ABSTRACT

Low-mass ($M_{500} < 5 \times 10^{14} M_\odot$) galaxy clusters have been largely unexplored in radio observations, due to the inadequate sensitivity of existing telescopes. However, the upgraded GMRT (uGMRT) and the Low Frequency ARray (LoFAR), with unprecedented sensitivity at low frequencies, have paved the way to closely study less massive clusters than before. We have started the first large-scale programme to systematically search for diffuse radio emission from low-mass galaxy clusters, chosen from the Planck Sunyaev-Zel’dovich cluster catalogue. We report here the detection of diffuse radio emission from four of the 12 objects in our sample, shortlisted from the inspection of the LoFAR Two Meter Sky Survey (LoTSS-I), followed up by uGMRT Band 3 deep observations. The clusters PSZ2 G089 (Abell 1904) and PSZ2 G111 (Abell 1697) are detected with relic-like emission, while PSZ2 G106 is found to have an intermediate radio halo and PSZ2 G080 (Abell 2018) seems to be a halo-haloc system. PSZ2 G089 and PSZ2 G080 are among the lowest-mass clusters discovered with a radio relic and a halo-relic system, respectively. A high ($\sim 30\%$) detection rate, with powerful radio emission ($P_{1.4\ GHz} \sim 10^{23}$ W Hz$^{-1}$) found in most of these objects, opens up prospects of studying radio emission in galaxy clusters over a wider mass range, to much lower-mass systems.

Key words: Galaxies: clusters: general – Radio continuum: general – X-rays: galaxies: clusters – large-scale structure of Universe

1 INTRODUCTION

Observations of diffuse radio emission due to synchrotron processes reveal the dynamical state and the non-thermal energy evolution in galaxy clusters. Though massive clusters ($> 5 \times 10^{14} M_\odot$) have been detected in abundance at radio-frequencies over the last few decades (e.g. van Weeren et al. 2019), the less massive ones ($< 5 \times 10^{14} M_\odot$) have remained largely unexplored. This is mainly due to limitations in sensitivity at the usual radio-frequencies. Further, the dearth of theoretical estimates for favourable detections in low-mass systems, with the currently available instruments, have so far discouraged systematic studies. For instance, while the theoretical prediction of Cassano et al. (2010) shows a low probability for halo detection in low-mass clusters with the Low Frequency ARray (LoFAR), the recent analysis of VLA and GMRT data of 75 high mass clusters with radio haloes by Cuciti et al. (2021) shows a large scatter in the radio power-mass correlation, leading to broader confidence levels at the lower-mass end, indicating the prospect of a better detectable fraction of radio haloes from them. It can be noted that, before uGMRT and LoFAR, only a handful of low-mass clusters had been detected with cluster radio emission (Bernardi et al. 2016; de Gasperin et al. 2017; Kale et al. 2017; Dwarkanath et al. 2018; Botteon et al. 2019; Knowles et al. 2019). However, in the absence of their detection, the understanding of the hierarchical formation of clusters, especially in the non-thermal regime, would remain incomplete.

Radio emission linked to the tenuous plasma of the intracluster medium (ICM) is diffuse in nature, with very low surface brightness ($\sim \mu$Jy arcsec$^{-2}$) and steep spectrum ($\alpha < -1$, with $S_\nu \propto \nu^\alpha$). Such detections are usually hundreds of kpc to Mpc in extent, and are mostly found in merging systems. Depending on their location in the cluster and the possible process of origin, they are divided into two major classes (Feretti et al. 2012). Such diffuse and feebly ($\sim 5\%$) polarised centrally-located, emission, possibly resulting from the turbulence in the ICM, is generally termed a ‘radio halo’. In contrast, comparatively strongly polarised ($\sim 30\%$) ‘radio relics’ usually originate from cluster merger shocks, and are mostly located at the cluster outskirts. Objects of a third kind, with central diffuse radio emission, but smaller in extent (100 – 500 kpc), are known as radio ‘mini-haloes’. These are usually found around the brightest cluster galaxy (BCG) in relaxed clusters with cool-cores, and their emission is thought to be of hadronic origin, i.e., from the secondary electrons produced from the central AGN (e.g. Ferrari et al. 2008; Giannini et al. 2019; Iagnesti et al. 2020).

