Prognostic role of distant disease-free interval from completion of adjuvant trastuzumab in HER2-positive early breast cancer: analysis from the ALTTO (BIG 2-06) trial

ABSTRACT

Background In HER2-positive breast cancer, time elapsed between completion of (neo)adjuvant trastuzumab and diagnosis of metastatic disease (‘trastuzumab-free interval’, TFI) is crucial to choose the optimal first-line treatment. Nevertheless, there is no clear evidence to support its possible prognostic role.

Methods In the Adjuvant Lapatinib and/or Trastuzumab Treatment Optimisation (ALTTO) trial, patients with HER2-positive early breast cancer were randomised to 1 year of either trastuzumab alone, lapatinib alone, their sequence or their combination. This exploratory analysis included only patients in the trastuzumab alone or trastuzumab plus lapatinib arms who developed a distant disease-free survival (DDFS) event. Overall survival (OS) was defined as time between date of DDFS event and death; age at diagnosis, tumour size and hormone receptor status were the variables included in the multivariate models.

Results Out of 8381 patients included in ALTTO, 404 patients in the trastuzumab alone and trastuzumab plus lapatinib arms developed a DDFS event, of which 201 occurred ≤12 months (group A) and 203 >12 months (group B) after completion of adjuvant trastuzumab. No significant difference in location of first DDFS event was observed (p=0.073); a numerically higher number of patients in group A than in group B developed brain metastasis (26% vs 15%). Choice of first-line therapy differed between the two groups (p=0.022): in group A, more patients received lapatinib (25% vs 11%) and less pertuzumab (8% vs 17%). Median OS was 29.3 and 18.4 months in groups B and A, respectively (adjusted HR 0.69; 95% CI 0.54–0.89; p=0.004). The longer OS for patients in group B was observed across the analysed subgroups as time between date of DDFS event and death; age at diagnosis, tumour size and hormone receptor status were the variables included in the multivariate models.

Conclusions TFI has prognostic value in patients with HER2-positive early breast cancer treated with adjuvant trastuzumab-based therapy. TFI is a valid tool to better individualise clinical recommendations and to design future first-line treatment trials for metastatic patients.

Key questions

What is already known about this subject?

► Despite its crucial role in guiding first-line treatment choices, there is currently lack of clear evidence to support the possible prognostic value of the time elapsed between completion of adjuvant trastuzumab and diagnosis of metastatic disease (‘trastuzumab-free interval’, TFI). A more profound understanding of how this interval might influence outcomes is crucial and may contribute to further individualise clinical recommendations and design future trials.

What does this study add?

► This exploratory analysis of the Adjuvant Lapatinib and/or Trastuzumab Treatment Optimisation (ALTTO) trial aimed to investigate the prognostic role of TFI in patients with HER2-positive early breast cancer that developed a distant disease-free survival event after exposure to adjuvant trastuzumab-based therapy. We observed that TFI has a strong prognostic value with a significantly better overall survival for patients relapsing >12 months following completion of adjuvant trastuzumab-based therapy. This result was observed irrespective of hormone receptor status and type of administered adjuvant anti HER2 therapy. These findings may indirectly support the current use of the 12-month cut-off to differently manage patients with HER2-positive breast cancer relapsing after prior exposure to anti-HER2 therapy in the early setting.

INTRODUCTION

Being historically considered an indicator of resistance to previously administered treatments, the time elapsed between the end of (neo)adjuvant therapy and diagnosis of metastatic breast cancer is among the crucial...
factors in the choice of the optimal first-line treatment following disease recurrence. This concept was first demonstrated in pivotal chemotherapy trials. Similarly, for patients with hormone receptor-positive breast cancer, the time since the end of adjuvant endocrine therapy is currently used by international guidelines to define resistance to endocrine therapy to guide not only treatment decision-making but also the eligibility for first-line endocrine treatment trials.

