Abstract This paper designs a distributed algorithm to seek generalized Nash equilibria of a robust game with uncertain coupled constraints. Due to the uncertainty of parameters in set constraints, the authors aim to find a generalized Nash equilibrium in the worst case. However, it is challenging to obtain the exact equilibria directly because the parameters are from general convex sets, which may not have analytic expressions or are endowed with high-dimensional nonlinearities. To solve this problem, the authors first approximate parameter sets with inscribed polyhedrons, and transform the approximate problem in the worst case into an extended certain game with resource allocation constraints by robust optimization. Then the authors propose a distributed algorithm for this certain game and prove that an equilibrium obtained from the algorithm induces an \( \varepsilon \)-generalized Nash equilibrium of the original game, followed by convergence analysis. Moreover, resorting to the metric spaces and the analysis on nonlinear perturbed systems, the authors estimate the approximation accuracy related to \( \varepsilon \) and point out the factors influencing the accuracy of \( \varepsilon \).

Keywords Approximation, distributed algorithm, \( \varepsilon \)-Nash equilibrium, robust game.

1 Introduction

Multi-agent systems involving a non-cooperative setting have attracted extensive research and applications in many fields, such as telecommunication power allocation and cloud computation\[1, 2\]. Due to some shared resources between players, such as communication bandwidth and network energy, coupled constraints are frequently considered in non-cooperative games. As a reasonable solution, a generalized Nash equilibrium (GNE) can be regarded as defined as a set of strategies that satisfies the local and coupled constraints, in which no player can...
profit from unilaterally deviating from its own strategy. Significant theoretic and algorithmic achievement of GNE seeking have been done, referring to [3, 4].

Recently, seeking equilibria in a distributed manner has become an emerging research topic, where players obtain the Nash equilibrium (NE) or GNE by making decisions with local information and communicating through networks. Various distributed algorithms have been proposed for GNE seeking, such as asymmetric projection algorithms [5], projected dynamics based on non-smooth tracking dynamics [6], and forward/backward operator splitting method [7] with extended to fully distributed games [8].

However, considering the impact of the inevitable uncertainties in practical games, it is often difficult to obtain the exact GNE directly in practice. One way to handle uncertainties is to utilize robust optimization [9], which addresses the robust counterpart of an optimization model with uncertain data/parameters. By employing the robust optimization approaches to deal with the uncertainties in games, the concept of robust game was first proposed in [10]. Hereupon, the works themed on robust game have been applied in various scenarios, such as human decision-making models in security setting, defensive resource allocation in homeland security, downlink power control problem with interfering channel information, and electric vehicle charging problem under demand uncertainty [11–14].

Nevertheless, the analysis of robust games with coupled constraints is less. Most of the previous works focused on the uncertainties in payoff functions or strategy variables, and very few studied the uncertainties in the parameters of the accompanied constraints. In addition, considering that coupled constraints often occur in actual games, distributed GNE seeking in robust games deserve further investigation. More recently, [15] studied a robust game with parameters uncertainty in coupled constraints, where an approximation method was proposed to find an $\varepsilon$-GNE of the original game in the worst case, but the estimation of $\varepsilon$ was not considered. As the approximation focuses on the parameter sets while $\varepsilon$ is affected by the feasible sets, it is hard to construct the relationship between the approximation accuracy and $\varepsilon$. Furthermore, the difficulty of solving the problem increases due to estimating $\varepsilon$ in a distributed setting. Therefore, the distributed robust game with general uncertainty is hard to be analyzed using the existing methods.

In this work, we study distributed GNE seeking of a robust game with general uncertainties, where the parameters in coupled constraints are from general uncertain convex sets, which is more generalized than the previous works without uncertainty in constraints [5, 6, 16], or restricted to special structure [17, 18]. Due to the complexity of uncertainty modeling, the parameter sets may not be equipped with exact analytic expressions or are endowed with high-dimensional nonlinearities, which makes it hard to obtain the exact equilibria directly. To solve this problem, we approximate uncertain parameter sets with inscribed polyhedrons and transform the approximate problem in the worst case into an extended certain game model with resource allocation constraints by robust optimization. Then we propose a distributed continuous-time algorithm for seeking a GNE of the certain game, followed by the convergence analysis. The proposed algorithm has lower dimensions than [15], and avoids discontinuities caused by tangent cones in [15, 19]. Moreover, by virtue of metric spaces and perturbed sys-
tems, an equilibrium obtained from the algorithm is proved to be an $\varepsilon$-GNE of the original game, and an upper bound of the approximation accuracy related to $\varepsilon$ is given.

