Twenty four hour imaging delay improves viability detection by Tl-201 myocardial perfusion scintigraphy

Abstract

Objective: Since twenty-four-hour imaging by Tl-201 myocardial perfusion scintigraphy has been introduced as an effective additional procedure, the aim of this study was to compare this method’s result with only rest redistribution procedure in the diagnosis of myocardial viability.

Methods: Thirty patients (Seven female, 23 male; mean: 59.8 ± 10.7, 55.8-63.8 years old) with diagnosis of coronary artery disease were involved in this study. All patients had anamnesis of previous myocardial infarction and/or total occlusion of any main artery in the coronary angiography. Myocardial perfusion scintigraphy with Tl-201 with rest four hour (early) redistribution and 24 hour delayed redistribution protocol were performed to all of the patients. The images were evaluated according to 17 segment basis by an experienced nuclear medicine physician and improvement of a segment by visual interpretation was considered as viable myocardial tissue.

Results: Viability was found at 52 segments in the early redistribution images and additional 18 segments in the 24 hour delayed images on segment basis in the evaluation of 510 segments of 30 patients. On per patient basis, among the 26 patients who had viable tissue, 14 (54%) had additional improvement in 24 hour delayed images. Three (12%) patients had viable tissue in only 24 hour delayed images.

Conclusion: Delayed imaging in Tl-201 MPS is a necessary application for the evaluation of viable tissue according to considerable number of patients with additional improvement in 24 hour images in our study, which is restricted to the patients with myocardial infarct.

Descriptors: Vascular diseases. Coronary artery bypass. Coronary artery disease.
INTRODUCTION

Myocardial infarction is a critical event and the most common cause of death all over the world. After myocardial infarction, another critical course begins which includes the decision of both presence and extent of the viable myocardial tissue. Since myocardial tissue sometimes preserves its viability by some adaptation methods during infarct, it is possible to observe viable tissue in patients who experienced myocardial infarction. The ‘hibernating’ myocardial tissue is a tissue with impaired flow and function, but with preserved viability. This state of the myocardial tissue can be seen especially by means of radionuclide imaging methods like Tl-201 and F-18 FDG PET/CT. Recently, new methods have been introduced to the field of imaging of the myocardial viability, such as cardiac applications of magnetic resonance imaging (C-MRI) or stress echocardiography [1]. However diagnostic power of the viability assessment by Tl-201 is underestimated because most of the recent comparative studies with Tl-201 imaging involve rest redistribution protocol [2]. The aim of this study was to investigate diagnostic importance of 24 hour delayed Tl-201 imaging in our series.

METHODS

Patients

Thirty patients (seven female, 23 male; mean: 59.8±10.7, 55.8-63.8 years old) with diagnosis of coronary artery disease were included in this study. Diagnosis of myocardial infarct was based on anamnese, electrocardiography results and/or coronary angiography results showing 100% narrowing of any main coronary artery. Sixteen patients underwent additional coronary angiography. All patients had documented myocardial infarction. Additionally, all the patients had segmental or global wall motion abnormalities and left ventricular impairment (mean ejection fraction: 30.9±8.9) according to the echocardiography results. Patient characteristics are summarized in the Table 1. All the patients’ informed consent forms were obtained prior to the study and after explaining the procedure and the research. Ethics committee approval was not deemed necessary since the study was performed retrospectively.

| Nº of patients | Age | Gender |
|----------------|-----|--------|
| 56-64 years | 7 female/23 male |

| | Angina | Smoking | Diabetes mellitus | Hypertension | Family history | Hyperlipidemia | Previous CABG |
|----------------|--------|----------|------------------|-------------|---------------|----------------|--------------|
| | 19     | 16       | 8                 | 14           | 5             | 9              | 3             |

CABG: Coronary artery bypass graft surgery

Myocardial perfusion scintigraphy

Tl-201 myocardial perfusion scintigraphy (MPS) with rest redistribution and delayed redistribution protocol were performed in all patients with the same imaging and acquisition protocols (same timing, filter, gated acquisition, reconstruction parameters (filtered back projection), attenuation and scatter correction). After a fasting period of at least four hours approximately 2 mCi (74 Mbq) Tl-201 (the dose was limited to 2 mCi in case reinjection was required, which did not happen in this approach) was injected via venous line into
the patients. Rest images were obtained at five-ten minutes, early redistribution images at 3-4 hours and late redistribution images at 24 hours after the injection.

Single photon emission computed tomography (SPECT) imaging was performed by a dual-head gamma camera equipped with low energy all purpose collimator (GE, Infina). The images were acquired over a 180° arc in 64 projections, each lasting 30 seconds (in case of insufficient quality of images by visual analysis, the imaging time was increased to 40 sec/per frame), in a 64x64 matrix and gated protocol. The butterworth filter with cutoff frequency of 0.5 and order of 10 was applied for the reconstruction of the images.