Disease-free interval has also a crucial role in patients with HER2-positive breast cancer to the extent that it should be considered as a key factor in the choice of the optimal first-line anti-HER2 therapy. Based on the inclusion criteria and results of the CLEOPATRA and EMILIA trials, respectively, the recommended first-line treatment is the combination of a taxane plus dual anti-HER2 blockade with trastuzumab and pertuzumab in patients recurring more than 12 months after the completion of (neo)adjuvant trastuzumab while TDM1 should be used in those developing disease recurrence while on (neo)adjuvant trastuzumab or within 6 months from its completion. In addition, the indication for TDM1 has been extrapolated for patients relapsing within 12 months of (neo)adjuvant trastuzumab completion although no data are available to guide the choice of the best first-line therapy when the time elapsed since completion of adjuvant trastuzumab is between 6 and 12 months. Notably, limited data are available on the performance of first-line therapies in patients relapsing following prior exposure to anti-HER2 targeted agents in the early setting.

Despite its crucial role in guiding first-line treatment choices, there is currently lack of clear evidence to support the possible prognostic impact of the time elapsed between completion of adjuvant trastuzumab and diagnosis of metastatic disease. Therefore, a more profound understanding of how this interval might influence outcomes is crucial and may contribute to further individualise clinical recommendations and design future trials. To address this important issue, we performed an exploratory analysis of the Adjuvant Lapatinib and/or Trastuzumab Treatment Optimisation (ALTTO) trial, the largest adjuvant randomised study conducted in patients with early-stage HER2-positive disease. In ALTTO, type and timing of first site of disease recurrence, as well as information on choice of first-line treatments received by patients who relapsed have been prospectively collected. Hence, this was a unique opportunity to investigate the impact of the time elapsed between completion of adjuvant trastuzumab and diagnosis of a distant relapse (‘trastuzumab-free interval’, TFI) on patients’ prognosis.

METHODS

Study design and patients

Details on the study design of the ALTTO trial were previously reported. Briefly, ALTTO (Breast International Group (BIG) 2-06/EGF106708 and North Central Cancer Treatment Group (Alliance) N063D) was an international, intergroup, open-label, randomised phase III study assessing the use of trastuzumab and/or lapatinib as adjuvant anti-HER2 targeted therapy in patients with HER2-positive early breast cancer.

To be eligible for the trial, the following inclusion criteria were required: completely excised and histologically confirmed invasive HER2-positive early breast cancer, node-positive disease or pathological tumour size of ≥1 cm in the case of no nodal involvement. Primary tumour samples from all patients were centrally tested to assess HER2 and hormone receptor status. HER2-positivity was defined according to the 2007 American Society of Clinical Oncology/College of American Pathologists guidelines. Expression of oestrogen and/or progesterone receptors in ≥1% tumour cells was the criteria used to define hormone receptor positivity.

Study procedures

Stratified permuted blocks with a 1:1:1:1 allocation ratio were used to prepare randomisation lists. Randomisation was performed with an interactive voice response system to one of the four anti-HER2 treatment arms: trastuzumab alone, lapatinib alone, sequential treatment with trastuzumab for 12 weeks followed by a 6-week washout period before other 34 weeks of lapatinib, and dual anti-HER2 blockade with trastuzumab plus lapatinib. In all treatment arms, adjuvant anti-HER2 therapy was administered for 1 year. Following the first interim analysis in 2011, the lapatinib arm was closed and adjuvant commercial trastuzumab was offered; a total of 1087 (51.8%) out of 2100 patients received at least one dose of trastuzumab.

For the purpose of the present analysis, only patients randomised to the 1-year duration trastuzumab arms (trastuzumab alone and trastuzumab plus lapatinib) were included.

