Identification and antibiotic susceptibility of lactobacilli isolated from turkeys

Marta Dec1*, Anna Nowaczek1, Dagmara Stępień-Pyśniak1, Jacek Wawrzykowski2 and Renata Urban-Chmiel1

Abstract
Background: The aim of this study was to identify Lactobacillus isolates derived from turkeys from six Polish farms and to characterize their phenotypic and genotypic antibiotic resistance profiles.

Results: Among 62 isolates identified by MALDI-TOF mass spectrometry and restriction analysis of 16S rDNA, the dominant species was L. salivarius (35%), followed by L. crispatus (21%), L. inlguviei (14.5%) and L. johnsonii (10%). A high prevalence of resistance to tetracycline (68% resistant isolates), lincomycin (64.5%) and enrofloxacin (60%) among the lactobacilli tested was observed. Fewer than 50% isolates were resistant to ampicillin (47%), erythromycin (45%), streptomycin (31%), chloramphenicol (29%) and gentamicin (10%). As many as 64.5% of the isolates showed multidrug resistance. High MIC values for ampicillin (≥64 μg/ml) were usually accompanied by elevated MICs for cephalosporins (≥16 μg/ml) and high MICs for tiamulin, i.e. ≥32 μg/ml, were noted in most of the turkey lactobacilli (61%). The occurrence of resistance genes was associated with phenotypic resistance, with the exception of five phenotypically susceptible isolates that contained the tetM, tetL, ermC, ermB or cat genes. The most frequently identified were ermB (45% isolates), tetL (40%), tetM (35%) and tetW (29%), and the occurrence of InuA (18%), cat (10%), ermC (6%), ant(6)-Ia (5%) and aade (5%) was less frequent. The mechanism of ampicillin resistance has not been elucidated, but the results of nitrocefin test confirmed that it is not involved in the production of beta-lactamases.

Conclusions: The high rate of antibiotic resistance observed in this study indicates the need to implement the principles of rational use of antibiotics in poultry. The presence of transmissible resistant genes in lactobacilli may contribute to the development of antibiotic resistant pathogenic strains that pose a threat to both poultry and consumers. The results of these studies may be useful for committees providing guidance on antibiotic susceptibility of microorganisms in order to revise and supplement current microbiological cut-offs values within the genus Lactobacillus.

Keywords: antibiotic susceptibility, Lactobacillus, poultry, resistance genes

Background
Bacteria of the genus Lactobacillus are Gram-positive, aerotolerant or anaerobic catalase-negative rods or cocco-bacilli with a G+C content usually below 54 mol% [1]. They are the most numerous group of lactic acid bacteria (LAB), with 228 species described to date (July 2018) [2]. Based on the 16S rRNA gene sequence, lactobacilli have been divided into 15 large phylogenetic groups, 7 small groups of two species each, and 7 groups represented by single Lactobacillus species [3]. Due to their high nutritional requirements, lactobacilli colonize environments rich in carbohydrate-containing substances: they are found on plants or material of plant origin, in fermented food products, or in association with mucous membranes of humans and animals. Lactobacillus species found in the gastrointestinal tract (GIT) have received a great deal of attention due to their health-promoting properties. By acidifying the intestines and through other antimicrobial mechanisms, they help to eliminate unfavourable microflora and maintain a natural microbial balance. Their positive effect on host also includes improved digestion and adsorption of nutrients, modulation of immune response and reduction of toxic and mutagenic compounds in the

Full list of author information is available at the end of the article
gut and serum cholesterol level [4]. Selected strains of *Lactobacillus* are used as probiotics for humans and animals, and interest in applications for these bacteria continues to grow.

The poultry industry is one of the fastest-growing segments of the livestock sector worldwide. Poland currently remains the largest producer and leading exporter of poultry meat in the European Union. Domestic production consists mainly of broiler chickens, but in recent years there has also been an increase in turkey meat production, which is currently estimated at over 400,000 tonnes per year [5]. Broiler turkey meat is valued all over the world for its delicate taste, low fat content and high levels of valuable protein. However, turkeys are considered difficult to raise, especially in the early stages, due to their sensitivity to adverse environmental conditions and high nutritional requirements [6]. They are also susceptible to many diseases, including bacterial infections, which can be primary or secondary [7].

These problems contribute to the frequent use of antibiotic drugs in turkey farming. Unfortunately, in many cases antibiotic therapy is not used rationally, which greatly contributes to the development of antibiotic resistance among bacteria, both pathogenic and commensal. The GIT, which is inhabited by a large number of diverse bacteria, is considered a reservoir of resistance genes [8]. In such a microbiologically rich environment, it may be possible to exchange genetic material between pathogenic, potentially pathogenic and non-pathogenic bacteria. It has been demonstrated that genetic resistance determinants located on mobile elements, such as plasmids, can be transferred horizontally not only between different *Lactobacillus* species but also to other species such as potentially pathogenic enterococci [9].