Diffuse radio sources in clusters have so far been detected mostly in massive systems (van Weeren et al. 2019). However, in various studies of low-mass clusters, evidence of mergers and non-gravitational processes (e.g. Lovisari, Reiprich, & Schellenberger 2015) is frequently observed, and AGN feedback processes are known to significantly affect such systems (e.g. Gaspari et al. 2011). Recent simulations of the evolution of turbulence and cosmic rays in low-mass systems show significant deviations from scaling relations found in richer clusters, having flatter slopes and higher fluctuations (e.g. Paul et al. 2021).

from four low-mass galaxy clusters. Following the details of data properties of these systems from publicly-available archival data. diffuse emission in LoTSS-I. Further, to understand the nature of the to confirm the Planck-SZ systems for which we found evidence ofacterise faint diffuse sources, particularly since the raw data are not that of LoTSS-I. Mosaic images from LoTSS-I are reported to suffer to the LoTSS-I (Shimwell et al. 2019) for evidence of diffuse emission, before following-up with uGMRT, we select only those located in the area of the sky between RA 161°.25 to 232°.5 and DEC +45° to +57°. This resulted in 14 objects (see Tab. 1), for which the LoTSS images are publicly available. We then visually inspected each of them in LoTSS-I maps and found that these two fall outside the edges of the provided mosaics. Finally, among the remaining 12 clusters, four (PSZ2 G080.16+57.65 (PSZ2 G080), PSZ2 G089.52+62.34 (PSZ2 G089), PSZ2 G106.61+67.61 (PSZ2 G106) and PSZ2 G111.75+70.37 (PSZ2 G111)) were found to have indications of diffuse radio emission, whereas the rest of the eight objects are devoid of any diffuse emission at the local RMS noise level as given in Tab. 1. Of these images, images of PSZ2 G096.14+56.25 are significantly affected by the PSF side-lobes of central bright sources (flux > 1 Jy). Independently, all four of these appear in the LoTSS sample of cluster radio sources (van Weeren et al. 2020). We then obtained the uGMRT (Gupta et al. 2017) Band 3 (300-500 MHz) data (proposal code: ddtC 157) with ~2 hours on-source time on each of these objects. Data reduction and imaging were primarily performed using the SPAM pipeline (for details see Intema et al. 2017). This is a powerful data analysis and imaging pipeline that takes care of direction-dependent variations (i.e., due to antenna beam pattern and due to ionosphere) in visibility, amplitude and phase, across the field of view. Using SPAM, wide-band uGMRT data were first split into six narrower bands, and each of them were initially calibrated for flux and band-pass using the source 3C286. The final SPAM-calibrated data for each narrow-band, after imaging, were combined to produce wide-band images using the WSclean package (Offringa et al. 2014), with the specific parameters as mentioned in Tab. 2. To make point source subtracted low resolution images, high-resolution point-source only images were first produced using an appropriate “uvcut” in WSclean and then the point sources were subtracted from the UV-data, using the FT and UVSUB tasks in CASA.

The radio flux densities (S) were measured within 3σ contours of each map (σ being the local rms noise), and flux density errors were estimated (σS) using the relation σS = \sqrt{(f \times S)^2 + N \sigma^2 + \sigma^2_{sub}}, where N is the number of beams within 3σ contours and σsub is the uncertainty due to compact source subtraction (applied to the point source subtracted maps). We assumed an usual f=10% for uGMRT and f=20% for LoTSS-I (as mentioned in Shimwell et al. 2019) of S to be the error due to calibration uncertainties. In addition to the usual method of flux density measurements within 3σ isophotes in radio images, we employed a more generic method to compute the radio flux density of halo-type diffuse radio sources in galaxy clusters, by fitting azimuthally-averaged brightness profiles with an exponential function (Murgia et al. 2009). The fitted exponential profile is of