Anti-HER2 treatment could be administered as per physician’s choice following chemotherapy completion (design 1), or concomitantly with a taxane after anthracycline-based chemotherapy (design 2) or with 6 cycles of docetaxel and carboplatin in an anthracycline-free regimen (design 2B). Adjuvant endocrine therapy had to be administered unless contraindicated according to local guidelines to all patients with hormone receptor-positive disease for at least 5 years. Radiotherapy was mandatory following breast-conserving surgery and was

Continued
performed after mastectomy based on the guidelines of each participating institution. Endocrine therapy and radiotherapy were administered after chemotherapy completion and concomitantly with anti-HER2 therapy.

As per study protocol, type and timing of first site of disease recurrence, as well as information on choice of first-line treatments that were administered to patients who developed disease recurrence had to be prospectively reported. For the purpose of the present analysis, only patients randomised in the trastuzumab alone and trastuzumab plus lapatinib arms who developed a distant recurrence were included. Patients who had other invasive disease-free survival (DFS) events (local and regional relapses, contralateral invasive breast cancers, second non-breast malignancies and deaths without event) with no distant recurrence were excluded from the present analysis.

The 12-month cut-off between the completion of adjuvant trastuzumab and the development of the first distant DFS (DDFS) event was used as the criteria to distinguish between two groups of patients relapsing with a TFI of ≤12 months (group A) and >12 months (group B). The choice of the 12-month cut-off was based considering the current recommendation for the choice of the first-line treatment,5 as well as a prior similar BIG research project conducted within the HERA trial.8

**Objectives and endpoints**

The aim of the current analysis was to investigate the prognostic role of TFI in patients with HER2-positive early breast cancer in terms of overall survival (OS) following the development of a DDFS event.

Baseline patients’ characteristics, patterns of relapse and choice of first-line treatment for metastatic disease were also assessed.

**Statistical methods**

Statistical assumptions and sample size calculations of the ALTTO trial were previously reported.5 The present analysis should be regarded as exploratory considering that it was not preplanned in the study protocol and the power of the statistical analyses performed was not prespecified. The updated ALTTO Database was used for all the analyses with a cut-off date of 14th of December 2016.11

Baseline characteristics, patterns of relapse and the choice of first-line treatment were compared between group A and group B according to TFI. Categorical variables were summarised with proportions and differences were tested using χ² test; continuous variables were reported using medians and IQR and differences were tested using Wilcoxon rank-sum test.

OS was defined as the time between the date of DDFS event and death. The impact of TFI on OS from distant recurrence was assessed in both univariate and multivariate Cox proportional hazards models. Age at diagnosis, tumour size and hormone receptor status were the variables included in the final multivariate models. Likelihood ratio test considered whether there was evidence of an interaction between TFI and hormone receptor status as well as between TFI and type of administered adjuvant.

Lambertini M, et al. ESMO Open 2020;5:e000979. doi:10.1136/esmoopen-2020-000979
The majority of patients (267, 66%) developed visceral metastasis as first DDFS event with no difference between the two groups (table 2). No significant difference in location of first DDFS event was observed (p=0.073); however, a numerically higher number of patients in group A developed brain metastasis (26% vs 15%).

After the development of DDFS events, no significant differences between the two groups were observed in terms of local treatments, use and type of chemotherapy (online supplemental table 1). First-line chemotherapy was administered to 251 (62%) patients. Taxane-based regimens were the most frequently used (57%). Among patients with hormone receptor-positive breast cancer, more patients in group A than group B received endocrine therapy as part of their first-line therapy (46% vs 29%; p=0.011). Anti-HER2 targeted therapy was part of the first-line treatment in 231 (57%) of the patients. The type of anti-HER2 treatment was differently distributed in the two groups (p=0.022): more patients in group A received lapatinib (25% vs 11%) and less pertuzumab (8% vs 17%).

Median follow-up after development of DDFS events was 17.5 months (IQR, 6.3–31.6 months), with no difference (p=0.092) between group A (15.2 months, IQR, 5.7–29.1 months) and group B (19.2 months, IQR, 7.1–33.6 months).

