at $z \sim 2$, Tacchella et al. (2018) found that the highest mass star-forming galaxies ($\log(M_{\star}/M_\odot) \gtrsim 11$) have the most significant dust obscuration, predominantly located at their centers. At low redshift with SDSS-IV MaNGA, Greener et al. (2020) recently showed that for star-forming spiral galaxies with $\log(M_{\star}/M_\odot) < 10.26$, there is $2.3 \pm 0.2$ times more dust attenuation of the Hα-emitting gas than the stellar continuum, but this ratio remains constant with galactocentric radius. These works suggest that at high redshift, there is likely negligible dust attenuation for galaxies with similar stellar masses to our CLEAR and 3-D-HST galaxies. As we move towards lower redshifts, there is a factor of $\sim 2.3$ excess dust attenuation of the Hα emission, but it follows a similar spatial distribution to the stellar continuum dust attenuation. The level of light profile extension due to dust should therefore be equivalent for both the stellar continuum and Hα emission. Hence dust is likely not driving the more extended Hα profiles relative to stellar continuum profiles at low redshift. This will be verified in our upcoming study on the evolution of spatially resolved Balmer decrements between $0.7 \lesssim z \lesssim 1.4$. Future James Webb Space Telescope (JWST) slitless spectroscopy will also help to firm up the nature of spatially resolved dust as a function of stellar mass and redshift.

The comparison of our observational results to TNG50 in Figure 10 supports the interpretation that dust is not responsible for the redshift evolution in Hα profiles. The TNG50 measurements are based on the location and intrinsic properties of the stellar particles and star-forming gas cells, without taking the effects of dust into consideration. In other words, the exact location of all star-forming elements is known: a fraction of them are not hidden by dust like they are when relying on Hα observations. Therefore, if the intrinsic Hα and continuum structure of TNG50 star-forming galaxies resemble those of real galaxies, the TNG50 sample act as a no-dust control sample to our observational samples of star-forming galaxies. The TNG50 results therefore inform us what evolution we should expect in the absence of dust or non-evolving dust profile gradients in Hα versus the stellar continuum. The fact that the TNG50 results follow our effective radii measurements so well further consolidates our conclusion that the observed evolution in Hα profiles is not due to dust, but something more intrinsic to galaxy evolution that would be captured by a cosmological simulation and not significantly affect galaxy dust profiles.

7.3.2. Inside-out Quenching versus Inside-out Growth

It is a natural consequence of inside-out growth via star formation that the inside-out cessation (or “quenching”) of star formation will follow in its wake. More specifically, if stars form at larger and larger galactocentric radii with time,
Furthermore, because Hα emission has a short lifetime compared to the stellar continuum, changes to Hα profiles will be more easily measurable between 0.5 ≲ z ≲ 1. It is therefore perhaps unsurprising that we measure a significantly larger extension in $R_{\text{eff}}$ likely due to inside-out growth and drop in surface density within 1 kpc likely due to inside-out quenching in Hα profiles than stellar continuum profiles between 0.5 ≲ z ≲ 1 (see Figure 10).

From $z \sim 1$ to $z \sim 0.5$, the average stellar continuum of a star-forming galaxy gains an increasing contribution from older stars that will reside predominantly near the center of star-forming galaxies. These older stars will be less obscured by gas due to the gas depletion that has occurred in the region during the same period. In such a scenario, one would expect that the stellar continuum becomes more compact towards lower redshifts for star-forming galaxies, since the contrast between the bulge and disk increase in favour of the bulge. Since this is not what we measure (see Figure 10), it tells us that the net effect on the stellar continuum profile of typical star-forming galaxies from $z \sim 1$ to $z \sim 0.5$ is that of inside-out growth via star formation. In other words, there is competition between the increasing brightness of the bulge and more luminous, young stars at large galactocentric radii for dominance of the stellar continuum profile at low redshift. Ultimately, the more luminous, younger stars at large galactocentric radii ensure the overall effect on the stellar continuum profile is one of extension and not contraction, albeit less significant than the extension measured in Hα (first column versus second column in the largest panel of Figure 10).