Bacteria, including lactobacilli, become resistant not only via the acquisition of resistance genes from other organisms through horizontal transfer (conjugation, transformation and transduction), but also by *de novo* mutation. The most well-known mechanisms of bacterial resistance include: i) modifications of the antimicrobial target (decreasing the affinity for the drug), ii) decreased permeability of a bacterial cell wall for drug, iii) activation of efflux mechanisms that extrude the medicine out of the cell, iii) production enzymes that destroy drug's structure, iv) development of an alternative metabolic pathway to those inhibited by the drug [10].

More and newer resistance mechanisms are emerging and spreading globally. Antibiotic-resistant strains propagated in these livestock pose a threat to animals and could be widely disseminated via the food chain. Commensal microflora of the GIT of poultry are frequently present in fresh poultry meat products and may serve as reservoirs of resistant genes that could be transferred to bacterial pathogens of people. Drug-resistant strains cause infections difficult to control and therefore the development of resistance in bacteria is associated with elevated morbidity and mortality rates and increased treatment costs in both animals and humans [11].

Lactobacilli are currently widely used as probiotic supplements, and the strains selected have to meet several criteria, including antibiotic susceptibility. In line with EFSA's FEEDAP Panel (European Food Safety Authority Panel on Additives and Products or Substances used in Animal Feed) recommendations, to differentiate resistant strains from susceptible ones, MIC values should be determined for the number of antibiotics and chemiotherapeutics. Strains showing acquired resistance should not be used as feed additives except when the basis or resistance is chromosomal mutation [12].

The aim of this study was to identify *Lactobacillus* isolates derived from turkeys, determine their antibiotic susceptibility and detect drug-resistance genes. To the best of our knowledge, no studies have previously been undertaken on characterization of turkey lactobacilli.

**Methods**

**Isolation of lactobacilli**

*Lactobacillus* bacteria were isolated from the fresh faeces or cloacae of 22 healthy turkeys from 6 large-scale poultry farms located in different parts of Poland (Lubelskie, Warmińsko-Mazurskie and Wielkopolskie voivodships). Samples were collected during the period from 2012 to 2013, numbering three or four per farm. The age of the birds ranged from 1 week to 15 weeks. No probiotics were administered on any farm.

Bacteria were isolated on MRS (Man, Rogosa and Sharp) medium (BTI, Poland) at 37°C for 48 h in 5% CO₂. All isolates were Gram-positive and catalase-negative. The strains were kept in deMan Rogosa Sharpe broth (MRS, BTI, Poland) containing ~20% glycerol at ~80°C.

**Species identification using MALDI-TOF MS**

The MALDI-TOF-MS analysis was done using a UltraflexXtreme MALDI-TOF mass spectrometer (Bruker, Germany). Bacterial colonies were smeared onto stainless steel MALDI MS target plate and overlaid with 1 µL of 70% formic acid before adding 1 µL of matrix solution. The analysis of the microbial mass spectra was carried out using MALDI Biotyper 3.0 software (Bruker, Germany) [13].

The results of pattern matching were expressed as numerical score ranging from 0 to 3.00 according to the criteria recommended by Bruker: log(score) ≥2.30 (2.30–3.00) - secured isolate identification at species level, log(score) 2.00 to 2.29 - probable identification at the species level, log(score) 1.70 to 1.99 indicates identification at genus level and score >1.70 no reliable identification ([http://www.bruker.com](http://www.bruker.com)). The triplicate spot scores
were recorded and the highest log(scores) (1.700-3.000) were considered reliable. If the difference between the log values (score) of the two best runs was less than 0.30, the identification was considered non-significant [13].

Identification of lactobacilli by 16S-ARDRA

Nine isolates for which definitive species identification was not obtained using MALDI-TOF MS (L. johnsonii/L. gasseri, L. crispatus/L. ultunensis, or L. oris/L. antri) were identified using Amplified Ribosomal DNA Restriction Analysis of 16S rDNA (16S-ARDRA). Isolation of bacterial genomic DNA from lactobacilli and amplification of 16S rDNA were performed according to the protocol described in our previous work [13].

Eight reference Lactobacillus strains were used in the experiment: L. antri LMG 22111, L. crispatus LMG 9479, L. gasseri LMG 13134, L. gasseri ATCC 19992, L. johnsonii LMG 18195, L. johnsonii LMG 9436, L. oris LMG 9848 and L. ultunensis LMG 22117. The 16S rDNA amplicons were digested with 3 restriction enzymes – AluI, MseI and Mbol (Thermo Scientific, USA), which were selected on the basis of in silico analysis using CLC Main Workbench software (Qiagen) and the 16S rDNA nucleotide sequences of the Lactobacillus strains, deposited in GenBank.