2 DATA SELECTION AND ANALYSIS

We produced a list of low-mass clusters (≤ 5 x 10^{14} M_\odot), from a total of 1653 objects published in the latest Planck SZ galaxy cluster catalogue (Planck-16). Since our goal is to first check the LoTSS-I (Shimwell et al. 2019) for evidence of diffuse emission, before following-up with uGMRT, we select only those located in the area of the sky between RA 161°.25 to 232°.5 and DEC +45° to +57°. This resulted in 14 objects (see Tab. 1), for which the LoTSS images are publicly available. We then visually inspected each of them in LoTSS-I maps and found that two of these fall outside the edges of the provided mosaics. Finally, among the remaining 12 clusters, four (PSZ2 G080.16+57.65 (PSZ2 G080), PSZ2 G089.52+62.34 (PSZ2 G089), PSZ2 G106.61+67.61 (PSZ2 G106) and PSZ2 G111.75+70.37 (PSZ2 G111)) were found to have indications of diffuse radio emission, whereas the rest of the eight objects are devoid of any diffuse emission at the local RMS noise level as given in Tab. 1. Of these images, images of PSZ2 G096.14+56.25 are significantly affected by the PSF side-lobes of central bright sources (flux > 1 Jy). Independently, all four of these appear in the LoTSS sample of cluster radio sources (van Weeren et al. 2020). We then obtained the uGMRT (Gupta et al. 2017) Band 3 (300-500 MHz) data (proposal code: ddtC 157) with ~2 hours on-source time on each of these objects.

Data reduction and imaging were primarily performed using the SPAM pipeline (for details see Intema et al. 2017). This is a powerful data analysis and imaging pipeline that takes care of direction-dependent variations (i.e., due to antenna beam pattern and due to ionosphere) in visibility, amplitude and phase, across the field of view. Using SPAM, wide-band uGMRT data were first split into six narrower bands, and each of them were initially calibrated for flux and band-pass using the source 3C286. The final SPAM-calibrated data for each narrow-band, after imaging, were combined to produce wide-band images using the WSclean package (Offringa et al. 2014), with the specific parameters as mentioned in Tab. 2. To make point source subtracted low resolution images, high-resolution point-source only images were first produced using an appropriate “uvcut” in WSclean and then the point sources were subtracted from the UV-data, using the FT and UVSUB tasks in CASA.

The radio flux densities (S) were measured within 3σ contours of each map (σ being the local rms noise), and flux density errors were estimated (σS) using the relation σS = \sqrt{(f \times S)^2 + N \sigma^2 + \sigma^2_{sub}}, where N is the number of beams within 3σ contours and σsub is the uncertainty due to compact source subtraction (applied to the point source subtracted maps). We assumed an usual f=10% for uGMRT and f=20% for LoTSS-I (as mentioned in Shimwell et al. 2019) of S to be the error due to calibration uncertainties. In addition to the usual method of flux density measurements within 3σ isophotes in radio images, we employed a more generic method to compute the radio flux density of halo-type diffuse radio sources in galaxy clusters, by fitting azimuthally-averaged brightness profiles with an exponential function (Murgia et al. 2009). The fitted exponential profile is of...
the form \( I(r) = I_0 \exp(-(r/r_e)^2) \), where \( r_e \) is the characteristic e-folding radius and \( I_0 \) is the peak surface brightness of the radio halo. Profiles were fit using a least-squares fitting algorithm. For statistical purposes, in each radio image, the surface brightness was sampled several times with different linear radial step sizes. Corresponding to the fitting parameters, \( I_0 \) and \( r_e \), for each surface brightness sampling, the flux densities were measured by integrating the fitted brightness profile up to three times the e-fold radius, i.e. \( 3r_e \), following Murgia et al. (2009). Accordingly, the statistical mean and standard deviation of fitted flux densities for each halo are reported in Tab. 3. All images used in this paper were manipulated and analysed using the CASA package (McMullin et al. 2007).