A similar picture to the one presented above was also proposed as an explanation for the results presented in Azzollini et al. (2009) which are remarkably similar to ours. They conducted an analogous study to ours using 270 Log$(M_*/M_\odot) \sim 10$ galaxies at $0 \lesssim z \lesssim 1$, but used the near ultraviolet (NUV) as their tracer for ongoing star formation. The NUV is dominated by flux from O, B, A and F stars that have lifetimes of $\lesssim 100\text{ Myr}$ (Kennicutt 1998; Kennicutt & Evans 2012) and so traces star formation occurring on longer timescales than the star formation traced by Hα (10 Myr). It is also well known that the ultraviolet is very sensitive to dust attenuation (Kennicutt & Evans 2012) and so can be more easily obscured than Hα emission.

Nevertheless, Azzollini et al. (2009) found that after dust correction, SFR surface density (traced by the NUV) decreases from $z \sim 1$ to $z \sim 0$, with the greatest decrease occurring at galactocentric radii $\lesssim 2\text{ kpc}$. The largest difference in stellar mass build up at $0 \lesssim z \lesssim 1$ is measured at $1.5\sim 2\text{ kpc}$ from the centre, suggestive of a decline in star formation activity within $\lesssim 1.5\sim 2\text{ kpc}$ for star-forming galaxies at $z \sim 0$. The SFR surface density is positively correlated with the gas surface density as per the Kennicutt-Schmidt law (Schmidt 1959; Kennicutt 1998; Kennicutt & Evans 2012). Hα emission

stars will also age in this direction. That is, the oldest stars will be nearest to the center of the galaxy. This remains true even in the absence of an inside-out quenching mechanism being present. It is worth noting however, that in TNG50, there is no inside-out quenching without AGN feedback (Nelson et al. 2021). The effects of these two physical processes with their varying degrees between 0.5 ≲ z ≲ 1 can successfully explain the results presented in this paper. We show a schematic representation in Figure 11 to help visualize our explanation. This picture demands that the radius within which inside-out quenching occurs is always smaller than the radius within which inside-out growth via star formation occurs. Because the stellar continuum includes light from all stars and Hα includes emission predominantly from young stars, this dictates that $R_{\text{eff, Hα}}/R_{\text{eff, Cont}} > 1$ and $\Sigma_r Hα/\Sigma_r \text{ Cont} < 1$ always. Within our errors, we see this is true for CLEAR, 3D-HST and KMOS3D (Figures 8 & 9). Because the stellar continuum encodes the integrated star formation history of a galaxy, the stellar continuum of an average $z \sim 1$ star-forming galaxy will have a higher contribution of younger stellar populations compared to the stellar continuum of an average $z \sim 0.5$ star-forming galaxy. This ensures $R_{\text{eff, Hα}}/R_{\text{eff, Cont}} \rightarrow 1$ and $\Sigma_r Hα/\Sigma_r \text{ Cont} \rightarrow 1$ towards higher redshifts. This is most apparent when comparing CLEAR and 3D-HST in Figure 8.

Because star formation is more prevalent at higher redshifts and declines towards lower redshifts (Madau & Dickinson 2014; Whitaker et al. 2014), the effects of inside-out quenching on galaxy light profiles will be more apparent on spatially resolved population studies of star-forming galaxies at lower redshifts. Between $z \sim 1$ and $z \sim 0.5$, inside-out quenching becomes increasingly significant. Consequently, its effects on the light profiles of star-forming galaxies becomes more apparent in spatially resolved measurements. Hα profiles are more sensitive to the significant depletion of gas within the inside-out quenching radius, because they trace ionized gas emission.
traces the gas ionized by the UV radiation from young stars. Therefore a fall in the H\textalpha{} stellar mass surface density within 1 kpc at fixed stellar mass from $z \sim 1$ to $z \sim 0.5$ in our work can be interpreted as a fall in star formation activity due to the exhaustion of gas within a galactocentric radius of 1 kpc.