Ten μl of PCR product was digested in 12.7 μl of restriction enzyme buffer containing 0.7 μl of enzyme (initial concentration of each restriction enzyme 10 U/μl) and left to react at 65°C (for MseI) or at 37°C (for AluI and Mbol) for 4 h. DNA electrophoresis and analysis of restriction profiles were carried out as described in a previous work [13].

Determination of minimal inhibitory concentration

Antibiotic susceptibility of all bacterial isolates was determined by the broth microdilution procedure [14], using the LAB susceptibility test medium (LSM) (Iso Sensitest broth containing 10% of MRS) recommended by ISO 10932/IDF 223 [15]. All dry powder antibiotics were purchased in Sigma-Aldrich (Poland), with the exception of ampicillin, which was obtained from Roth (USA). As the source of enrofloxacin and tiamulin, ready-made solutions of drugs were used (Enrocin, 50 mg/ml, Vet-Agro, Poland and Biomutin, 200 mg/ml, BIOWET DRWALEW S.A. Poland). Cephalosporins were dissolved in water and stock solutions for other antimicrobial agents were prepared as described in our previous work [16].

Fresh cultures grown overnight on LSM medium were used to prepare the bacterial suspensions in 0.9% NaCl (final optical density at 600 nm was 0.5). Then, 50 μl of a bacterial suspension previously diluted 1:500 in an LSM medium with 50 μl of the antibiotic solution were mixed together on a microplate. The plates were incubated 48 h at 37°C in 5% CO₂ and then the MICs were read visually as the lowest concentration of antimicrobial substance that inhibited the growth of bacteria. Enterococcus faecalis ATCC 29212, Lactobacillus johnsonii ATCC 33200 and S. aureus ATCC 29213 were included as a quality control strains (to control of antibiotics potency and quality of medium) [15, 17, 18]. Lactobacillus johnsonii ATCC 33200 were run in parallel with wild-type Lactobacillus isolates in each trial.

The EFSA’s FEEDAP Panel guidelines [12] were used to interpret the results ampicillin, tetracycline, erythromycin, streptomycin, gentamicin and chloramphenicol. For lincomycin and enrofloxacin, the criteria suggested earlier by Cauwers et al [19] and Dec et al. [16] were adapted. The bacteria were considered resistant if the MIC was ≥64 μg/ml for lincomycin and enrofloxacin. No cut-off values for tiamulin, cephalothin, cefuroxime and ceftiofur were proposed due to insufficient number of isolates and no bimodal MIC distribution for most Lactobacillus species.

Detection of resistance genes

To detect resistance genes and Tn916/Tn1545-like transposon (integrase gene Int-Tn), 23 gene-specific PCR primer pairs were used (Table 1). The PCR mixture for detection of single resistance genes was prepared in a 25 μl volume containing 2.5 μl 10x Dream Taq Buffer, 0.12 μl Dream Taq DNA polymerase (5 U/ml, Thermo Fisher Scientific), 1.25 μl 8 mM dNTPs mix (Blirt, Poland), 0.8 μl of each of two primers (10 pmol/μl, Sigma-Aldrich, Poland), 1 μl template DNA (~20 ng) and 18.5 μl water (Sigma-Aldrich, Poland). Multiplex PCR for detection of some tetracycline, macrolide and aminoglycoside resistance genes (Table 1) was carried out following previously described protocols [20, 21].

DNA amplification was performed using an Eppendorf Mastercycler at following conditions: 5 min at 95°C, 30 cycles with 40 s at 95°C, 40 s at 50-64°C (according to the annealing temperature for the individual primers; Table 1) and 75 s at 72°C and 8 min of final extension at 72°C. PCR products (8 μl) were analysed by electrophoresis (100 V) on 2% agarose gels containing ethidium bromide (0.5 ug/ml).

As a positive control there were used Lactobacillus and Enterococcus wild isolates containing resistance genes as well as reference strain Staphylococcus aureus ATCC 33591 (Table 2). The PCR products obtained for representative wild-type strains were sequenced, and the results of comparative analysis using the NCBI BLAST algorithm (http://www.ncbi.nlm.nih.gov/Blast.cgi) confirmed that the amplicons are counterparts of the resistance genes (Additional file 1).

