Abstract. While humans can effortlessly transform complex visual scenes into simple words and the other way around by leveraging their high-level understanding of the content, conventional or the more recent learned image compression codecs do not seem to utilize the semantic meanings of visual content to its full potential (Fig. 1). Moreover, they focus mostly on rate-distortion and tend to underperform in perception quality especially in low bitrate regime, and often disregard the performance of downstream computer vision algorithms, which is a fast-growing consumer group of compressed images in addition to human viewers. In this paper, we (1) present a generic framework that can enable any image codec to leverage high-level semantics, and (2) study the joint optimization of perception quality, accuracy of downstream computer vision task, and distortion. Our idea is that given any codec, we utilize high-level semantics to augment the low-level visual features extracted by it and produce essentially a new, semantic-aware codec (Fig. 3). And we argue that semantic enhancement implicitly optimizes rate-perception-accuracy-distortion (R-PAD) performance. To validate our claim, we perform extensive empirical evaluations and provide both quantitative and qualitative results.

1 Introduction

The pervasive use of mobile devices equipped with powerful cameras has pushed the generation of high-definition images and videos to an unprecedented rate. Such constant and ubiquitous data collection poses an urgent motivation for better visual data compression techniques.

Consider how humans compress visual input (Fig. 1): The sender first comprehends the visual content and then extracts high-level semantic descriptions. She then describes them in a few words and the receiver, upon obtaining this information, can reconstruct visually complex scenes. The fact that we can all leverage our understanding and associate concise high-level concepts such as “boat” with pixel intensities and arrangements enables us to condense even tens of millions of pixels into several words and

\*Work done during internship at SenseBrain.
the other way around. Being able to effortlessly leverage high-level meanings of visual content to increase the efficiency of its processing has been a long-sought goal since at least the advent of MPEG-7 [31]. However, efforts in this direction have seen limited success due to the sheer difficulties in computationally implementing how humans extract and leverage the high-level meanings of low-level visual features. As of today, existing image compression algorithms still underutilize high-level semantics [20, 10, 44, 4, 5, 46, 47, 7, 8, 9, 42, 35, 29, 33, 24, 48, 45, 28].

Another limitation in existing codec design paradigms is that the models are typically optimized only for rate-distortion (R-D), yet the traditional R-D metrics are insufficient especially in low bitrate [11, 12], causing the codecs to produce visually unappealing results in low-rate compression.

Apart from human viewers, existing codecs also ignore “machine viewers”: the downstream computer vision algorithms performing various tasks such as face recognition, object tracking, etc. With the fast-expanding use of machine learning tools in image understanding tasks, rate-accuracy (R-A), where “accuracy” refers to the performance of downstream machine viewers, must become another important axis when evaluating image codec.

We propose a simple framework to implicitly achieve joint perception-accuracy-distortion optimization with any given image codec through semantic enhancement (JPAD-SE). The idea is to augment the hidden representations constructed from low-level features by existing codecs with high-level semantics. Concretely, concurrent to a given image codec \( c \), we additionally build a semantics codec \( s \) to reconstruct visual content from semantics. To compress, the encoders \( e \) and \( e_s \) work to convert the image and its semantics into compressible hidden codes. These codes will be stored or transmitted. To decompress, \( d \) and \( d_s \)

---

3 As a sign of the image compression community realizing the severity of this issue, the low-rate track of the 2020 Workshop and Challenge on Learned Image Compression (CLIC) is for the first time using human ratings over PSNR/MS-SSIM [51] as the primary metric [3].
reconstruct visual content from the respective hidden codes. Then a fusing network $F$ combines their outputs to produce the final reconstruction (Fig. 3). Effectively, we enhance a given codec $c$ with $s$ and $F$, producing a new, semantic-aware codec with $c, e_s$ jointly as the encoder and $d, d_s, F$ together as the decoder.

By simply enabling the codec to leverage semantics, we are implicitly optimizing for perception-accuracy-distortion performance: First, just like humans know that the sky is usually blue and grass green, a semantic-aware codec can learn what low-level features are more likely to appear in different semantic regions. This “prior knowledge” enables the decoder to create more natural and perceptually pleasing reconstructions. This also helps remove noise on the low-level visual features without training on noisy examples since noise can be considered as unnatural visuals. Second, this high-level comprehension of the image helps the codec retain important semantic information that is critical for downstream computer vision tasks such as object detection or tracking. Last but not least, since complex low-level features can often be packed into concise high-level semantic concepts, more information can be conveyed using a blend of semantics and low-level visuals than using only the latter. Therefore, a semantic-aware codec can leverage this extra degree of freedom and save bits.