Furthermore, our results are consistent with those of Tacchella et al. (2015b) who showed that star-forming galaxies with similar stellar masses to our CLEAR and 3D-HST galaxies at $z \sim 2.2$ also exhibit centrally suppressed SFR surface densities when compared to their stellar mass surface densities. These authors put forward a picture in which the bulges and outer regions of galaxies are built concurrently, with a ‘compaction’ scenario responsible for the high central surface mass densities (see also Tacchella et al. 2018). They also noted the often irregular morphologies of the SFR spatial distributions, with bright clumps at large galactocentric radii. Such morphologies are also prevalent at $z \sim 0.5$ in our work (e.g. GS4 29845, GS 49441 and GN 22285 in Figures 1 & 2).

The results presented in Azzollini et al. (2009) and Tacchella et al. (2015b) provide us with independent verifications that irrespective of the star formation tracers used and when dust obscuration is insignificant (see Section 7.3.1) or corrected for, spatially resolved H\textalpha{}/NUV and stellar continuum morphological measurements are measuring the same physical processes acting in typical star-forming galaxies as a function of redshift. Because these physical processes are a product of how inside-out growth operates and inside-out growth is expected in our canonical model of galaxy formation (see Section 1), it is perhaps unsuprising that the TNG50 simulation captured its effect on the H\textalpha{} and stellar continuum $R_{\text{eff}}$ so well.

8. SUMMARY

Using deep HST WFC3 G102 grism spectroscopy of star-forming galaxies from the CLEAR survey (Section 2.1), we have studied spatially resolved star formation using H\textalpha{} emission line maps at $z \sim 0.5$ in this paper. The CLEAR data set made it possible to study spatially resolved star formation over a wide range in redshift for the first time, by comparing our results to analogous studies conducted at $z \sim 1$ and $z \sim 1.7$ with the 3D-HST (Section 2.2) and KMOS\textsuperscript{3D} (Section 2.3) surveys.

We processed, stacked, and analysed our data using the same methodology as 3D-HST, but deferred to improved methods where our more sophisticated software allowed for them.

Our main conclusions are as follows:

1. The H\textalpha{} effective radius for star-forming galaxies with $\log(M_*/M_\odot) \geq 8.96$ at $z \sim 0.5$ is $1.2 \pm 0.1$ times larger than the effective radius of their stellar continuum (Figure 6, second panel of Figure 8 and Table 2). Interpreting H\textalpha{} emission as star formation, this implies star-forming galaxies at $z \sim 0.5$ are growing inside-out via star formation.

2. The H\textalpha{} to stellar continuum effective radius ratio measured at $z \sim 0.5$ from CLEAR agrees within 1\& with the values measured at $z \sim 1$ and $z \sim 1.7$ from the 3D-HST and KMOS\textsuperscript{3D} surveys (second panel of Figure 8 and Table 2). This implies there is no change in the pace of inside-out growth via star formation with redshift.

3. By removing the Sérsic index – effective radius degeneracy with the stellar mass surface density within one kiloparsec, $\Sigma_{\text{1kpc}}$, we unveil a redshift evolution in the H\textalpha{} to continuum $\Sigma_{\text{1kpc}}$ ratio (bottom panel of Figure 8, Tables 2 and 3). Star-forming galaxies at $z \sim 0.5$ have a $(19 \pm 2)\%$ lower surface density in H\textalpha{} relative to their stellar continuum within 1 kpc at a fixed stellar mass of $\log(M_*/M_\odot) = 9.5$.