Patients in group B had a significantly longer OS as compared with those in group A. Median OS was 29.3 and 18.4 months in groups B and A, respectively (adjusted HR 0.69; 95% CI 0.48–0.98; p=0.004; figure 1A and online supplemental table 2). Similar results were observed when patients treated with first-line pertuzumab-based therapy (n=29) were excluded with a median OS of 26.8 and 18.2 months in groups B and A, respectively (adjusted HR 0.66; 95% CI 0.51–0.86; p=0.002; figure 1B and online supplemental table 2).

The longer OS for patients in group B as compared with those in group A was observed across the analysed subgroups with no interaction according to hormone receptor status (p=0.814) nor type of administered adjuvant anti-HER2 treatment (p=0.233).

In groups B and A, respectively, median OS was 33.6 and 23.1 months among patients with hormone receptor-positive disease (adjusted HR 0.69; 95% CI 0.48–0.99; figure 2A and online supplemental table 2), and 19.2 and 14.1 months among those with hormone receptor-negative disease (adjusted HR 0.68; 95% CI 0.48–0.98; figure 2B and online supplemental table 2).

In groups B and A, respectively, median OS was 29.3 and 21.3 months among patients who received trastuzumab alone (adjusted HR 0.80; 95% CI 0.55–1.17; figure 3A and online supplemental table 2), and 29.4 and 17.0 months among those who received trastuzumab plus lapatinib (adjusted HR 0.55; 95% CI 0.38–0.80; figure 3B and online supplemental table 2) as adjuvant anti-HER2 treatment.

### RESULTS

A total of 8381 patients with HER2-positive early breast cancer were randomised in ALTTO between June 2007 and July 2011. Among patients enrolled in the trastuzumab and trastuzumab plus lapatinib arms (N=4190), 404 (9.6%) developed a DDFS event of which 201 occurred ≤12 months (group A) and 203 >12 months (group B) following completion of adjuvant trastuzumab (online supplemental figure S1).

Baseline clinicopathological characteristics are summarised in table 1. As compared with patients in group B, those in group A were older (p=0.013), had larger tumours (p=0.004) and had more often hormone receptor-negative disease (p<0.001). No difference in nodal status, nor in type of administered systemic therapy was observed between the two groups.

### Table 2 Location of first disease relapse at a distant site

| Type of metastatic presentation (distant relapse)* | Group A (≤12 months) | Group B (>12 months) |
|-------------------------------------------------|----------------------|----------------------|
| No. (%) | N=201 | N=203 | P value |
| Visceral | 139 (69) | 128 (63) | 0.195 |
| Non-visceral | 62 (31) | 75 (37) |

*Patients with bone, skin, lymph node and soft tissue were considered as non-visceral; all the others were considered as visceral.

†For patients who developed relapse in more than one organ, the first site of distant metastasis was defined by prespecified importance in the following order: brain, liver, lung, bone and others. The category ‘others’ included: skin, lymph node, soft tissue, pleura and other rarer sites of relapse.

anti-HER2 treatment. Results were presented using the Kaplan-Meier survival plots.

Considering the significant OS benefit associated with the use of pertuzumab-based first-line therapy and the observed different distribution of its use between groups A and B, an exploratory OS analysis was conducted by excluding patients exposed to this anti-HER2 agent.

Statistical analyses were two-sided; p values of <0.05 were considered statistically significant. Statistical analyses were performed by DAT using SAS V.9.4.

### Table 2 Location of first disease relapse at a distant site

| Type of metastatic presentation (distant relapse)* | Group A (≤12 months) | Group B (>12 months) |
|-------------------------------------------------|----------------------|----------------------|
| No. (%) | N=201 | N=203 | P value |
| Visceral | 139 (69) | 128 (63) | 0.195 |
| Non-visceral | 62 (31) | 75 (37) |

*Patients with bone, skin, lymph node and soft tissue were considered as non-visceral; all the others were considered as visceral.