We test on Cityscapes [18] and ADE20k [57,58] at 1024×512 resolution with learned and conventional codecs (JPEG, JPEG 2000 [44], WebP [20], and BPG [10]) as the backbone image codec $c$ and semantic and instance segmentation maps as the semantics. We both quantitatively and qualitatively show that our semantically-enhanced (SE) codecs achieve favorable rate-perception-accuracy-distortion performance as quantified via a large-scale user study, accuracy of a downstream bounding-box object detec-
Fig. 3: Our proposed framework consists of a given backbone image codec $c$, a semantics codec $s$, and a fusing network $F$. To compress, we use $e$ and $e_s$ together as the encoder that constructs a hidden representation of the image with both high-level semantics and low-level visuals. To decompress, $d$, $d_s$, and $F$ work jointly as the decoder. $d$ and $d_s$ reconstruct visual content from the compressed visuals and semantics, respectively. $F$ fuses their outputs to produce the final result. The 3D modules are learned, whereas the 2D ones are not necessarily so. In particular, we tested with both learned and engineered codecs as the backbone $c$. For the learned components, a three-phase training scheme was proposed to effectively learn a balance between distortion and perception quality [11,12]. We focus on segmentation maps as semantics for this work although the framework is generic.

To sum up, the main contributions of this work include:

- **Evaluating a novel idea**: We conduct a systematic study on the efficacy of semantics as a fundamental substitute for visuals in the general image compression setting.

- **A framework**: We propose a generic framework that enables any given codec, learned or hand-crafted, to leverage high-level semantics.

- **New codec evaluation metrics**: We focus on perception-accuracy-distortion performance on full-resolution images quantified by a large-scale user study, accuracy of downstream bounding-box object detection, and three distortion metrics.

- **An observation**: We hypothesize and verify using extensive empirical evaluations that enhancing codecs with high-level semantics has the effect of implicitly optimizing perception-accuracy-distortion.
2 Related Work

Image Compression The key components of an image codec include an encoder, which transforms the original image into a more compressible representation, and a decoder, which reconstructs the image from a possibly quantized version of this new representation. Traditionally, these components were hand-crafted by experts. Some commonly used engineered image codecs include JPEG, JPEG 2000 [44], WebP [20], BPG [10], PNG [2], and FLIF [1]. PNG and FLIF are designed only for lossless compression. Many works on learned compression have emerged over recent years and the proposed codecs with learnable components produced favorable results compared to the traditional ones but are conceptually much simpler due to their end-to-end nature [4, 46, 47, 8, 9, 42, 35, 29, 33, 24, 48, 45]. Our proposed method can work with any learned or engineered image codec, leveraging high-level semantics to improve compression quality as measured by joint PAD performance.

Semantics for Image Compression Most existing codecs do not explicitly utilize high-level semantics during encoding or decoding. [37, 29] proposed methods for content-weighted bitrate control without explicitly utilizing high-level semantics. [5, 6] explored explicitly utilizing semantics in image compression but to a limited extent. To be specific, [5] only used semantics for bitrate allocation in a somewhat constrained setting, requiring that users choose to preserve some semantic regions while ignoring others. Moreover, [5] ignored R-D performance and only quantified R-P performance of its semantics-aware codec indirectly through an uncommon mIoU vs. bpp curve. [6] used semantics only for up/downsampling and focused only on R-D performance. Also, BPG was used to compress the residuals of its semantics-aware codec, making it difficult to assess the contributions from semantics. Our work differs from the previous two works mainly in the following three aspects. First, we study how semantics can be explicitly used as a fundamental substitute to the low-level visuals instead of only as some auxiliary side information. Second, our work considers the general compression setting without any limiting assumption such as that distinct semantic regions are of different levels of importance to the end user, which is essential to [5]. Finally, through rigorous quantitative study, we demonstrate the improved performance of our semantics-aware codecs in terms of R-P, R-D, and R-A.

It is worth noting that the recent learned codecs, due to their end-to-end nature, might be implicitly leveraging semantics. Nevertheless, no existing work concretely verified this hypothesis and our work demonstrates that explicitly employing semantics achieves significant improvements in R-PAD performance.

Perception Quality Image quality assessment is a complicated topic and it has been long known that a small distortion as measured by a simple pairwise metric function does not guarantee better visual quality [51]. [11] defined a measure for human perception quality to be $L_{\text{div}}(p_{\mathbf{x}}, p_{\tilde{\mathbf{x}}})$, where $L_{\text{div}}$ is a divergence measure between probability density (or mass) functions and $p_{\mathbf{x}}$, $p_{\tilde{\mathbf{x}}}$ are the density (or mass) functions of the synthesized and the real images, respectively. This measurement essentially assigns a higher perception quality to synthesizers that are able to produce pixel values and arrangements that are more likely to appear in real-world. And it has been shown to correlate...
well with human opinion scores primarily in GAN studies [12]. In this work, we quantify perception quality directly through a user study that, to the best of our knowledge, has the largest scale among existing studies in terms of the number of codecs tested, the range of bitrates covered, and the number of users involved.

To optimize perception quality, existing works add a quantification term for perception in the form of some GAN loss to the overall objective function [48, 43, 5]. In contrast, we show that sending semantics to the decoder naturally helps increase perception quality. Note that in some cases (when \( s \) and \( F \) in Fig. 3 are implemented with one network), our method can be interpreted as a blend of these two methods.

**Compression Objective** In existing works, most focus only on R-D and ignore perception quality [44, 20, 10, 44, 46, 47, 7, 8, 9, 42, 39, 33, 24, 48, 45, 6]. Many codecs in this category fail to produce reconstructions that look good to humans despite their excellent R-D performance [5]. The underlying reason of this mismatched performance is that distortion, including the more recent “perceptual” distortions [51, 23, 55], is fundamentally at odds with perception quality especially in low bitrate settings [11]. This suggests that when designing codecs, we should simultaneously consider at least these two metrics for better overall reconstruction quality.