4. The $\Sigma_{\text{1kpc,H\textalpha{}}}/\Sigma_{\text{1kpc,Cont}}$–stellar mass relation has a linearly declining relation with stellar mass at all redshifts, with a non-evolving slope between $0.5 < z < 1$ (bottom panel of Figure 8 and Table 3).

5. We advocate for the use of $\Sigma_{\text{1kpc}}$ over other morphology parameters for similar studies to ours in the future (Section 6.4). The reduced scatter due to the breaking of the Sérsic index – effective radius degeneracy increases precision in $\Sigma_{\text{1kpc}}$ measurements compared to morphology parameters that rely on Sérsic index or effective radius alone. Furthermore, its reliance on the inner, most highest signal-to-noise ratio region – and therefore most well-determined part of the stellar continuum and H\textalpha{} light profiles (Figure 7) – increases its sensitivity towards radial trends that are otherwise washed out at large radii (Figure 9).

6. We find that most of the redshift evolution seen in the $\Sigma_{\text{1kpc,H\textalpha{}}}/\Sigma_{\text{1kpc,Cont}}$–stellar mass relation is driven by changes in H\textalpha{} profiles, with a factor 2 larger drop in $\log(\Sigma_{\text{1kpc,H\textalpha{}}})$ than $\log(\Sigma_{\text{1kpc,Cont}})$ from $z \sim 1$ to $z \sim 0.5$ (Figure 10).

7. By comparing our observational results to analogous measurements of galaxies from the TNG50 hydrodynamical simulation in Pillepich et al. (2019), we find good agreement in $R_{\text{eff}}$ measurements. Using this comparison, we rule out dust or any physical processes that would alter the shape of galaxy dust profiles as a likely driver for the observed redshift evolution (Section 7.3.1).

8. Our results and similar observational results in the literature are consistent with the picture in which the inside-out cessation (or “quenching”) of star formation
that naturally follows in the wake of inside-out growth via star formation significantly reduces $\Sigma_{1\text{kpc},\text{HI}}$ from $z \sim 1$ to $z \sim 0.5$ (Section 7.3.2).

In our follow up paper, we will verify whether there is any redshift evolution in the dust profiles of star-forming galaxies by measuring spatially resolved Balmer decrements using the CLEAR dataset at $z \sim 0.7$ and comparing it to the analogous study done with the 3D-HST survey at $z \sim 1.4$ (Nelson et al. 2016b). This will provide us with a quantitative dust correction and unveil whether or not dust attenuation towards H II regions evolves with redshift.

ACKNOWLEDGMENTS

JM thanks Matteo Fossati, Erica J. Nelson and Annalisa Pillepich for providing the KMOS3D, 3D-HST and TNG50 measurements respectively, which made the comparisons to Wilman et al. (2020), Nelson et al. (2016a) and Pillepich et al. (2019) possible. JM also thanks Robert Kennicutt for helpful discussions regarding the results in this paper. This work is based on data obtained from the Hubble Space Telescope through program number GO-14227. Support for Program number GO-14227 was provided by NASA through a grant from the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Incorporated, under NASA contract NAS5-26555. This work is supported in part by the National Science Foundation through grant AST 1614668. VEC acknowledges support from the NASA Headquarters under the Future Investigators in NASA Earth and Space Science and Technology (FINESST) award 19-ASTRO19-0122. This work was supported in part by NASA contract NNG16PJ33C, the Studying Cosmic Dawn with WFIRST Science Investigation Team. JM, CP and VEC are also grateful for the support from the George P. and Cynthia Woods Mitchell Institute for Fundamental Physics and Astronomy at Texas A&M University.

Software: This research made use of Astropy, a community-developed core Python package for Astronomy (Price-Whelan et al. 2018). The python packages Matplotlib (Hunter 2007), NumPy (van der Walt et al. 2011), and SciPy (Virtanen et al. 2020) were also extensively used. Parts of the results in this work make use of the colormaps in the CMasher (van der Velden 2020) package.

Facilities: HST (NASA/ESA)