The remainder is organized as follows. Section 2 provides notations and preliminary knowledge, while Section 3 formulates a distributed robust game with parameter uncertainties in coupled constraints. Then Section 4 provides a distributed algorithm based on a resource allocation problem after a proper approximation and gives the convergence analysis. Section 5 shows that the equilibria of the designed algorithm are $\varepsilon$-GNE of the original problem in the worst case and obtains an upper bound of the value $\varepsilon$, and Section 6 presents numerical examples for illustration of the proposed algorithm. Finally, Section 7 concludes the paper.

2 Preliminaries

In this section, we introduce some basic notations and preliminary knowledge.

Denote $\mathbb{R}^n$ (or $\mathbb{R}^{m \times n}$) as the set of $n$-dimensional (or $m$-by-$n$) real column vectors (or real matrices), and $I_n$ as the $n \times n$ identity matrix. Let $1_n$ (or $0_n$) be the $n$-dimensional column vector with all elements of 1 (or 0). For a column vector $x \in \mathbb{R}^n$, $x^T$ denotes its transpose. Take $\text{col}\{x_1, \cdots, x_n\} = (x_1^T, \cdots, x_n^T)^T$ as the stacked column vector obtained from column vectors $x_1, \cdots, x_n$. $\| \cdot \|$ as the Euclidean norm, and $\text{relint}(D)$ as the relative interior of the set $D$. Denote $\text{ker}(M)$ as the kernel of the matrix $M$, $\text{Im}(M)$ as the image space of the matrix $M$ and $\text{span}(x)$ as the spanning subspace by vector $x$. Denote $E_v(c) \subseteq \mathbb{R}^n$ as an ellipsoid that

$$\sum_{i=1}^{n} \frac{(x_i - c_i)^2}{v_i^2} \leq 1$$

with the center at point $c \triangleq (c_1, \cdots, c_n)$ and the semiaxis $v \triangleq (v_1, \cdots, v_n)$.

A set $\Omega \subseteq \mathbb{R}^n$ is convex if $\omega x_1 + (1 - \omega)x_2 \in \Omega$ for any $x_1, x_2 \in \Omega$ and $0 \leq \omega \leq 1$. For a closed convex set $\Omega$, the projection map $\Pi_{\Omega} : \mathbb{R}^n \rightarrow \Omega$ is defined as

$$\Pi_{\Omega}(x) \triangleq \arg\min_{y \in \Omega} \|x - y\|.$$ 

Especially, denote $[x]^+ \triangleq \Pi_{\mathbb{R}^n}(x)$ for convenience.

A mapping $F : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is said to be monotone (strictly monotone) on a set $K$ if

$$(F(x) - F(y))^T (x - y) \geq 0 \ (> 0), \quad \forall x, y \in K, x \neq y.$$ 

Given a set $K \subseteq \mathbb{R}^n$ and a map $F : K \rightarrow \mathbb{R}^n$, the variational inequality problem $\text{VI}(K, F)$ is defined to find a vector $x^* \in K$ such that

$$(y - x^*)^T F(x^*) \geq 0, \quad \forall y \in K,$$

whose solution is denoted by $\text{SOL}(K, F)$. When $K$ is closed and convex, the solution of $\text{VI}(K, F)$
can be equivalently reformulated via projection as
\[ x \in \text{SOL}(K, F) \Leftrightarrow x = \Pi_K(x - F(x)). \]

Moreover, if $K$ is compact, then $\text{SOL}(K, F)$ is nonempty and compact. If $K$ is closed and $F(x)$ is strictly monotone, then $\text{VI}(K, F)$ has at most one solution (see [3, Proposition 1.5.8, Corollary 2.2.5, and Theorem 2.3.3]).

Take $X, Z \subseteq \mathbb{R}^n$ as two non-empty sets. For $y \in \mathbb{R}^n$, denote $\text{dist}(y, Z)$ as the distance between $y$ and $Z$, i.e.,
\[ \text{dist}(y, Z) = \inf_{z \in Z} \| y - z \|. \]

Define the Hausdorff metric of $X, Z \subseteq \mathbb{R}^n$ by
\[ H(X, Z) = \max \left\{ \sup_{x \in X} \text{dist}(x, Z), \sup_{z \in Z} \text{dist}(z, X) \right\}. \]

The Hausdorff metric integrates all compact sets into a metric space.