[5] focuses on R-P while ignoring distortion completely. The reconstructions look appealing at the first glance but have low fidelity. Some others [48, 43] focus on joint perception-distortion optimization, but only on thumbnail images. To the best of our knowledge, we are the first to focus on jointly optimizing perception quality, accuracy, and distortion.

**Semantic Image Synthesis** Semantic image synthesis methods aim at synthesizing photorealistic and semantically consistent images from given semantic descriptions such as text, sketches, and semantic segmentation maps [52, 53, 54, 56, 22, 39, 40, 59, 50, 36, 16, 38]. This problem can be modeled and subsequently solved with a conditional GAN as follows. Given semantics \( x_{\text{sem}} \), one would like a generator \( G \) that can generate an image \( G(x_{\text{sem}}) \) that has the given semantics and is distributed according to the distribution of some real image \( x \). This goal can be achieved by training \( G \) (and a discriminator \( D \)) with the following conditional GAN objective function:

\[
L_{\text{GAN}} = \mathbb{E} f(D(x, x_{\text{sem}})) + \mathbb{E} g(D(G(x_{\text{sem}}), x_{\text{sem}})),
\]

where \( f \) and \( g \) depend on the GAN formulation used.

Recent methods have been able to synthesize high-definition photographic images with pixel-level semantic accuracy from semantic segmentation maps using conditional GANs [59, 50, 36, 16, 38]. Instance-wise low-level visual features are sometimes used to enhance the realism of the synthesized images [50]. For semantic image synthesis, there is no “original image” and the evaluation standards are completely different: The generated images are typically evaluated in terms of perception quality and semantic consistency. In this work, we consider rate, perception quality, performance of downstream vision algorithms, and distortion with respect to the original image.
3 Building Semantically-Enhanced Codecs

The Main Pipeline  Denote the input image as \( x \in X \) and its semantics \( x_{\text{sem}} \in X_{\text{sem}} \), where \( X \) is a space of real tensors with shape \( H \times W \times C \). The semantics can be obtained computationally with another component that may be jointly optimized with our compression pipeline. Consider a given backbone image codec \( c = d \circ e \), where \( e : X \rightarrow Z \) is an encoder, \( d : Z \rightarrow X \) a decoder, \( \circ \) denotes function composition, and \( e(x) \in Z \) is a hidden representation of \( x \) in some feature space \( Z \) that will be transmitted after potential quantization. Concurrent to \( c \), consider a semantics codec \( s = d_s \circ e_s \), where \( e_s : X_{\text{sem}} \rightarrow Z_{\text{sem}} \) is again an encoder, \( d_s : Z_{\text{sem}} \rightarrow X \) a decoder, and \( e_s(x_{\text{sem}}) \) a hidden representation of \( x_{\text{sem}} \). On top of \( c \) and \( s \), define another network \( F : X \times X \rightarrow X \) that maps the tuple \( (c(x), s(x_{\text{sem}})) \) to \( \tilde{x} \), the reconstructed image. Concisely, this pipeline can be described as follows.

\[
\begin{align*}
x & \mapsto c(x) \\
x_{\text{sem}} & \mapsto s(x_{\text{sem}}) \\
\{ (c(x), s(x_{\text{sem}})) \} & \xrightarrow{F} \tilde{x}
\end{align*}
\]

Fig. 3 gives a schematic illustration of this framework. And as a concrete example, \( c \) can be JPEG and \( s \), \( F \) neural networks that may be jointly optimized. When \( c \) is a learned codec, it may be included in the joint optimization. The proposed framework enjoys wide applicability since any existing image codec can be plugged into the pipeline as the backbone \( c \) and be enhanced semantically.

Note that high-level semantics can take many forms. For example, one can use a class segmentation map, an instance segmentation map, sketches, a set of bounding boxes, text descriptions and so on. And each form potentially requires an architecturally different \( s \).

A valid choice for \( d_s \) is a GAN conditioned on the semantics. Then the overall objective function is a weighted combination of a distortion term, a GAN term (Eq. 1 with \( d_s \) in the place of the generator), and optionally, a rate term. It is worth noting that the optimization for perception quality and accuracy is implicitly achieved via utilizing semantics instead of explicitly including loss terms in the objective function. Note that in the case where \( d_s \) and \( F \) are implemented as a single network, the GAN term has an additional effect of enhancing perception quality as it can be viewed as a divergence measure between the densities of \( \tilde{x} \) and \( x \) [19].

We empirically found it ideal to train the model in separate stages instead of in one stage with a weighted combination of all loss terms. The strategy is described in the following subsection.

A Three-Phase Training Scheme  To have \( d_s \) successfully learn how to synthesize visuals from semantics, one may begin with training it to minimize only the GAN loss \( L_{\text{GAN}} \) in Eq. 1 with \( d_s \) in the place of the generator), and optionally, a rate term. It is worth noting that the optimization for perception quality and accuracy is implicitly achieved via utilizing semantics instead of explicitly including loss terms in the objective function. Note that in the case where \( d_s \) and \( F \) are implemented as a single network, the GAN term has an additional effect of enhancing perception quality as it can be viewed as a divergence measure between the densities of \( \tilde{x} \) and \( x \) [19].