Nitrocefin test

In this test Lactobacillus isolates displaying phenotypic resistance to ampicillin were used. A loopful of overnight

culture grown on MRS agar around the ampicillin disks (induction of β-lactamase production) was smeared on the moisturized nitrocefin strips (DIAGNOSTICS Inc., Slovak Republic). If red color appeared on the strips in 15 min, bacteria were considered as beta-lactamase positive. Three isolates of E. coli in which the bla TEM-1 gene was previously detected [22] were used as positive control.

**Results**

**Identification of lactobacilli**

A total of 62 isolates with rod-shaped morphology were classified as bacteria of the genus Lactobacillus with a Biotype log(score) equal to or greater than 1.70. For 4 (6%) isolates the log(score) was 2.3-3.0, for 34 (55%) it was 2.00-2.29, and for 24 (39%) it was 1.70-1.99 (Additional file 2).

For 53 isolates (85%) the best matches (1.700-3.000) were considered to be correct species identification. Identification of the remaining 9 strains was considered ambiguous because the first and second best matches (log(score) 1.7-2.3) indicated different species, and the difference between their log(score) values were less than 0.30. For 5 of these samples the best match indicated L. johnsonii and the second best match L. gasseri, for 2 samples the best match indicated L. crispatus and the second best match L. ultunensis, and for another 2 samples the best match indicated L. oris and the second best match L. antri.

Among the 62 isolates identified to the species level (log(score) 1.7-3.0), the species identified were L. salivarius – 22 strains, L. crispatus/L. ultunensis – 2, L. inlguviei – 9, L. johnsonii -1, L. johnsonii/L. gasseri – 5, L. oris – 3, L. oris/L. antri – 2, L. saerimneri – 3, L. agilis – 2, and L. reuteri – 2 strains (Additional file 2).

**Identification of lactobacilli using 16S-ARDRA**

Analysis of the electrophoretic profiles obtained by digestion of 16S rDNA amplicons with selected restriction enzymes showed that the use of MseⅠ allowed for differentiation between L. gasseri and L. johnsonii but not between L. crispatus and L. ultunensis or between L. oris and L.antri. Different electrophoretic profiles for L. crispatus and L. ultunensis were obtained only following digestion with MboI, and differences between L. oris and L. antri appeared after digestion with AluI.

Analysis of the electrophoretic restriction profiles showed that all the strains previously identified in MALDI-TOF MS as L. johnsonii/L. gasseri belonged to the species L. johnsonii, 2 isolates identified as L. crispatus/L. ultunensis belonged to the species L. crispatus, and 3 species determined as L. oris/L. antri belonged to the species L. oris (Fig. 1).

The electrophoretic profiles of digested 16S rDNA amplicons contained 3-6 restriction fragments ranging from 82 to 920 bp (Additional file 3).

**Antimicrobial susceptibility testing**

The MIC of 12 antibiotic agents was analysed for 62 Lactobacillus isolates from turkeys. The MIC range was 0.25-64 μg/ml for ampicillin, 0.25-64 μg/ml for cephalothin, ≤0.125-64 μg/ml for cefuroxime, ≤0.125-64 μg/ml for cefotaxime, 2-512 μg/ml for tetracycline, ≤0.25-64 μg/ml for erythromycin, ≤1-1,024 μg/ml for lincomycin, ≤1-1,024 μg/ml for streptomycin, 2-128 μg/ml for gentamycin, 1-128 μg/ml for chloramphenicol, ≤0.5-256 µg/ml for tiamulin, and ≤1-256 μg/ml for enrofloxacin (Table 3). According to the established criteria, 68% of isolates were resistant to tetracycline, 64.5% to lincomycin, 60% to enrofloxacin, 47% to ampicillin,

45% to erythromycin, 31% to streptomycin, 29% to chloramphenicol, and 10% to gentamicin (Table 4). High MIC values for ampicillin (≥ 64 μg/ml) recorded for 15 (24%) isolates (L. salivarius and L. crispatus) were usually accompanied by elevated MICs for cephalosporins (≥ 16 μg/ml) (Additional file 2). As much as 90% Lactobacillus isolates showed a MICs range for tiamulin from 2 to 256 μg/μl, and for 10% (6) isolates (1 L. reuteri, 2 L. johnsonii and 3 L. ingluviei) we recorded a particularly low tiamulin MICs, ie. ≤0.5 μg/ml (Table 3).

Multiple-drug resistance (resistance to at least 3 groups of antimicrobial agents) was observed for 64.5% of lactobacilli, and 43.5% isolates showed cross-resistance between erythromycin and lincomycin. Simultaneous resistance to streptomycin and gentamicin was recorded for 6% of isolates (Table 4). Only three L. ingluviei isolates (I22b, I23c and I24b), derived from the same farm, showed susceptibility to all the drugs tested, and their MIC values for tiamulin were as low as ≤0.5 μg/ml (Table 3).