For multi-wavelength follow-up, we obtained PanSTARRS-1 (optical) data for all the objects, and, in X-rays, XMM-Newton data of ~35 ks (ObsID:08210404010), ~15 ks (ObsID:0821040301) and ~44 ks (ObsID:0827020801) for PSZ2 G080, PSZ2 G089 and PSZ2 G111, respectively and the Chandra observations for PSZ2 G106 (15 ks, ObsID:21708). The Chandra data were reduced using CIAO v4.11, CALDB 4.8.4 following the standard data reduction threads and using re-projected blank-sky background files. The XMM-Newton data were analysed using SAS v18 and the latest calibration files. We used the “IMAGES” tool to clean high background images. XMM-Newton data were analysed using SAS v18 and the latest calibration files. We used the “IMAGES” tool to clean high background images. XMM-Newton data were analysed using SAS v18 and the latest calibration files. We used the “IMAGES” tool to clean high background images.

3 DETECTION FROM LOTSS-I AND uGMRT BAND 3

The measured parameters of these newly detected objects with cluster radio emission from uGMRT and LoTSS-I are outlines in Tab. 3. The details of individual objects are individually presented below.

3.1 A candidate radio relic in cluster PSZ2 G089.52+62.34

This is a low-redshift (z=0.07008) cluster with SZ mass \( M_{500}^{SZ} = 1.83^{+0.19}_{-0.20} \times 10^{14} M_\odot \) (Planck-16). The rich galaxy cluster Abell 1904 is located well within this source, ~4′ away from PSZ2 G089 centre. The reported 1D velocity dispersion of the Abell cluster is 803 km s\(^{-1}\) (Stubble & Rood 1999), which is high value given its mass, and might be indicative of an ongoing merger. This is consistent with the elongated mass distribution along SW to NE (Flin & Krywult 2006), the evidence of substructures found in our XMM maps and the high X-ray luminosity (\( L_X = 2.54^{+0.03}_{-0.02} \times 10^{44} \, \text{erg s}^{-1} \)) of the source.

A peripheral diffuse radio structure was noticed towards the NE of this cluster in LoTSS-I, low-resolution image (local \( \sigma_{144}=200 \, \mu Jy \, \text{beam}^{-1} \); Fig. 1 (a)). In our uGMRT Band 3 image, we detect this peripheral radio emission as well, and it is shown as black contours within the blue-dashed polygonal area in Fig. 1(a). The largest linear size (LLS) and width of this elongated diffuse emission, as measured in the uGMRT maps, are 205 kpc and 45 kpc respectively. Its flux density is \( S_{400} = 6.6 \pm 0.7 \, \text{mJy} \) at uGMRT Band 3 and, for the same region, the LoTSS-I flux density is estimated to be \( S_{144} \approx 19.9 \pm 3.1 \, \text{mJy} \), van Weeren et al. (2020) have reported a larger relic, as well as a second part of the relic, in their improved LoTSS-II images. This could not be detected in our uGMRT maps (at a higher frequency) at the reported RMS noise level of 50 mJy beam\(^{-1}\). Such morphological dissimilarity between images at different frequencies is common for steep-spectrum radio sources.

In Fig. 1 (a), uGMRT contours are overlaid on a PanSTARRS 1 optical image, where no optical counterpart of this diffuse radio emission is seen. XMM X-ray contours show two prominent substructures, marked as ‘A’ and ‘B’ in Fig. 1 (b), possibly in the process of merger along the SW to NE direction. As is usual for radio relics, the convex and elongated radio structure at the outskirts of this cluster coincides with the outer X-ray contours, placed well ahead of the merging clumps, perpendicular to the merging axis (see Fig. 1 (b)). This structure is found about 4′ away from the bigger X-ray substructure (‘A’). Though clear evidence of a thermal shock is absent in the low-exposure (15 ks) XMM data, interestingly, a sudden dip in the X-ray surface brightness profile, for the sector 100° – 170° shown in Fig. 1 (d), with a residual of more than 2σ from the β-model fit (see Fig. 1 (c)), certainly indicates the presence of an apparent shock front at a similar distance (~4′) as the radio diffuse emission.