We empirically found it ideal to train the model in separate stages instead of in one stage with a weighted combination of all loss terms. The strategy is described in the following subsection.
Some valid choices for $L_{\text{dist}}$ include the $L^1$ loss, PSNR, or MS-SSIM \cite{51}. Finally, to mitigate the issue that GAN loss usually dominates distortion loss, leading to hallucination artifacts \cite{5}, we jointly optimize all networks with respect to $L_{\text{dist}}$ only. We summarize the three training phases below, in which we ignore the rate term for simplicity.

- **Phase 1**: Train $d_s$ to minimize $L_{\text{GAN}}$ in Eq. \ref{eq:1} with $d_s$ being the generator therein.
- **Phase 2**: Train $s$, $F$ (and $c$, if applicable) to minimize $\lambda L_{\text{GAN}} + L_{\text{dist}}$ for some $\lambda > 0$;
- **Phase 3**: Train $s$, $F$ (and $c$, if applicable) to minimize $L_{\text{dist}}$.

**Compressing the Semantics** Instead of implementing the semantics encoder $e_s$ with yet another network, we propose a simple but effective non-learned approach to better utilize some characteristics of semantics in the form of a segmentation map. \cite{5} We observe that pixel-wise semantics in the form of a segmentation map usually contains large uniform areas separated by a few class or instance boundaries. Instead of compressing the map as a bitmap image, which is prone to creating semantically impossible artifacts such as blurred boundaries, we represent it with a set of paths, each being the boundary of a semantic region. For each path, we additionally store a single number encoding the class or instance identity of the semantic region. And we only keep the two end points for each line segment in the paths. The path-based representation can be obtained from the map with a graph traversal algorithm. Since the boundaries rarely change drastically in natural images, we apply a simple delta encoding on the paths and entropy code the resulting sequences to further reduce the bitrate. This algorithm is lossless but if desired, one can convert it to a lossy one by smoothing the paths. On Cityscapes at $1024 \times 512$ resolution, this method (lossless version) reduces the average semantics overhead (class and instance segmentation maps combined) from approximately 0.30 bpp (computed using the rendered maps) to approximately 0.03 bpp.

### 4 Experiments

In this section, we present the experimental results of our codecs on Cityscapes \cite{18} and ADE20k \cite{57,58} both at $1024 \times 512$ resolution. The former consists mostly of street scenes and the latter generic everyday images. We test our pipeline using both learned and conventional codecs including JPEG, JPEG 2000, WebP, and BPG as the backbone codec $c$. Extensive ablation study will be performed to demonstrate the usefulness of semantics. Note that we focus our evaluations on low and medium bitrates since distortion and perception diverge most severely in this regime and empirically, existing codecs typically fail to provide visually appealing results, which necessitates a better compression method and also helps demonstrate the effectiveness of semantics for improving compression quality.

In these experiments, we keep our instantiation of the general framework simple for two reasons: First, we would like to show that even with a simple implementation and little engineering effort, semantic enhancement can bring significant improvements

\cite{5} proposed a similar method with limited motivation and details.
to perception-accuracy-distortion, which would further prove the usefulness of high-level semantics in compression. Second, this work focuses on evaluating the high-level idea of leveraging semantics instead of pursuing state-of-the-art performance. Thus, we feel that leaving out many sophisticated engineering used in other learned compression works can help simplify the presentation and make the interpretation of results easier.

4.1 On Choice of Baselines

Note that different from most existing works on learned compression, we are not proposing a single new codec. Rather, we are proposing a generic framework that can be used to enhance any given codec. As a result, our experimental evaluations focus on demonstrating the relative improvements gained from semantic enhancement with respect to the chosen backbone codecs to show the usefulness of semantics. This contrasts most existing works, where it would make sense to compare one or two newly proposed codecs “in parallel” against existing methods. Therefore, when interpreting our results, each codec should be primarily compared against and only against its semantically-enhanced counterpart.

Also, note that we mostly employ engineered codecs such as BPG as our backbone codecs due to their speed and memory efficiency. And we extensively test with all popular engineered lossy codecs. Due to the wide applicability of our method, we cannot exhaustively evaluate all possible backbone codecs. Nevertheless, at the time of this writing, BPG still performs on par with state-of-the-art learned codecs in terms of R-D [28]. Thus, our results on BPG should let us gauge how much improvement our SE pipeline can bring to existing learned codecs. We leave rigorously comparing more learned codecs against their SE counterparts as future work.

4.2 Experimental Details

We refer the readers to the supplementary materials for details on ADE20k and on architecture and training.