Clear bimodal distribution of MICs indicative of acquired resistance was observed for tetracycline (for all species beside L. salivarius). Bimodal distribution was also noted for ampicillin MICs for L. johnsonii and L. crispatus isolates and MICs of enrofloxacin for L. salivarius, L. agilis and L. oris. Regarding the susceptibility of L. salivarius to ampicillin and tetracycline, we noted three MIC ranges, which could indicate the presence of sensitive, intermediate and resistant strains. In the case of aminoglycosides, chloramphenicol and tiamulin, distribution of MIC values was unimodal for most Lactobacillus species (Table 3).

Detection of antibiotic resistance genes
Of the 23 considered resistance genes, 10 were detected in the tested lactobacilli. We found tet genes conferring resistance to tetracyclines in 42 (68%) isolates, including 41 phenotypically resistant to tetracycline and one susceptible strain (it contained tetM and tetL genes). The most frequently identified tet gene was tetL, which was observed in 40% of isolates, followed by tetW (37%) and tetM (29%) (Table 5). The presence of individual tet genes seems to be correlated with the species. The tetM gene was found in L. salivarius, L. crispatus and L. agilis; tetL was detected in L. salivarius, L. agilis, L. crispatus, L. oris, and in one isolate of L. ingluviei. The presence of the tetW gene was unique for the species belonging to the phylogenetic group of L. delbrueckii (L. johnsonii and L. crispatus) and L. reuteri (L. oris, L. ingluviei and L. reuteri). The co-occurrence of tetM and tetL was characteristic for L. salivarius, L. agilis and L. crispatus. The tetL and tetW genes were present simultaneously only in L. crispatus, L. oris and L. ingluviei isolates.

Among the genes coding for resistance to macrolides and lincosamides, the most frequent was ermB (in 45% of isolates), rarely ermC (6%) and lnuA (18%). The rRNA methylase ermA gene was detected in all isolates resistant to erythromycin (27 isolates with MIC≥64 μg/ml) and in one isolate with a susceptible phenotype (L. salivarius 21b, MIC=0.5 μg/ml) (Tables 3, 5). The ermC gene (encoding methylase) was detected in 4 isolates of L. salivarius, including 2 phenotypically resistant to erythromycin and 2 susceptible to this antibiotic. Three of these ermA-positive isolates were resistant to lincomycin.

Fragments highlighted in grey indicate MIC cut-off values (μg/mL) as indicated in the Methods. The number of isolates carrying the gene in question is given in brackets after the name of the gene. The absence of a number following the name of the gene means that all isolates contain the gene tet* = tetM or tetL or tetW

Table 4 Number of resistant *Lactobacillus* strains determined on the basis of MIC breakpoints established for the antibiotics

| Strain        | Number of strains | do not showing any resistance | resistant to one drug only | with multidrug resistance | displayed resistance against | ampicillin (MIC ≥ 2 or 4 or 8 μg/ml) | tetracycline (MIC ≥ 2 or 16 or 32 μg/ml) | erythromycin (MIC ≥ 2 μg/ml) | lincomycin (MIC ≥ 64 μg/ml) | streptomycin (MIC ≥ 32 or 128 μg/ml) | gentamycin (MIC ≥ 32 μg/ml) | chloramphenicol (MIC ≥ 28 μg/ml) | enrofloxacin (MIC ≥ 64 μg/ml) | erythromycin and lincosamycin | streptomycin and gentamycin |

Page 9 of 14
The \textit{InuA} gene (encoding lincosamide O-nucleotidyltransferase) was detected in 11 strains, all of which were resistant to lincomycin (Table 3).

Among genes determining resistance to aminoglycoside antibiotics, \textit{ant(6)-Ia} and \textit{aadE} encoding \textit{ANT(6)} adenyltransferases were detected. They occurred simultaneously in 3 isolates (5\%) of \textit{L. salivarius} showing resistance to streptomycin (MIC\textsubscript{50} ≤ 22 \textmu g/ml). The results of the sequence analysis of PCR products indicated that \textit{aadE} and \textit{ant(6)-Ia} are the same gene detected by different primers (Additional file 1).

The \textit{cat} gene encoding chloramphenicol acetyltransferase, which converts chloramphenicol to inactive diacetyl chloramphenicol [23], was present in 6 isolates (11\%) of \textit{L. ingluviei}, 4 of which were resistant to chloramphenicol (MIC\textsubscript{50} ≤ 8 \textmu g/ml) (Tables 3, 5).

The \textit{lsaE} gene coding for multidrug efflux pumps was present in 3 isolates of \textit{L. salivarius} with high MIC values for tiamulin, i.e. >256 \textmu g/ml (Tables 3, 5). These \textit{lsaE}-positive isolates also contained the \textit{aadE} or \textit{ant(6)-Ia} gene conferring resistance to streptomycin.