†For patients who developed relapse in more than one organ, the first site of distant metastasis was defined by prespecified importance in the following order: brain, liver, lung, bone and others. The category ‘others’ included: skin, lymph node, soft tissue, pleura and other rarer sites of relapse.

Median follow-up after development of DDFS events was 17.5 months (IQR, 6.3–31.6 months), with no difference (p=0.092) between group A (15.2 months, IQR, 5.7–29.1 months) and group B (19.2 months, IQR, 7.1–33.6 months).

Patients in group B had a significantly longer OS as compared with those in group A. Median OS was 29.3 and 18.4 months in groups B and A, respectively (adjusted HR 0.69; 95% CI 0.48–0.98; p=0.004; figure 1A and online supplemental table 2). Similar results were observed when patients treated with first-line pertuzumab-based therapy (n=29) were excluded with a median OS of 26.8 and 18.2 months in groups B and A, respectively (adjusted HR 0.66; 95% CI 0.51–0.86; p=0.002; figure 1B and online supplemental table 2).

The longer OS for patients in group B as compared with those in group A was observed across the analysed subgroups with no interaction according to hormone receptor status (p=0.814) nor type of administered adjuvant anti-HER2 treatment (p=0.233).

In groups B and A, respectively, median OS was 33.6 and 23.1 months among patients with hormone receptor-positive disease (adjusted HR 0.69; 95% CI 0.48–0.99; figure 2A and online supplemental table 2), and 19.2 and 14.1 months among those with hormone receptor-negative disease (adjusted HR 0.68; 95% CI 0.48–0.98; figure 2B and online supplemental table 2).

In groups B and A, respectively, median OS was 29.3 and 21.3 months among patients who received trastuzumab alone (adjusted HR 0.80; 95% CI 0.55–1.17; figure 3A and online supplemental table 2), and 29.4 and 17.0 months among those who received trastuzumab plus lapatinib (adjusted HR 0.55; 95% CI 0.38–0.80; figure 3B and online supplemental table 2) as adjuvant anti-HER2 treatment.
DISCUSSION

To our knowledge, this is the largest analysis aiming to investigate the prognostic impact of TFI in patients with HER2-positive early breast cancer that developed a DDFS event after exposure to adjuvant trastuzumab-based therapy. We observed that TFI has a strong prognostic role with a significantly better OS for patients relapsing >12 months following the end of adjuvant trastuzumab-based therapy. This result was observed irrespective of hormone receptor status and type of administered adjuvant anti-HER2 therapy. These findings may indirectly support the current use of the 12-month cut-off to differently manage patients with HER2-positive breast cancer relapsing after prior exposure to anti-HER2 therapy.

Whereas the 12-month cut-off is commonly used in clinical practice, limited evidence is available so far on its role in influencing the prognosis of patients. A prior exploratory analysis of the HERA trial including 187 patients developing a DDFS events following exposure to adjuvant trastuzumab investigated the potential prognostic role of TFI. No statistically significant relationship between TFI and OS was observed (adjusted HR 0.98; p=0.27). However, median OS from the development of a DDFS event was numerically longer among patients with a TFI >12 months after the end of adjuvant trastuzumab (23.7 vs 17.8 months; p=0.47). Similarly, an Italian retrospective study including 101 patients showed that the 6-month cut-off for the TFI appeared to have prognostic value but the result did not reach statistical significance. Median OS was 48.3 and 29.5 months for patients with a TFI of more and less than 6 months, respectively (HR 0.73; 95% CI 0.39–1.37; p=0.331). With a larger sample size, our analysis shows the important prognostic role in influencing the prognosis of patients.

Figure 1  Overall survival (OS) in the whole cohort of patients (A) and after excluding those who received first-line pertuzumab-based therapy (B).
of TFI with an almost 11-month absolute median OS advantage (18.4 vs 29.3 months) for patients relapsing >12 months following completion of adjuvant trastuzumab (adjusted HR 0.69; 95% CI 0.54–0.89; \( p=0.004 \)).