Dataset For Cityscapes, we trained the models on the densely-annotated training set of 2975 images. For evaluation, we randomly sampled 10 images from each of the three cities in the validation set to create a test set. We used the ground truth class segmentation map and instance boundary map instead of learned ones as the semantics to simplify the set-up and focus more on compression. Nevertheless, we provide results from using learned semantics at test time to demonstrate how our pipeline would perform with the currently available segmentation technology. In these cases, the class (instance) segmentation maps were extracted by a trained DeepLab v3+ [15] (Mask R-CNN [21]). One may also train the compression pipeline with learned semantics or jointly train the segmentation network with the codec and we leave this as a future work. For Cityscapes, the semantics was losslessly compressed following descriptions in Section 3. A PPM [17] coder was used on the delta encoded boundaries. On the 30-image test set of Cityscapes, the average semantics bpp overhead is 0.03.
Evaluation  To quantify R-P performance, we conducted a comprehensive user study on Amazon Mechanical Turk (MTurk). For each pair of original and SE codecs with comparable bpp values, we created a questionnaire consisting of a sequence of images for 30 distinct workers by randomly sampling 10 images out of our 30-image Cityscapes test set, producing a total of 300 responses per comparison. For each image in a questionnaire, we presented the original and reconstructions from the two codecs with relative orders of the latter two randomized. The task for the worker was to choose between the compressed images which one they thought was a better compressed version of the original with the only standard being their subjective opinion. As quality control, three sanity checks were added to random positions in each questionnaire using 3 more randomly chosen test images, in which one of the compressed images was produced by a lossless codec. Failing to choose the lossless codec in any of the sanity checks will cause a response to be rejected and the job reposted to other workers. We also rejected responses finished within 60 seconds to further filter out workers that picked images quickly at random and happened to have passed all three sanity checks by luck.

To measure R-A performance, we used bounding-box object detection as an example to show that the SE codecs produce reconstructions that not only look better to human viewers but also enable machines to achieve better performance on high-level vision tasks. For this study, we used a trained Faster R-CNN from [14] for bounding-box object detection on the codec reconstructions. Detection performance is reported using AP@IoU=.50:.05:.95, the primary challenge metric of COCO 2019 [30]. We used LPIPS [55], MS-SSIM [51], and PSNR as the distortion metrics to quantify R-D performance. LPIPS measures the distance between two images using the deep features learned by a trained classification network. We used the authors’ official implementation (v0.1) with default settings, which uses an AlexNet [26] as the trained network. Note that although LPIPS was named a “perceptual” metric by the authors, it is still a pairwise metric that does not perfectly align with the perception quality [11]. Nevertheless, the authors in [55] showed that LPIPS aligns with human perception much better than the more traditional distortion losses.

4.3 Main Results

In this section, we present the main results of our study. Following the trend in learned image compression community [3], we consider human ratings to be the most important metric among perception, accuracy, and distortion and therefore present R-P results first since in low-rate compression, human raters are much more reliable than traditional distortion metrics [11,12,3]. Quantitative evaluations will be performed on Cityscapes and qualitative results will be provided for both Cityscapes and ADE20k. We refer the readers to the supplementary materials for the qualitative results on ADE20k.

Rate-Perception  Fig. 4 quantitatively shows that the SE codecs produce more visually appealing reconstructions compared to the originals. Indeed, the SE codecs are almost

5 We did not choose segmentation because our pipeline involves transmitting segmentation maps to the receiver’s end. Thus, there would be no need to perform segmentation again.
Fig. 4: Rate-perception performance on Cityscapes. Each pair of neighboring bars represent two codecs compared by human raters. The raters were given the original test images and asked to choose from the pair which one they thought produced better compressions of the originals. The height of each bar shows the % of times this codec is preferred among 300 distinct user responses. Text annotations are the bpp values. For this and all results in the paper, the bpp overhead from semantics has already been included in the bpp values of the SE codecs. “LS” refers to using learned semantics extracted by off-the-shelf segmentation networks at test time. The SE models are almost always preferred, often by a considerable margin.

always preferred by the human raters, often by a considerable margin. From the visualizations in Fig. 2 it is clear that the SE codecs “understood” the images. To be specific, the original codecs typically failed to respect boundaries between semantic regions, producing image patches that lack realism. This can be seen in between the tires and the road surface, among other places. Indeed, we know that tires are not the same as the road surface in real-world, yet the non-SE codecs do not “understand” this. Even worse, some non-SE codecs produced severe artifacts, which are essentially low-level features that are not possible in real scenes. In comparison, even though the SE codecs could not get all the details correct due to the low bpp allowances, they preserved well the semantic boundaries and they rarely produced low-level features that are incoherent or unnatural.

Rate-Perception: Robustness Against Noise on Low-Level Visuals We have argued and demonstrated that the high-level knowledge gained via training helps the SE codecs produce more natural and perceptually appealing reconstructions. Intuitively, it should therefore also help the SE codecs distinguish between valid low-level features and artifacts for any given semantics. For undesired artifacts such as noise, the SE codecs should be able to filter them out in the reconstruction. As proof of concept, we added Gaussian noise to a test image to be compressed. And from Fig. 5, we can see that the SE codec indeed filtered out the added noise at test time whereas the original codec tried to reconstruct noise as well, which, in most scenarios, is undesirable.

It is worth pointing out that the SE model can achieve this denoising effect without having been trained with noisy examples. In contrast, existing denoising pipelines require noisy images for training. To obtain noisy images, one either ex-
plicitly device a synthetic noise model, which makes the generation process cheap but does not necessarily produce realistic noisy images [34]. Alternatively, one captures real noisy images and sometimes the corresponding ground truth images from the real world, which is certainly a nontrivial procedure [13].