None of the \textit{Lactobacillus} isolates contained the \textit{tetK}, \textit{tetO}, \textit{ermA}, \textit{mefA/E}, \textit{blaZ}, \textit{mecA}, \textit{aph(3')-IIIa}, \textit{aac(6')-le-aph(2')-Ia}, \textit{aph(2')-Ic}, \textit{aph(2')-Id}, \textit{ant(4')-Ia} and \textit{aac(6')-Iii}

\textit{NITROCEFIN TEST} The results of the nitrocefin test for the rapid chromogenic detection of beta-lactamase activity [24] was negative for all \textit{Lactobacillus} isolates phenotypically resistant to ampicillin.

\textbf{DISCUSSION} In this paper we have presented the first report on the identification and antibiotic susceptibility of lactobacilli from farm turkeys.

Bacteria were identified to the species level using MALDI-TOF MS and, if uncertain results were obtained, identification was further based on 16S rDNA analysis. The reliability and effectiveness of MALDI-TOF MS in typing lactobacilli has been confirmed by several authors and high agreement has been observed between results obtained in mass spectrometry and in various genetic methods, even if the log(score) values were lower than 2.00 [13, 25, 26]. However, in this work we found that MALDI-TOF MS had insufficient discriminatory power to differentiate closely related species such as \textit{L. johnsonii} and \textit{L. gasseri}, \textit{L. crispatus} and \textit{L. ultunensis}, and \textit{L. oris} and \textit{L. antri}. Homology between \textit{L.}

Johnsonii and *L. gasseri* at the sequence level of 16S rDNA and other genes is known to be very high [27], and the similarity of the 16S rDNA sequence between *L. crispatus* and *L. ultunensis* and between *L. oris* and *L. antri* has been estimated at 98.2% and 99.8%, respectively [28]. The results of our work showed that the genetic similarity between these species translates into similarity in cellular protein profiles. However, as shown by restriction analysis of 16S rDNA, despite high homology between mass spectra of closely related species, the first best match (log(score) ≥ 1.70) was correct for all questionable samples. The issue of ambiguous differentiation of closely related species identified in this study in isolates from turkeys, i.e., *L. crispatus*, *L. johnsonii*, and *L. gasseri*, has been addressed also in our earlier paper [13].

The Lactobacillus species identified in this study in isolates from turkeys are in line with those found in poultry worldwide. Several reports have pointed out the predominance of *Lactobacillus crispatus*, *L. salivarius*, *L. reuteri*, and *L. johnsonii* among intestinal autochthonic chicken lactobacilli [29, 30]. In Poland, the dominant *Lactobacillus* species in geese and chickens are *L. salivarius* and *L. johnsonii*, and the remaining species which have been identified in turkeys, i.e., *L. crispatus*, *L. ingluviei*, *L. reuteri*, *L. oris*, *L. agilis* and *L. saerimneri*, were isolated with a lower frequency [25, 31].

Among the lactobacilli tested we found high prevalence of resistance to tetracycline (68% resistant isolates), lincomycin (64.5%), enrofloxacin (60%) and ampicillin (50%). The frequency of resistance to other antimicrobial agents, i.e. erythromycin, aminoglycosides and chloramphenicol, ranged from 10% to 45%. The high level of antibiotic resistance observed in this study is probably due to the widespread use of antimicrobial drugs on turkey farms. The history of the use of antibiotics in the flocks from which Lactobacillus isolates were derived was not made available. However, according to the inspection carried out in Poland in 2015-2016 by the Supreme Audit Office, antibiotics were detected in 88% of turkey farms (in water or feed). The standards for doxycycline and enrofloxacin were exceeded most often, and antibiotics most commonly used in Poland in animal husbandry include tetracyclines and penicillins [32]. These facts may justify the high prevalence of resistance to ampicillin, tetracycline and enrofloxacin in the tested lactobacilli.

High prevalence of tetracycline resistance (68% of isolates) in turkey lactobacilli is in line with our earlier research demonstrating that 75% of Lactobacillus isolates from chickens in Poland are resistant to this antibiotic [16]. Similar results obtained also Cauwerts et al. [33], who recorded nearly 80% resistance to tetracycline among lactobacilli from Belgian broiler farms. The observed tetracycline resistance was due to the presence of tet genes, which code for energy-dependent efflux proteins (tetL) or for a protein that protects bacterial ribosomes from the action of tetracyclines (tetM, tetW) [34]. The incidence of tetL, tetM and tetW genes in turkey lactobacilli is similar to that occurring in Lactobacillus isolates from chicken farms in Poland and Belgium [16, 33]. The tetW and tetM genes are also widespread in Lactobacillus bacteria isolated from humans and food products [35]. Our finding that the tetW gene is characteristic for the isolates belonging to the phylogenetic group *L. delbrueckii* and *L. reuteri*, and that its occurrence among isolates of the *L. salivarius* group is sporadic, is consistent with previous research on chicken lactobacilli [16].