**Image interpretation**

The images were evaluated in short axis, vertical and horizontal long axe slices, and in bull’s eye imaging. This was done according to 17 segment basis by two independent experienced nuclear medicine physicians and improvement of any segment by visual interpretation (greater than 50% uptake increase) was considered as viable myocardial tissue. The analysis of scores (0-4 scores and % scores) was performed by the same physicians.

**Statistical analysis**

The comparison of the scores was done by paired samples T test and $P<0.05$ was considered statistically significant. SPSS 15.0 was used for the analysis.

**RESULTS**

In the evaluation of 510 segments of 30 patients, 52 segments in early redistribution images and other 18 segments in delayed redistribution images were considered viable on a segment basis. In order to consider the improvement between the rest-redistribution and delayed redistribution images, a significant difference between % scores of the segments ($P<0.05$) or improvement of 0-4 scores by at least one degree was accepted as a threshold. On per patient basis, among the 26 patients who had viable tissue, 14 (54%) had additional improvement on delayed images. Three (12%) patients had viable tissue only on delayed imaging (Figure 1). Additionally all the patients had global or segmental wall motion abnormalities and mean ejection fraction value obtained from rest redistribution images was $30.9 \pm 8.9$ according to Gated acquisition.

**Table 2. Myocardial perfusion scintigraphy results of patients who have angiography results.**

| Angiography | Redistribution | Delayed Imaging |
|-------------|----------------|-----------------|
| 1           | LAD 100%       | Inferior, septum|
| 2           | LAD 80%, Cx 90%| Septum          |
| 3           | LAD-LIMA 100%  | Anteroseptal, inferior mid apical |
| 4           | LAD 95%, Cx 100%| Anterior mid    |
| 5           | LAD 100%       | Apex            |
| 6           | LAD 100%, Cx 50%, RCA 95% | Anterior mid |
| 7           | LAD 95%        | Septum          |
| 8           | LAD 100%, RCA 90% | Apex         |
| 9           | LAD 98%, Cx 90%, RCA 95% | -             |
| 10          | LAD 100%       | Inferior apical |
| 11          | LAD 70%, Cx 100%, RCA 70% | Septum |
| 12          | RCA 80%        | Inferior apical |
| 13          | Cx 90%         | Septum          |
| 14          | LAD 100%, Cx 95%, RCA 100% | Septum, anteroseptal, inferoseptal |
| 15          | LAD 100%, Cx 40%, RCA 100% | Anterior mid apical |
| 16          | LAD 100%, Cx 70%, RCA 100% | Anteroseptal mid |

**Fig. 1 - Short axis, vertical axis, horizontal axis, and bulls eye TI-201 MPS images of a patient who has viable tissue only in 24 hour images in septum and anteroseptal wall**
The improved segments at rest redistribution and delayed imaging of patients who underwent angiography are summarized in Table 2.

Unfortunately, all the patients were out of follow up after the establishment of the viability. There was no information regarding further management of the patients, whether or not they underwent coronary artery bypass graft surgery (CABG), and what their results were.

DISCUSSION

Since mortality associated with the heart failure is significantly high, it is important to perform revascularization in patients who might benefit from this procedure. According to a meta-analysis study, revascularization procedures have provided improvements in 79.6% of patients with viable tissue [3]. Viability assessment have gained importance ever since risk factors associated with CABG operations, especially in elderly patients, have become known [4,5]. Viability assessment by means of radionuclide imaging methods is generally effective because these methods provide functional assessment of the myocardial tissue. TI-201 is a potassium analog and enters myocytes via an active transport mechanism involving the Na+/K+ adenosine triphosphate (ATP) transport system. When TI-201 enters intracellular space, it goes back to the systemic circulation through diffusion [6].

This kinetic redistribution, which is specific to this agent, allows viability assessment by TI-201 imaging. The tracer is taken by hibernating myocardium and it can be seen at three hours after injection of radiopharmaceutical. Since Pohost et al. [7] first introduced TI-201 as a viability agent further studies have shown that 24 hour injection provides important prognostic data [8,9]. Perrone-Filardi et al. [10] observed improvement in approximately 20% of segments in late images, especially in mild to moderately persistent defects. Rest redistribution imaging at three hours is not a sufficient approach as documented in a series which showed 75% of the viability were reported as scars, according to rest-redistribution only TI-201 imaging [11].