Our work potentially opens up new directions for image denoising research, in which one does not need at all or no longer need as many noisy images for training to achieve the same level of denoising effect. This contrasts a branch of works aiming at removing the need for noisy-clean pairs during training [27] since our framework only requires clean-clean pairs.

**Rate-Accuracy** From Fig. 6, we see that for all of the five codecs, the object detector performs much better on the SE codecs’ outputs. In practice, this means that one can now transmit fewer bits to the receiver’s end for the machine agent to achieve a certain level of performance, that is, the agent can make a better decision faster. For the ever-growing set of machine-based vision tasks including autonomous driving and face recognition, this observation potentially makes the SE codecs more suitable than the existing ones. And considering how rapidly the industry is embracing automated algorithms for vision tasks and how ubiquitous these tasks are, these results are highly relevant and the SE codecs are much better geared toward an AI-powered future.

**Rate-Distortion** From Fig. 7, 8 and 2, we see that for all codecs, the SE models achieved comparable or better distortion at most bpp values. On both LPIPS and MS-SSIM, which are the distortion metrics that align more closely with human perception among the three [51,55], the SE codecs outperformed the originals in all cases except for BPG.

Note that to achieve their superior performance in terms of the more important R-P metric, the SE codecs likely had to compromise R-D to some extent due to the known
Fig. 7: Rate-distortion performance on Cityscapes. ↑ (↓) means the higher (lower) the better. Among the three distortion metrics used, PSNR, the most traditional one, has been known to be inconclusive in quantifying compression quality [51, 55]. LPIPS [55] and MS-SSIM [51] have been shown to align much better with human perception. The SE models achieve better or comparable rate-distortion performance, especially when characterized by the more accurate LPIPS and MS-SSIM.

Fig. 6: Rate-accuracy performance on Cityscapes. Each AP value was calculated with the same off-the-shelf bounding-box object detector operating on the codec’s reconstructions at that bpp. The higher the AP, the more accurate the detection. For all codecs, the SE model enables the downstream object detector to detect much more accurately at any given bpp.

Further, since compressing semantics is not the main focus of this work, we always losslessly compressed semantics using the aforementioned simple method, creating a constant bpp overhead of 0.03 that becomes significant in some of the extreme low-bitrate settings in which the evaluated BPG-SE models mainly operated, where it may suffice to use lossy compression instead and reduce rate.

For the models using a learned codec as \(c\), we also provide results from using learned semantics at test time. These SE models still obtained performance comparable to those using ground truth semantics despite the imperfect segmentation between distortion and perception [11, 12]. Further, since compressing semantics is not the main focus of this work, we always losslessly compressed semantics using the aforementioned simple method, creating a constant bpp overhead of 0.03 that becomes significant in some of the extreme low-bitrate settings in which the evaluated BPG-SE models mainly operated, where it may suffice to use lossy compression instead and reduce rate.

These SE models still obtained performance comparable to those using ground truth semantics despite the imperfect segmentation between distortion and perception [11, 12]. Further, since compressing semantics is not the main focus of this work, we always losslessly compressed semantics using the aforementioned simple method, creating a constant bpp overhead of 0.03 that becomes significant in some of the extreme low-bitrate settings in which the evaluated BPG-SE models mainly operated, where it may suffice to use lossy compression instead and reduce rate.

For the models using a learned codec as \(c\), we also provide results from using learned semantics at test time. These SE models still obtained performance comparable to those using ground truth semantics despite the imperfect segmentation between distortion and perception [11, 12]. Further, since compressing semantics is not the main focus of this work, we always losslessly compressed semantics using the aforementioned simple method, creating a constant bpp overhead of 0.03 that becomes significant in some of the extreme low-bitrate settings in which the evaluated BPG-SE models mainly operated, where it may suffice to use lossy compression instead and reduce rate.

4.4 Ablation Study

The Importance of Semantics To rigorously validate the usefulness of semantics, we performed an extensive ablation study using various codecs. First, we zeroed out the semantic channels of a trained JP2-SE model during test time. Comparing Fig. 2k with 2j and also the first row of Table 1, we conclude that the removal of semantic information at test time significantly worsened performance and in particular, caused the codec to behave similarly to the original JP2 and produce blurred semantic boundaries. However, it may be that the same quality improvement can be achieved using any learned post-processing module without semantics had we removed semantics during training such that the model adapts to its absence at test time. To rule out this possibility, we trained one SE model for each engineered backbone codec from scratch with the semantics channels zeroed out throughout. The GAN loss was left unchanged during training and these models did not use semantics at test time. From Fig. 9b and 9d, it can be seen from the silhouette of the car that without semantics, the codec returned to producing reconstructions with blurred semantic boundaries and unnatural details. Rows 2-5 of Table 1 further quantitatively verifies that the use of semantics is indispensable for the improved compression performance of SE codecs.