Since van Weeren et al. (2020) have provided the combined flux density for two parts of the relic and we could detect only one part of it in our uGMRT maps, it was not possible to compute a meaningful spectral index. We have however made a rough estimate of an average spectral index between the uGMRT detection and its co-located LoTSS-I counterpart, found to be \( \alpha = 1.40 \) ~ 1.08, suggesting a case of relic emission. In the absence of stronger evidence, we classify it as a candidate relic.

3.2 A radio relic and trailing emission in PSZ2 G111.75+70.37

PSZ2 G111.75+70.37, identified with the poor cluster Abell 1697 is a moderately distant cluster at a spectroscopic redshift of \( z = 0.1813 \). The estimated mass for the cluster in the Planck-16 catalogue is \( M_{500}^{SZ} = 4.34^{+0.32}_{-0.33} \times 10^{14} M_\odot \) and its estimated XMM X-ray luminosity is \( L_X = 5.26^{+0.30}_{-0.40} \times 10^{44} \, \text{erg s}^{-1} \). This cluster is reported to host a radio relic and a ultra-slow spectrum trailing emission, as tentatively estimated from LoTSS-I and NVSS maps (Paul et al. 2020).

In this case, we detect both the radio structures in our uGMRT band 3 low-resolution map (see Fig. 2 (a)); RMS noise \( \sigma_{400} = 100 \, \mu Jy \, \text{beam}^{-1} \), similar to those seen in LoTSS-I (\( \sigma_{144}=420 \, \mu Jy \, \text{beam}^{-1} \)). However, no clear evidence of radio halo emission, as found by van Weeren et al. (2020), could be seen in our maps.

The relic is 750 kpc long and 350 kpc in width (marked as ‘R’ in Fig. 2 (a)), having a uGMRT flux \( S_{400}(R) = 49.7 \pm 5.0 \, \text{mJy} \). The distance from the Planck cluster center to the peak relic emission is about 850 kpc. The trailing emission (marked as ‘T’ and enclosed within the dashed ellipse) is large, about 450 x 350 kpc in projected extent, but is very faint (\( S_{400}(T) = 15.3 \pm 1.6 \, \text{mJy} \)).

The LoTSS-I flux for the two detected structures and the region same as uGMRT are \( S_{144}(R) \approx 130.2 \pm 26.1 \, \text{mJy} \) and \( S_{144}(T) \approx 41.7 \pm 8.3 \, \text{mJy} \). Accurate spectral index estimation with these values would not be possible because of the fact that the LoTSS-I map that is available to us for this object is contaminated with significant artefacts as mentioned in van Weeren et al. (2020).

Fortunately, the NVSS map for this cluster contains a detection of a major part of the relic. Combining the images at 1.4 GHz (NVSS) and the matched \( \nu \)-coverage map at 400 MHz (uGMRT), we produced a spectral index map as shown in Fig. 3. The average spectral index of the proposed relic part (i.e. ‘R’, common area with 3σ detection of NVSS) is about \( \alpha_{1420} = -1.40 \pm 0.01 \). The spectral index at the relic front is \( \alpha_{144} = -0.93 \pm 0.01 \), which gradually steepens to
Table 3. Radio (uGMRT: 400 MHz & LoTSS-I: 144 MHz (for the same area as uGMRT observations)) and X-ray (XMM: 0.5-8 keV & Chandra: 0.5-3 keV) properties.

| Object       | Abell name | $S_{400}(3\sigma)$ (mJy) | LoTSS-I flux* (mJy) | $S_{144}^\gamma$ (mJy) | Size (uGMRT) (kpc) | Model Halo | $L_x$ (10$^{44}$ erg s$^{-1}$) |

Here H, R and T represents halo, relic and trailing emission. * Flux density for the same area as uGMRT 3σ area. ↑↑ As reported in van Weeren et al. (2020).