The high rates of resistance (45-63%) to MLS antibiotics (macrolides, lincosamides and streptogramins) observed in turkey lactobacilli are in line with our recent study showing that 70% of lactobacilli derived from chickens in Poland were resistant to lincomycin and 42% were resistant to macrolides [16]. Similar findings were reported by Cauwerts et al. [19] for Lactobacillus bacteria isolated from broiler chicken in Belgium. The bimodal distribution of MIC values for erythromycin, which suggests acquired resistance, has been also recorded earlier for lactobacilli of various origins [19, 36].

Phenotypic resistance to MLS antibiotics in the turkey lactobacilli was associated with the presence of erm genes, which encode rRNA methylases, and the lnuA gene, which encodes lincosamide O-nucleotidyltransferase. The high incidence of the *ermB* gene (in 45% of isolates) and the lower incidence of *ermC* (6%) is consistent with previous studies on the antibiotic susceptibility of chicken Lactobacillus strains [16, 19]. In contrast, the frequency of the lnuA gene in turkey lactobacilli (18%) was about half of that noted in chicken isolates (39%) in Poland, although phenotypic resistance to lincomycin was very similar in both species [16]. The presence of the *ermC* gene not only in resistant but also MLS-susceptible Lactobacillus isolates has also previously been reported by other authors [16, 25].

The incidence of ampicillin resistance (47% resistant isolates) recorded in this study is much higher than that observed by other researchers working on poultry LAB [37, 38]. The ampicillin resistance rate in chicken lactobacilli (26%) from Polish farms is almost half that of turkey Lactobacillus isolates [16]. High MIC values for ampicillin (≥64 μg/ml) recorded for 24% isolates were usually accompanied by elevated MICs for first, second and thirs generation cephalosporins (≥16 μg/ml) indicating cross-resistance. The mechanism of resistance of the lactobacilli to ampicillin remained unexplained, but the results of the tests carried out excluded the involvement of β-lactamases. This is line with studies by other authors [23, 39], who have demonstrated the absence of
the blaZ gene encoding β-lactamase in lactobacilli phenotypically resistant to penicillins. The third generation cephalosporins are usually highly resistant to β-lactamases.

Among turkey lactobacilli, 30% of isolates showed resistance to chloramphenicol, and for most of them (12 of 18 phenotypically resistant) the MIC was 8 µg/ml, while the EFSA threshold is 4 µg/ml. Higher MIC values, i.e. 16-128 µg/ml, and the presence of the chloramphenicol acetyltransferase cat gene were characteristic only for L. ingluviei isolates, although two cat-positive strains were considered phenotypically susceptible. A similar range of MIC values for chloramphenicol, i.e. 1-8 µg/ml for most lactobacilli tested, has been observed by other authors [16, 39, 40], while high MIC values ≥32 µg/ml have been noted only occasionally [14, 16, 40]. The presence of the cat gene among chloramphenicol-susceptible Lactobacillus isolates has also been observed in our previous work, and more precise studies by Hummel et al. [23] showed that the cat gene was not expressed (RNA level) in some cat-positive but phenotypically susceptible LAB strains.

In this work, we observed a fairly high frequency of resistance to streptomycin (31%), while gentamicin resistance was much less prevalent (10%). A similar percentage (12.5-31%) of aminoglycoside-resistant strains was recorded for chicken lactobacilli in Poland [16]. More frequent occurrence of resistance to streptomycin than to gentamicin among lactobacilli from various sources was also demonstrated by Danielsen and Wind [40]. Of the genes that determine resistance to aminoglycosides, only two are found in, i.e. aadE and ant(6)-Ia, in 3 isolates of L. salivarius showing phenotypic resistance to streptomycin. According to Ramires and Tolmasky [41], aadE and ant(6)-Ia encode O-adenyltransferases that confer resistance to streptomycin and belong to the ANT(6) group of modifying enzymes but the results of sequence analysis of PCR products indicated that aadE and ant(6)-Ia are the same gene detected by different primers. The aadE or ant(6)-Ia gene has been previously detected in L. salivarius strains from chicken [16] and in L. casei and L. plantarum isolates from food sources or human biopsy samples [42].