Dilsizian et al. [12] were the first to report the ‘reinjection technique’, which includes a lower dose (1 mCi/37 MBq) TI-201 injection at three hours and then reimaging. However, 24 hour imaging with TI-201 still preserves its diagnostic significance as documented in a recent study [13]. In this comparative study with echocardiography follow up, researchers observed 20% more segments with viability in the 24 hour images that had not improved in rest redistribution imaging. We found 26% (18 out of 70 viable segments) additional segments with improvement in the 24 hour images. Although previous researchers performed 24 hour imaging with a higher TI-201 dose (3-4 mCi/111-148 mBq) we did not increase the dose.

The justification for increasing the dose of radiopharmaceutical is the poor image quality of TI-201 especially in decreased dose of 24 hour images. However the image quality of our study at 24 hours was in fact comparable to the early redistribution images even close to Tc-99m MIBI images, according to visual interpretation and target non target ratio (2.03; 2.16 and 3.03, respectively). We just preferred to increase the time frame (40 sec versus 30 sec per frame), if necessary. The patient based analysis of the viability assessment in our study revealed that an important percentage of patients (54%) had additional viable tissue in 24 hour images. Since the patients who were included in this study all had fixed defects on rest TI-201 imaging, this finding is of great importance. The most important result of this study is patients who had improvement only in 24 hour imaging (three patients, 12%), which was not observed in any previous study. However, due to the small sample size the ratio of these patients should be evaluated in a larger study population. In future studies this percentage might increase.

The cardiac Tc-99m labeled tracers have superior image quality compared to TI-201. That is why there are new approaches with Tc-99m compounds employed in the viability assessments. Maurea et al. [14] have shown that administering nitrate during Tc-99m MIBI imaging might demonstrate viable tissue in patients with chronic heart failure. A recent comparative study using this method and the TI-201 reinjection approach has demonstrated comparable results and good agreement between the two methods [15].

Another recent approach with Tc-99m compounds has included Tc-99m labeled HL91, which is introduced as an alternative application for the viability assessment. Viability was defined as reduced Tc-99m MIBI uptake and increased Tc-99m HL91 uptake; a ‘mismatch’ pattern, especially in the three hour images, which showed high diagnostic accuracy [16].

The most important advance in the field of viability imaging was F-18 FDG PET/CT. Viability assessment by means of F-18 FDG PET has shown significant superiority over 24 hour TI-201 imaging [17]. F-18 FDG PET has been considered as the gold standard imaging method for detection of myocardial viability [18]. Additionally, according to previous studies, F-18 FDG PET has been able to provide prognostic information [3,19].

Stress echocardiography is another modality which shows viable tissue in the myocardium. According to a meta-analysis sensitivity, specificity, and positive and negative predictive values of dobutamin stress echocardiography were found to be 81%, 80%, 77%, and 85%, respectively [20]. The same researchers have mentioned that radionuclide methods have higher sensitivity and stress echocardiography has higher specificity.

Cardiac magnetic resonance (MR) imaging for assessment of the myocardial viability is a new method which can clearly identify cardiac tissue in all the myocardial layers with superior spatial resolution compared to the radionuclide...
methods. An analysis of viability assessment by cardiac MR has concluded that MR is an excellent tool to demonstrate viability [21]. A comparative study with cardiac MR and TI-201 imaging has documented that MR has higher specificity, negative predictive value and overall accuracy; however, in that study the TI-201 imaging was performed in a rest redistribution manner [2]. Cardiac MR has had comparable diagnostic accuracy with PET according to a previous study [22].

One of the important characteristics of our study is the homogeneity of our study population, which consists only of patients with documented myocardial infarction. In other studies about viability assessment there have been patient populations with angiographically significant coronary artery disease (CAD), or patients with left ventricular impairment with myocardial infarction in some (50%) of the patients [23,24]. In those studies, significant percentages of the segments were already nonviable (144/398 and 56/240, respectively). However, the primary pathology of our patients was CAD with known myocardial infarct tissues thus our study includes subjects with perinfarct viable tissue.

Another study about viability assessment by both rest redistribution TI-201 and contractile reserve assessment by low-dose dobutamine protocol included 41 patients, 39 of whom had documented myocardial infarction, and found the protocol easy and feasible [25]. Although their analysis did not include additional late TI-201 imaging, their study group was similar to ours and a smaller percentage of the segments in their analysis was nonviable (33/890), as in our study. This especially enabled our study to evaluate more segments regarding viability.

Limitations of this study were its retrospective structure and lack of all the patients’ angiography or follow up results. Quantification of the data also couldn’t be performed because of a technical problem associated with our analysis program.

CONCLUSION

According to our results the 24 hour TI-201 imaging is a necessary application for the identification of viable myocardial tissue. Considering the large number of patients who benefit from this additive method, this study can encourage future comparative studies with 24 hour imaging protocol and new diagnostic applications in this area.

There is no conflict of interest.