Figure 1. Panel (a): Contours of uGMRT (Black, at −3, 3, 5, 7, 9, 18… × $\sigma_{340}$) and LoTSS-I (Magenta, at −3, 3, 6, 9, 18… × $\sigma_{144}$) of PSZ2 G089.52+62.34 are plotted over the PanSTARRS-I ‘i’-band image. Panel (b): X-ray contours plotted on the uGMRT (grayscale) image and contour maps. The Planck SZ centre is marked as blue ’×’ and Abell cluster centre as green ‘+’ for all the images in this paper. The physical scale for the images is 1.34 kpc/arcmin. Panel (c): The X-ray surface brightness profile fitted with $\beta$-model and its residues (for the sector 100° – 170°, as shown in Panel (d)).
Figure 2. Panel (a): uGMRT and LoTSS-I contours are plotted on PanSTARRS-I $i'$-band image of source PSZ2 G111.75+70.37. Contours (levels same as Fig. 1) of uGMRT (Black), LoTSS-I (Magenta) with RMS noise of 100 and 420 $\mu$Jy beam$^{-1}$, respectively. Panel (b): XMM contours (red) are plotted over uGMRThighresolutiongrayscaleimageandcontours(at-3,3,6,9,18,36 $\sigma$, where $\sigma$ = 65 $\mu$Jy beam$^{-1}$). The physical scale for the images is 3.05 kpc/00.

Figure 3. Spectral index map of the relic found in the cluster PSZ2 G111.75+70.37, prepared using the uGMRT (400 MHz) and NVSS (1.4 GHz) images.

\[ \alpha_{\text{tail}} = -1.87 \pm 0.01 \] towards the inside edge of the relic. Therefore, it reasonably follows the predictions of the commonly-used continuous injection spectrum model for radio relics i.e., $\alpha_{\text{in}}^{1420} = -0.93 \sim \alpha_{\text{in}}^{1440} + 0.5$.

Our XMM-Newton contours in Fig. 2 (b) clearly show substructures merging along the SW to NE direction, and the relic is found ahead of this at the cluster outskirts, perpendicular to the merging axis. This is suggestive of a typical binary merger of clusters producing peripheral radio relics. All the possible scenarios for the origin of radio emission in this cluster have been discussed in detail in Paul et al. (2020).

3.3 A radio halo-relic system in cluster PSZ2 G080.16+57.65

PSZ2 G080.16+57.65 (or PSZ2 G080 in short), also identified with the cluster Abell 2018, is another low redshift ($z = 0.0878$) poor cluster in our sample, having mass $M_{500} = 2.51^{+0.20}_{-0.21} \times 10^{14} M_\odot$ (Planck-16), and a moderate X-ray luminosity $L_X = 8.14^{+0.04}_{-0.03} \times 10^{43}$ erg s$^{-1}$. A cluster named GMBCG J225.28318+47.27663 (Hao et al. 2010) shown as a magenta cross in Fig. 4 (b), is within 2' of PSZ2 G080, with a comparable redshift $z = 0.0882$ and mass $M = 2.86 \pm 0.26 \times 10^{14} M_\odot$, indicating that they are the same object.

We found a large, 1 Mpc peripheral bow-like structure and an indication of diffuse radio emission in the central region of this cluster in our uGMRT high-resolution map (see Fig. 4 (a)). The peripheral structure in this cluster is very faint with a flux $S_{500} = 13.3 \pm 1.4$ mJy, but at an unusual distance of 1.3 Mpc away from the cluster centre, beyond the virial radius (self-similar fiducial $r_{200} = 1.2$ Mpc). The spectral index of $\alpha_{400} \sim -1.4$, as computed using our uGMRT and 144 MHz (reported in van Weeren et al. (2020)) fluxes, as well as, its peripheral location and bow-like shape suggest it to be a steep-spectrum radio relic.