In addition, our results provide further evidence on the different behaviour of HER2-positive tumours according to hormone receptor status. As compared to patients with hormone receptor-positive disease, those with hormone receptor-negative tumours had higher likelihood to relapse within 12 months following completion of adjuvant trastuzumab and had poorer OS irrespective of TFI. These data further highlight the need to pursue in research efforts aiming to improve the outcomes of patients with metastatic HER2-positive disease with different approaches according to hormone receptor status. These efforts would be even more relevant for patients relapsing during or soon after completion of anti-HER2 therapy who are characterised by particularly poor outcomes.

The different recommendations on the use of first-line therapy in patients relapsing after prior exposure to anti-HER2 therapy are currently mostly based on the inclusion criteria of major randomised trials conducted in the metastatic setting. However, a small number of patients included in these trials were enrolled after failure of (neo) adjuvant anti-HER2 therapy. Limited evidence, derived mostly from small retrospective studies, is currently available on the performance of first-line anti-HER2 therapy in patients relapsing after prior exposure to targeted agents in

![Figure 2](image)

**Figure 2** Overall survival (OS) in patients with hormone receptor (HR)-positive breast cancer (A) and in patients with HR-negative breast cancer (B).
Based on these studies, it cannot be excluded that patients exposed to anti-HER2 targeted treatment in the early setting may experience a smaller benefit with first-line therapy. In ALTTO, type of treatment received after experiencing disease relapse was collected, but no proper data are available on the duration of first-line systemic therapy with a specific focus on anti-HER2 agents. Therefore, the performance of first-line anti-HER2 treatments in patients with relapse after adjuvant trastuzumab-based therapy could not be assessed. In the ongoing adjuvant trials, collecting information on duration of exposure to subsequent lines of therapy should be considered a research priority to improve the counselling of patients relapsing following exposure to anti-HER2 targeted treatment in the early setting. In addition, real-world data from the currently ongoing registries in the advanced setting should also be considered an important source of data to explore this unmet medical need.

With the current availability of several effective targeted agents as (neo)adjuvant and post-neoadjuvant treatment for patients with HER2-positive breast cancer, defining the optimal performance of first-line anti-HER2 therapies in those relapsing after prior exposure in the early setting is becoming a clinically relevant research area.

The present analysis has some limitations that should be acknowledged. This is an unplanned exploratory...
analysis and with a relatively small sample size. Some potential important prognostic factors (like performance status and disease volume) were not available and so they could not be included in the multivariate model. Notably, 66% of the patients included in this analysis received trastuzumab sequentially to chemotherapy (design 1). In addition, only 57% of the patients received first-line anti-HER2 therapy and few of them received the more recently approved targeted therapies including pertuzumab and T-DM1. These circumstances may explain the poorer OS observed in our study when compared with current expectations in this setting.35 However, major strengths are that these results come from a large phase III trial, and that the data used for the analyses were prospectively collected during trial conduction as requested and detailed in the study protocol. Only patients receiving adjuvant trastuzumab-based treatment for 1 year were included to mirror current clinical standard.

In conclusion, our exploratory analysis conducted within the ALTTO trial suggests that the 12-month cut-off for the TFI has a strong prognostic role. Patients experiencing a DFS event ≤12 months following the completion of adjuvant trastuzumab had a significantly shorter OS (defined as time between the development of DFS event and death) than those relapsing >12 months. These findings may help physicians in counseling patients with HER2-positive disease relapsing after exposure to anti-HER2 therapy in the early setting and confirm that TFI is a valid tool to further individualize clinical recommendations and to design future trials in the metastatic setting. Additional research efforts are awaited to further explore the performance of first-line anti-HER2 targeted therapy in patients relapsing following exposure to these agents in the early setting.