Let $\mathcal{X}$ and $\mathcal{Y}$ be $m$-dimensional subspaces of $\mathbb{R}^n$, respectively. The canonical angles between them are defined to be
\[ \vartheta_i(\mathcal{X}, \mathcal{Y}) = \arccos \sigma_{m-i+1} (X^T Y), \quad i = 1, 2, \ldots, m, \]
where $X$ and $Y$ are matrices whose columns form orthonormal bases of $\mathcal{X}$ and $\mathcal{Y}$, and $\sigma_i(X^T Y)$, $i = 1, 2, \ldots, m$, are decreasingly ordered singular values of $X^T Y$. Denote the canonical angles between $\mathcal{X}$ and $\mathcal{Y}$ by $\vartheta(\mathcal{X}, \mathcal{Y}) \triangleq (\vartheta_1(\mathcal{X}, \mathcal{Y}), \ldots, \vartheta_m(\mathcal{X}, \mathcal{Y}))$. The following lemma reveals the metric about canonical angles between $\mathcal{X}$ and $\mathcal{Y}$.[20, 21].

**Lemma 2.1** Let $\varrho: \mathbb{R}^n \rightarrow \mathbb{R}$ be a symmetric gauge function. Define $\psi: \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}$ of $\mathcal{X}$ and $\mathcal{Y}$ by
\[ \psi(\mathcal{X}, \mathcal{Y}) = \varrho(\vartheta(\mathcal{X}, \mathcal{Y})). \]

Then $\psi$ is called an angular metric. Moreover, let $\mathcal{X}_\perp$ and $\mathcal{Y}_\perp$ be the orthogonal complements of $\mathcal{X}$ and $\mathcal{Y}$, respectively. The nonzero canonical angles between $\mathcal{X}$ and $\mathcal{Y}$ are the same as those of $\mathcal{X}_\perp$ and $\mathcal{Y}_\perp$, which means that $\psi(\mathcal{X}, \mathcal{Y}) = \psi(\mathcal{X}_\perp, \mathcal{Y}_\perp)$.

Consider a class of comparison functions. A continuous function $\alpha: [0, a] \rightarrow [0, \infty)$ is said to belong to class $\mathcal{K}$ if it is strictly increasing and $\alpha(0) = 0$. It is said to belong to class $\mathcal{K}_\infty$ if $a = \infty$ and $\alpha(r) \rightarrow \infty$ as $r \rightarrow \infty$.

Moreover, the information sharing among the players can be described by a graph $\mathcal{G} = (\mathcal{I}, \mathcal{E})$, with the node set $\mathcal{I} = \{1, 2, \ldots, N\}$ and the edge set $\mathcal{E}$. $A = [a_{ij}] \in \mathbb{R}^{n \times n}$ is the adjacency matrix of $\mathcal{G}$ such that if $(j, i) \in \mathcal{E}$, then $a_{ij} > 0$, which means that $i$ can obtain the information from $j$ and $j$ belongs to $i$’s neighbor set; $a_{ij} = 0$ otherwise. $\mathcal{G}$ is said to be undirected if $(j, i) \in \mathcal{E} \Leftrightarrow (i, j) \in \mathcal{E}$, and $\mathcal{G}$ is to be connected if any two nodes in $\mathcal{I}$ are connected by a path. The Laplacian matrix is $L = \Delta - A$, where $\Delta = \text{diag} \{d_1, \ldots, d_N\} \in \mathbb{R}^{N \times N}$ with $d_i = \sum_{j=1}^{N} a_{ij}$. When $\mathcal{G}$ is an undirected connected graph, 0 is a simple eigenvalue of Laplacian $L$ with the
eigenspace \( \{a1_n | a \in \mathbb{R} \} \), and \( L1_n = 0_n \), while all other eigenvalues are positive.

## 3 Problem Formulation

Consider an \( N \)-player game with a global coupled constraint as follows. For \( i \in I \equiv \{1, \cdots, N\} \), player \( i \) has an action variable \( x_i \) in a local action set \( \Theta_i \subseteq \mathbb{R}^n \). Denote \( \Theta = \prod_{i=1}^{N} \Theta_i \subseteq \mathbb{R}^{nN} \), \( x = \text{col}\{x_1, \cdots, x_N\} \in \Theta \) as the action profile for all players, and \( x_{-i} = \text{col}\{x_1, \cdots, x_{i-1}, x_{i+1}, \cdots, x_N\} \) as the action profile for all players except player \( i \). The cost function for player \( i \) is \( J_i(x_i, x_{-i}) : \mathbb{R}^{nN} \to \mathbb{R} \).