The only radio point source found inside this cluster (in NED) is a radio galaxy, exactly at the centre of the Abell cluster (green '+') in Fig. 4 (b), and at a similar redshift $z = 0.0873$, confirming it to be a member of the cluster. This also matches with a radio peak seen in our uGMRT map (see 'A' in Fig. 4 (b)). The other bright but extended radio source ('B') in uGMRT and LoTSS-I maps cannot be seen in VLA First or any other higher-frequency radio surveys. There is no
Figure 4. Panel (a): uGMRT high-resolution colour map and contours (black) and LoTSS-I contours (magenta) for the cluster PSZ2 G080.16+57.65 (contours are at the same level as Fig. 1(a) with RMS noise $\sigma = 55$ and 240 $\mu$Jy beam$^{-1}$, respectively). Panel (b): uGMRT contours (blue) plotted over the PanSTARRS-I $i'$-band image, zoomed into the central halo region. The centre of the GMBCG J225.28318+47.27663 cluster, clearly associated with this source, is shown as a magenta cross. The physical scale for the images is 1.64 kpc.

Figure 5. XMM contours (red) over uGMRT point source subtracted map of the source PSZ2 G080.16+57.65.

optical source in NED identified as a galaxy that coincides with ‘B’, which confirms its nature as a diffuse radio source.

We produced a point-source subtracted image to map the central diffuse emission in this cluster, following the method described in § 2. We found a halo-like emission with a size ~ 540 x 490 kpc and flux density $S_{400} = 19.3 \pm 2.0$ mJy (see Fig. 5) within 3$\sigma$ contours. Unlike van Weeren et al. (2020), we found no radio bridge connecting the relic and the halo, in our uGMRT point-source-removed maps, which have an RMS of $\sigma = 120$ $\mu$Jy beam$^{-1}$.

Fig. 5 reveals an elongated and clumpy X-ray map, indicative of a non-relaxed state. The radio structure uncovered here is found to be well-enclosed by the bigger X-ray clump, the peak of which also coincides with the centre of cluster GMBCG J225 (magenta ‘x’), establishing its connection to the ICM of the cluster. Following an alternative method of estimating the flux density of the radio-halo, as described in § 2, we computed a flux density of $18.0 \pm 0.01$ mJy within the 3 e-folding radius (see Tab. 3). In comparison, van Weeren et al. (2020) computed a flux density of 92 mJy for the same halo, giving rise to an average spectral index $\alpha_{400} \approx -1.6$. Though this is indicative of an ultra-steep spectrum radio halo, the radio emission is neither centrally located as in archetypal radio haloes, nor found at the cluster outskirts as are the radio relics, making it difficult to firmly assign an identity to it.

3.4 PSZ2 G106.61+66.71, an intermediate halo?

PSZ2 G106.61+66.71 is the highest redshift ($z = 0.33140$) cluster in our sample detected with diffuse radio emission. This rich cluster with 82 galaxy members within a radius $r_{200} = 1.76$ Mpc (Wen & Han 2013) with an SZ mass $M_{500} = 4.67^{+0.35}_{-0.57} \times 10^{14} M_{\odot}$ (Planck-16). The BCG in this cluster is a radio bright source (NVSS J133024+490846, ‘A’) and about 180 kpc away from the Chandra X-ray peak (see Fig. 6 (a)&(c)).

Both uGMRT and LoTSS-I ($\sigma_{144}$=300 $\mu$Jy beam$^{-1}$) radio maps show the indication of an extended diffuse emission around the BCG (see Fig. 6 (a)). To study the diffuse emission in detail, we produced a point source subtracted uGMRT image by the method described in § 2. The contours of this image (black; Fig. 6 (c)) reveals that the diffuse emission has an extent of at least ~ 550 x 530 kpc (at 3$\sigma$). The computed flux density (using the profile fit method described in § 2) is 6.6±0.01 mJy within the 3 e-folding radius i.e., $3r_e = 507 \pm 17$ (see
The value of the radio power estimated from these values is rather high $P_{1,4GHz} = 6.34 \pm 0.19 \times 10^{23}$ W Hz$^{-1}$ at 1.4 GHz. Such an emission feature is usually seen in cool-core clusters as radio mini-haloes, albeit usually with an extent less than 500 kpc. Our Chandra X-ray analysis shows a low-brightness core with non-smooth profile (see Fig. 6 (d)), usually a feature of a weak cool-core cluster. X-ray maps also show elongation and substructures (red contours in Fig. 6 (c)). The total X-ray luminosity of the cluster is on the high side $L_X = 3.97_{-0.3}^{+0.4} \times 10^{44}$ ergs$^{-1}$, given its velocity dispersion, indicative of a merger.