The present study provides the second report on the sensitivity of lactobacilli to tiamulin. In our previous work on chicken lactobacilli, we proposed a concentration of 8 µg/ml as a breakpoint for distinguishing sensitive and resistant strains. In the present study we have not adopted this cut-off point, nor have we proposed other breakpoint values, due to the MIC distribution and insufficient number of isolates of most Lactobacillus species. However, the high MIC values of tiamulin, i.e. ≥32 µg/ml, noted in the majority (61%) of turkey lactobacilli suggest the prevalence of resistance to this antibiotic. As in the earlier studies on chicken lactobacilli [16] only 10% isolates were tiamulin MIC values as low as ≤0.5 µg/ml. The genetic resistance of most Lactobacillus strains with high MIC values for tiamulin has not been determined. The lsaE gene that codes for ATP-dependent drug efflux pump was detected only in 3 L. salivarius isolates with high MIC values (128-256 µg/ml) of tiamulin. Therefore, it is likely that the low sensitivity of the lactobacilli to this pleuromutulin is the modification of the target, i.e. 23S rRNA at the peptidyl transferase center of the 50S subunit [43]. All lsaE-positive isolates simultaneously contained the aadE/ant(6)-la gene conferring resistance to streptomycin. This observation is in line with our recent findings on chicken lactobacilli [16] and previous reports describing the occurrence of lsaE within plasmid or chromosomal clusters comprising several resistance genes, including aadE [44].

The percentage of enrofloxacin-resistant Lactobacillus strains (MIC≥64 µg/ml) in the turkeys (60%) was higher than in chickens (48%) and in geese (23%) in Poland [16, 45]. Lactobacilli from other sources, such as dairy products or cattle intestine, are usually sensitive to enrofloxacin [46, 47]. The Tn916/Tn1545-like conjugative transposon that was identified in three strains of L. salivarius, is commonly found in various bacteria, including enterococci and streptococci, but not in lactobacilli [48, 49]. The coexistence of integrase gene int-Tn and tetM, tetL and ermB genes observed in these studies is consistent with the literature data, according to which members of the Tn916-Tn1545 family carry the tetracycline-resistance determinant tetM, as well as additional resistance genes [49].

Conclusions

Our work is the first report on the identification and antibiotic susceptibility of Lactobacillus bacteria from turkeys. We have shown the predominance of L. salivarius (35%) and L. crispatus (21%) among turkey lactobacilli and a high frequency of resistance (≥45% resistant isolates) to tetracycline, lincomycin, ampicillin and erythromycin. These data indicate that antibiotic resistance has reached a dangerous level in the commensal microflora, and the high rate of ampicillin resistance thus far observed in lactobacilli is particularly alarming. There is need to promote the rational use of antibiotics in poultry farming to limit the development of resistance in bacteria. More emphasis should be placed on alternative therapies and the implementation of biosecurity practices, which are the most effective, cheapest and safest way to prevent the spread of disease on farms. Consideration should also be given to amending legislation
governing the use of antibiotics in livestock. The level of antibiotic resistance may be reduced by introducing an obligation to report to the regulatory authorities the use of antibiotics on farm and by requiring antibiotic resistance tests before antibiotic use.

Our studies have shown that the natural intestinal microflora of turkeys is a reservoir of resistance genes. Many of them were previously found in LAB on the mobile element, which can be readily transferred to other bacteria inhabiting the intestine of the host and spread in the environment [9, 48]. Further research is needed to clarify the mechanism of low sensitivity of lactobacilli to beta-lactam antibiotics and pleuromutilins.

Acknowledgements

The authors thank Prof. Stanislaw Winiarczyk for shering mass spectrometer during identification of lactobacilli using MALDI-TOF MS and Krzysztof Bourdo, DVM, for his assistance in collecting the samples from turkeys.

Funding

The research was financed by the Polish National Science Centre (NCN), project no. 2017/01/X/NZ/00478. The funds received were used to purchase the materials necessary to perform the tests. The financing body did not participate in research design, analysis of results or writing of the manuscript.

Availability of data and materials

All data generated or analysed during this study are included in this published article and its supplementary information files.

Authors’ contributions

MD designed the study, performed laboratory tests regarding genetic differentiation of lactobacilli, determination of MICs and detection of resistance genes, interpreted the data, supervised all experiments and drafted the manuscript. AN and DS-P were responsible for collecting the test material, isolating lactobacilli and performing DNA electrophoresis. JW identified bacteria by MALDI-TOF MS. RU-C isolated DNA from bacteria. All authors read and approved the final manuscript.

Ethics approval and consent to participate

The faecal samples and cloacal from the birds were collected by a veterinarian as part of his work. According to Polish law (the act on experiments on animals of 21 January 2005), permission from the ethics commission is not required for this type of sample collection. All animal owners agreed to collect material for testing.

Consent for publication

Not applicable.

Competing interests