Contribution From GAN Apart from being a tool for leveraging semantics, the GAN in our framework also helps improve perception quality when $d_s$ and $F$ are implemented with a single network since GAN loss can be interpreted as a divergence measure between the original density and that of the reconstruction. On the other hand, GAN is known to create hallucination artifacts even in the presence of a distortion loss and we proposed a distortion-loss-only training phase to mitigate this issue. The question, however, is whether our third training phase washed off all the improvement in perception quality introduced by GAN. To prove that our training scheme enables GAN to contribute to perception quality without introducing severe hallucination artifacts, we trained a JPEG-SE model with the GAN component (hence also semantics) removed throughout and compare it with the same model trained with only the semantics removed. From Fig. 9c and 9d it is evident that GAN helped produce much more vibrant
Table 1: Ablation study: Each table entry corresponds to bpp/% of times this codec is preferred when compared against the full SE model among 300 distinct user responses/AP@IoU=.50:.05:.95/LPIPS↓/MS-SSIM↑ on the Cityscapes test set. ↑ (↓) means the higher (lower) the better. Notations: “-s” means “no semantics” and “-sg” “no semantics or GAN”. The stage(s) at which the ablation was performed is specified afterwards with “tt” meaning “during both training and test” and “test” meaning “only during test”. “-Phase 3” means the model has been trained without Phase 3. The full SE model has the best overall R-PAD performance in each original-SE-SE (ablated) triplet.

| Codec | Original SE | SE (Ablated Models) | Ablation |
|-------|-------------|----------------------|----------|
| JP2   | .12/2.67/.024/.450/.8809 | .11/-/.075/.363/.8826 | -s; test |
| JPEG  | .25/10.33/.043/.310/.8986 | .22/-/.193/.299/.9172 | -s; tt |
| JP2   | .24/10.67/.086/.320/.9263 | .15/-/.186/.326/.9075 | -s; tt |
| BPG   | .08/14.33/.114/.299/.9383 | .08/-/.222/.311/.9260 | -s; tt |
| WebP  | .16/8.67/.168/.240/.9517 | .16/-/.223/.221/.9563 | -s; tt |
| JPEG  | .25/10.33/.043/.310/.8986 | .22/-/.193/.299/.9172 | -s; tt |
| JP2   | .08/2.00/.005/.519/.8479 | .08/-/.084/.399/.8415 | -s; tt |
| WebP  | .16/8.67/.168/.240/.9517 | .16/-/.223/.221/.9563 | -s; tt |

colors than what could be achieved with a vanilla learned post-processing module. And from the second and sixth rows of Table 1 removing GAN even caused a performance drop in terms of distortion and accuracy. Note that the user preference rates on the two rows were both computed with respect to the SE baseline and therefore cannot be used to conclude that the removal of GAN did not significantly affect the perceptual quality.

The Three-Phase Training Scheme  Fig. 10b makes it clear that the models trained without Phase 3 produced reconstructions with heavy hallucination artifacts. In comparison, the distortion-loss-only Phase 3 effectively improved the fidelity of the reconstructed images. This, however, came at a price of decreased perception quality and detection accuracy (the last two rows of Table 1), which is expected since in the evaluated bitrates, distortion and perception quality diverge severely.

5 Conclusion

In this paper, we proposed a generic framework that can be used to semantically enhance any image codec. Our work is the first to study the efficacy of high-level semantics as a fundamental substitute to low-level visual features in the general compression setting. Moreover, in contrast to how existing works mostly focus only on rate-distortion, we are the first to consider the joint optimization of perception quality, distortion, and performance of downstream vision algorithms on full-resolution images, which are all essential metrics for evaluating image codecs.

Despite its simplicity, an instantiation of our framework effectively improved the perception-accuracy-distortion performance of existing learned and engineered codecs.
Fig. 9: Ablation study: “-sg;tt” means the model has been trained and tested without semantics or GAN; “-s;tt” means the model has been trained and tested without semantics. The effect of semantics cannot be attained with purely low-level visuals even with the help of GAN, as 9b and 9d suggest. 9c and 9d show that GAN can help improve perception quality through creating more vibrant colors without severely increasing distortion or adding hallucination artifacts. Full images are provided in the supplementary materials.

by enabling them to leverage high-level semantics in the form of segmentation maps. And extensive ablation study was performed to validate that the use of semantics is indispensable for the improved performance.

Fig. 10: Ablation study: “-Phase 3” means the model has been trained without Phase 3. Without the stabilization from the distortion-loss-only Phase 3, the reconstructions suffer heavily from hallucination artifacts and high distortion. Full images are in the supplementary materials.

A Architecture and Training

Dataset (ADE20k) We trained the models on the full training set of 20210 images. For evaluation, we randomly sampled one image from each leaf folder in the dataset directory, creating a total of 682 images. We then randomly split this set into a validation set and a test set. During training, we used the best hyperparameters from Cityscapes and saved the best models according to their validation performance on our ADE20k validation set. The images were all reshaped to $1024 \times 512$.

Note that the images in ADE20k have already been compressed by JPEG and therefore are no longer suitable for a rigorous quantitative analysis for compression performance. We mainly show qualitative results as proof of concept that our method works well both for specialized images such as street scenes and in the wild for any generic image.