This is not the typical scenario for a mini-halo found in relaxed, cool-core clusters. Thus, a second possibility is that the cool-core in this cluster has been dislodged from its original location due to a recent merger. Radio emission in PSZ2 G106, therefore, may be an intermediate radio halo, similar to other cases reported by, for instance, Savini et al. (2018); Kale, Shende, & Parekh (2019) and Raja et al. (2020).
In this context, it is important to mention that the cluster PSZ2 G089, with $M_{SZ} = 1.8 \times 10^{14} M_{\odot}$, is among the lowest mass clusters detected with a radio relic, and PSZ2 G808 with $M_{SZ} = 2.5 \times 10^{14} M_{\odot}$ is the lowest mass cluster to host both a radio halo and a Mpc size relic. In the latter case, the relic, at a distance 1.3 Mpc from the cluster centre, is the only such specimen in a cluster with the relic found beyond the virial radius, and is an outlier in the scaling relation between radio relic power and spatial extent. With these new detections, we update the $P_{1.4 \text{ GHz}} - M_{500}$ correlation in a much wider range of masses, especially towards the lower mass end.

We note that the unavailability of corrected LoTSS-I images (i.e. LoTSS-II images) in the public domain restricted us from making the spectral index maps that would provide further indications for the accurate classification of these sources. Nevertheless, the results obtained from our sample consisting of a small number of low-mass clusters are crucial, considering their rarity, and the implications of their existence on the study of non-thermal emission mechanisms over a wide range of masses of such systems. This also motivates us to examine low-mass clusters with SKA precursors such as uGMRT and MeerKAT etc. with a larger data set.

4 SUMMARY AND CONCLUSIONS

As a result, we provide the first systematic search for diffuse radio emission from low-mass clusters ($< 5 \times 10^{14} M_{\odot}$), in the overlap region of the Planck SZ catalogue (PSZ2) and the LoTSS data release 1, confirmed by deep uGMRT maps at 400 MHz obtained by us. Out of 12 clusters in our sample (see § 2), four are detected with diffuse radio emission. The peripheral structures detected in PSZ2 G111 and PSZ2 G080 clusters are the steep-spectrum relics. In the absence of accurate spectral properties, similar emission found in PSZ2 G089 is currently speculated to be that from a relic. Cluster PSZ2 G808 also hosts a radio halo along with the relic, and PSZ2 G106 is detected only with a central diffuse emission, argued to be an intermediate radio halo.

In this context, it is important to mention that the cluster PSZ2 G809, with $M_{SZ} = 1.8 \times 10^{14} M_{\odot}$, is among the lowest mass clusters detected with a radio relic, and PSZ2 G808 with $M_{SZ} = 2.5 \times 10^{14} M_{\odot}$ is the lowest mass cluster to host both a radio halo and a Mpc size relic. In the latter case, the relic, at a distance 1.3 Mpc from the cluster centre, is the only such specimen in a cluster with the relic found beyond the virial radius, and is an outlier in the scaling relation between radio relic power and spatial extent. With these new detections, we update the $P_{1.4 \text{ GHz}} - M_{500}$ correlation in a much wider range of masses, especially towards the lower mass end.

We note that the unavailability of corrected LoTSS-I images (i.e. LoTSS-II images) in the public domain restricted us from making the spectral index maps that would provide further indications for the accurate classification of these sources. Nevertheless, the results obtained from our sample consisting of a small number of low-mass clusters are crucial, considering their rarity, and the implications of their existence on the study of non-thermal emission mechanisms over a wide range of masses of such systems. This also motivates us to examine low-mass clusters with SKA precursors such as uGMRT and MeerKAT etc. with a larger data set.
