EFFECTS OF SAGITTAL BALANCE DIFFERENCES ON SPONDYLOLISTHESIS

ABSTRACT

Objectives: This study aimed to compare the lumbar lordosis (LL) and spinopelvic parameters of patients with stage 1–2 spondylolisthesis to those of the normal population and demonstrate the importance of these parameters in sagittal balance. Methods: The lumbosacral parameters on the lateral radiographs of a total of 125 patients were retrospectively compared. Lumbosacral parameters including pelvic incidence (PI), pelvic tilt (PT), sacral slope (SS), lumbar lordosis angle (LLA), L5 incidence (L5I), L5 slope (L5S), and sacral table angle (STA) were compared between groups. Results: Comparison of the parameters between groups revealed no sex-based differences (p > 0.05). Conclusions: Abnormal sagittal spinopelvic parameters are commonly examined for their effects on the development of spondylolisthesis and should be used in routine practice. We found that the low SS values in our study, unlike those of other similar studies, may be a compensatory mechanism developed to reduce pain and maintain sagittal balance. Level of Evidence II; retrospective study.

Keywords: Spondylolisthesis. Lumbar vertebrae. Lordosis.

INTRODUCTION

The humans are the only living creatures which have lordotic lumbar curvature and lumbar lordosis (LL) is one of the most important parameters to be examined in sagittal balance evaluations due to its variability. Lumbar lordosis, which varies depending on the shape and the position of the pelvis and the relationship between sacral slope (SS) and pelvic tilt (PT), is thought to be the main mechanical cause of the degenerative diseases of the spine. The loss of the LL is an expected finding with the changes in the center of gravity in the aging spine and degenerative disc diseases, which cause spondylolysis, spondylolisthesis, and collapse on discs. With the activation of the other compensatory mechanisms accompanying the loss of lumbar lordosis, the thoracic, thoraco-lumbar and sacral angles would change. The two basic variables affected in the compensation mechanisms are pelvic tilt (PT) and SS with the change of LL in degenerative processes. The term pelvic incidence (PI) is equal to the sum of the two variables, PT and SS. In the classification of the spinal study group, spondylolisthesis was classified as six types, and spinopelvic parameters which were assessed using the angle of the shifting, PI, SS, PT and sagittal vertical line of C7 were taken into account when evaluating these types. In this classification, low-grade spondylolisthesis was
classified as meyering stage 0-2, shift below 50%; while high-grade spondylothesis as meyering > 3 and shift >50%. Today, this classification is commonly used. Abnormal PI and spinopelvic parameters play essential roles in the development and progression of many spinal diseases including spondylolysis, spondylothesis and various other spinal pathologies. Recent studies showed that pelvis morphology or PI and its orientation significantly affect the sagittal spinal geometry of LL especially, both in healthy and diseased states. Because PT and SS are variable parameters that are affected by the position, pelvic and other sagittal parameters should be assessed withstanding lateral radiographs. Our aim in this study is to compare the values of the LL and spinopelvic parameters of patients with stage 1-2 spondylolisthesis to the normal population and to show the importance of these parameters regarding sagittal balance.

MATERIALS AND METHODS
This retrospective study was approved by the ethics committee of Bolu Abant Izzet Baysal University (20187/119). Participants were signed the informed consent form. Among the patients who referred to the neurosurgery outpatient clinic with the complaints of lumbar pain and sciatalgia between 2016 and 2017, seventy-five patients who had no spinal pathology detected with direct radiography (DR) and lumbar magnetic resonance imaging (MRI), and fifty patients with spondylolisthesis were included. The lateral radiographs of a total of 125 patients were evaluated comparatively and retrospectively concerning the lumbosacral parameters. The exclusion criteria were undergone spinal surgery, lumbar infection, tumor, hip joint disease; the inclusion criteria were the age of 18-70 years and the presence of the lateral radiography which was optimal for the lumbosacral parameter measurement.