Architecture We implemented $d_s$ and $F$ using a single network with the same architecture as in [50]. The class segmentation map was one-hot encoded to form 35 channels in addition to the 3 RGB channels (reconstruction from $c$), corresponding to the 35 classes in Cityscapes (for ADE20k, this number is 150 plus an extra null class). Another instance edge map was concatenated, forming a total of 39 channels that was sent to $d_s/F$ (155 for ADE20k). For $c$, we tested with JPEG, JPEG 2000, WebP, BPG, and an autoencoder-based learned codec. BPG was implemented using the official libbpg [6]. JPEG, JPEG 2000, and WebP were implemented with Pillow [7]. For the autoencoder, the encoder (decoder) consists of 4 convolutional (transposed convolutional) layers, each downsampling (upsampling) the image by 2. We added a binarization layer in between to quantize the continuous hidden activations to binary codes, using the method specified in [46]. A PPM [17] coder was used on the bitstream produced by the binarizer to further reduce bitrate. For simplicity, we did not explicitly estimate and minimize the entropy of the bitstream during training. This learned backbone codec was jointly trained with the rest of the model for Phase 2 and 3. We leave testing with more advanced learned backbone codecs as a future work. To compress semantics, we used the simple lossless compression method described in Section 3.

Training We used LS-GAN [32] as our GAN formulation. For the first and second training phases, we supplemented the GAN loss with VGG loss [23] and GAN feature matching loss [50]. We trained models using engineered $c$ with the $L^1$ loss as the distortion term and all other models with the MSE loss to demonstrate that our framework works well with any generic distortion loss. Adam [25] was used as the optimizer and we set the learning rate to 0.0001 with no scheduling. We trained the

---

7 https://github.com/python-pillow/Pillow
networks on Cityscapes (ADE20k) for 30, 30, and 50 (5, 5, and 7) epochs for the three phases, respectively. Except for the objective function formulation, all settings remain unchanged across the three phases for a given model. All experiments were performed on an NVIDIA Tesla V100 GPU. The inference time depends on the underlying backbone image codec and its compression settings. As a reference, each test image took on average 1 second to process for JPEG-SE with the backbone JPEG codec running at quality 15^8.

B  Full Table for R-D Performance

See Table 2 for the complete results of the R-D performance of all the models that we have trained and tested. We put each SE codec side-by-side against its original to clearly demonstrate how high-level semantics affected codec performance. This provides more insights in addition to the R-D curves in Fig. 7.

In this table, the SE codecs achieved better distortion performance in nearly all comparisons. This comes at the price of an extra 0.03 bpp overhead from semantics which necessarily worsens the R-D performance. Although, note that this overhead is based on our primitive lossless semantics compression method described in Section 3. Given that compressing semantics has not been a major research focus in the past and that few works on this topic exist, we believe that more efficient methods can be developed in the future and we hope that our work can draw attention to this largely unexplored area, which would help the SE codecs approach the R-D performance upper bound given in Table 2.

C  Full Images of Visualizations in Main Text

See Fig. 11, 13, and 14 for the full images of Fig. 2, 9, and 10, respectively.

D  More Visualizations for Cityscapes

See Fig. 15, 16, and 17 for more visualizations on Cityscapes. In Fig. 15 and 16 the codecs operate in their respective low bitrate settings whereas for Fig. 17 we demonstrate codecs operating under relatively higher bitrates. In these images, we see the same trend we saw in images from the main text. Specifically, the SE codecs produce results with similar distortion but better perception quality, which can be clearly seen especially in semantic boundaries: No color bleeding is observed from the SE codecs. In contrast, this unnatural and visually unappealing phenomenon is pervasive in the originals when working in the illustrated bitrate settings. This is perhaps because in these low to medium bitrates, the compressed hidden code cannot perfectly preserve all low-level features. In this case, the SE codecs can use their knowledge on what low-level visual features are more likely to appear in each semantic region to make an educated

^8 This is using Pillow’s metrics. All other JPEG settings were kept at Pillow’s defaults for this test.
Table 2: Full table for R-D performance of all models. The bpp of an SE codec equals that of its backbone codec overhead from semantics. The bpp values from the visuals differ for learned and learned-SE because we retrained a new backbone codec for the latter. In learned (LS), the SE models used learned semantics extracted by off-the-shelf segmentation networks at test time. The SE model almost always achieves superior distortion performance. The better in each original-SE pair is marked in bold. The SE model almost always achieves superior distortion performance.
guess on the features given semantics. In contrast, the originals do not have this extra degree of freedom and can only use information in the hidden code, which is highly incomplete and therefore leads to visually unappealing reconstructions.

E Visualizations for ADE20k

See Fig. 18, 19 and 20 for visualizations from ADE20k.
Fig. 11: Full images for Fig. 12
Fig. 12: Semantics (class seg. map) for Fig. 11

Fig. 13: Full images for Fig. 9
Fig. 14: Full images for Fig. 10. Additionally, we also provide visualization for a WebP model trained without Phase 3, the quantitative performance of which we reported in Table 1.
Fig. 15: More visualizations for Cityscapes. These results mainly illustrate codec performance in low bitrate.
Fig. 16: More visualizations for Cityscapes. These results mainly illustrate codec performance in low bitrate.
Fig. 17: More visualizations for Cityscapes. In contrast to Fig. [11, 15] and [16] here we mainly demonstrate codec performance in medium bitrate, in which the perceptual quality difference is still visible.
Fig. 18: Visualizations for ADE20k. Note how the original image is clearly noisy but all the SE codecs filtered out the noise whereas some originals tried to reconstruct noise as well when given enough bpp allowance (e.g., WebP and JPEG).