A single senior radiologist obtained all lumbosacral parameters on the lateral radiographs obtained on the standing patients via the hospital PACS (imaging) system. The parameters we used for the evaluation were PI, PT, SS, lumbar lordosis angle (LLA), L5 incidence (L5I), L5 slope (L5S) and sacral table angle (STA). PI was the angle between the vertical line passing through the middle point of the superior sacral end plate and the line connecting the femur head axis to this mid point; PT was the angle between the vertical line passing through the femur head axis and the line connecting the femur head axis to the sacral end plate midpoint; SS was the angle between the superior sacral end plate and the horizontal line; LLLA was the angle formed by the intersection of the vertical lines from each of the parallel lines which were drawn from the upper-end plates of the first lumbar vertebrae and the sacral vertebra ; L5I was the angle between the line perpendicular to the middle point of the superior L5 end plate and the femur head axis; L5S was the angle between the upper-end plate of the L5 vertebrae and the horizontal line and the STA was the angle between the superior end plates of the sacrum and the line of the posterior sacrum edge (Figure 1). Statistical analysis showed normal distribution in patient and healthy groups and independent sample T-test was performed for the comparison. It was considered significant when the P value was below 0.05. Independent sample T-test was used to assess the gender effect for each parameter, ANOVA test was used to assess the age effect.

RESULTS
A total of 125 patients, 50 with spondylolisthesis and 75 normal, included in the study ranged between the age of 18-70 years, with a mean age of 49 years. The spondylolisthesis group consisted of 12 males and 38 females and the healthy group consisted of 38 males and 37 females. Lumbosacral parameters including PI, PT, SS, LLA, L5 incidence, L5S and STA values were compared in healthy and spondylolisthesis groups. Grade 1 listhesis was detected in 43 patients, and grade 2 listhesis was detected in 7 patients in the listhesis group, and when they were compared regarding the lumbosacral parameters, there was no significant difference. PI, PT, LLA, L5I, L5S values were significantly higher, and STA was significantly lower in the patient group (p<0.05). There was no significant difference in SS values between the two groups (Table1). When each parameter were compared between males and females to assess the gender effect in patient and healthy groups, there was no significant difference between males and females in the measurements. When the healthy and patient groups were divided into three subgroups as 18-39 years, 40-59 years and over 60 years old to evaluate the effect of the age; it was found that there was no significant difference between all age groups in all parameters in both groups.

DISCUSSION
In our study, there was a significant relationship between the development of spondylothesis, and the horizontal and retrovert position of the pelvis due to the increase in PI and PT values and the increased LLA, increased L5I and low STA values as the
When the LL gets flattened (the static waist), the SS becomes the greater the LL becomes (the dynamic waist). On the contrary, sacral slope (SS) was first noted by Stagnara.

When pelvic incidence increases, pelvic tilt is equal to the sum of PT and SS. Since PT has a narrow range it is effective in the formation of isthmic spondylolisthesis, and the larger PI and sacral slope could lead spine to shift. In the study conducted by Yukawa et al., thoracic kyphosis and LL showed no significant change between 20 and 60 years of age, but both of them decreased significantly over 70 years of age in Japanese society. PT increases with age, while SS decreases with age. In many other studies to evaluate sagittal spinopelvic parameters, lumbosacral parameters were shown to remain relatively constant throughout life after skeletal maturation. Kim et al. found that there was no significant difference in PI, PT, and SS values between young and old males. Similarly, in our study, there was no significant difference between lumbosacral parameters in terms of age and gender in both healthy and diseased patients.

In our study, the PT values of spondylolisthesis patients were different from other similar studies, may be a compensation mechanism; are the spinopelvic parameters which are commonly used nowadays for their effects on the development of developing a pars defect than PI, and that the relation of the STA values predisposed to spondylolysis by an increase in shear force resulting in producing more mechanical stress in pars interarticularis. A more vertical sacral table (i.e. a lower STA value) means that there is higher shear stress on the disc and therefore a greater tendency to shift forward in the upright position. In our study, we found that low STA values increased predisposition to spondylolisthesis in accordance with the literature.

| Lumbar lordosis angle | 52.9 ± 13.3 | 48.2 ± 11.8 | 0.042 | 0.002 |