Moreover, there exists a coupled inequality constraint shared by all players. Denote \( K \subseteq \mathbb{R}^{Nn} \) as the set for this coupled constraint. Considering that the parameters in constraints are given in general uncertain convex sets, the action profile \( x \) needs to satisfy

\[
x \in K \triangleq \left\{ x \in \mathbb{R}^{Nn} \ \bigg| \ \sum_{i=1}^{N} \omega_i^T x_i \leq b, \ \omega_i \in M_i \subseteq \mathbb{R}^n, \ \forall i \in I \right\},
\]

where \( M_i \) is convex and compact. For any \( \omega_i \in M_i \), the inequality constraint must be satisfied. Denote the feasible action set of this game by \( X \equiv K \cap \Theta \). Then, the feasible set of player \( i \) is

\[
X_i(x_{-i}) \triangleq \left\{ x_i \in \Theta_i \ \bigg| \ \sum_{j \neq i,j \in I} \omega_j^T x_j \leq b - \sum_{j \neq i,j \in I} \omega_j^T x_j, \ \omega_i \in M_i \right\}.
\]

To sum up, given \( x_{-i} \), the \( i \)th player aims to solve

\[
\min_{x_i \in \mathbb{R}^n} J_i(x_i, x_{-i}) \ \text{s.t.} \ x_i \in X_i(x_{-i}).
\]

**Definition 3.1** (\( \varepsilon \)-generalized Nash equilibrium) A profile \( x^* \) is said to be an \( \varepsilon \)-generalized Nash equilibrium of the game (1) if

\[
J_i(x^*_i, x_{-i}^*) \leq J_i(x_i, x_{-i}^*) + \varepsilon, \ \forall i \in I, \ \forall x_i \in X_i(x_{-i}),
\]

with a positive constant \( \varepsilon \). Particularly, \( x^* \) is said to be a GNE when \( \varepsilon = 0 \).

The main task of this paper is to design a distributed dynamics for seeking a GNE of the robust game (1), where each player can only access its local payoff function and feasible decision set under a multi-agent network. The \( i \)th player may only know \( \omega_i^T x_i \) and the parameter uncertainty set \( M_i \), rather than \( \sum_{i=1}^{N} \omega_i^T x_i \). To fulfill the cooperations between players for solving (1), the players have to share their local information through a network \( G \). On the other hand, restricted by the uncertainty of \( \omega_i \), we aim to find a GNE of (1) in the worst case, i.e., a GNE satisfies all possible constraints, which is defined as

\[
x^* \in \left\{ x \in \Theta \ \bigg| \ \sum_{i=1}^{N} \max_{\omega_i \in M_i} \omega_i^T x_i \leq b \right\}.
\]
However, it is very difficult to solve the worst-case solution directly, because the challenge comes from the fact that $\omega_i$ is arbitrarily selected from a general uncertain convex set $M_i$, which may be endowed with high-dimensional nonlinearities or have no analytical expression. Therefore, we consider finding an $\varepsilon$-GNE of the game (1) in the worst case with a practical approximation, and analyze the approximation accuracy related to $\varepsilon$, which overcomes the difficulty of estimating $\varepsilon$ in [15].

Remark 3.1 In our distributed game, the decision variable $x_j$ can be observable by the $i$th player, if $J_i(x_i, x_{-i})$ depends explicitly on $x_j$, for any $j \in I$. Thus, player $i$ can get its local gradient by observing the decisions influencing $J_i(x_i, x_{-i})$. This observation model has also been adopted in [7, 15]. On the other hand, there have also been methods for distributed GNE seeking when each player cannot observe the full decisions that its cost function depends on, referring to [19, 22]. Here, we do not consider this circumstance, where this simplification does not affect the focus of our research.

The following assumptions are associated with the game (1).

Assumption 3.1

- For $i \in I$, $\Theta_i$ is compact and convex. Besides, there exists $x \in \text{relint}(\Theta)$ such that $\sum_{i=1}^{N} \omega_j^T x_j < b$, $\omega_j \in M_j \subseteq \mathbb{R}^n$, $\forall j \in I$.
- For $i \in I$, $J_i(x)$ is Lipschitz continuous in $x$, while $J_i(x)$ is continuously differentiable in $x_i$. Moreover, the pseudo-gradient $F(x) \triangleq \text{col}\left\{\nabla x_1 J_1(x_{-1}), \cdots, \nabla x_N J_N(x_{-N})\right\}$ is strictly monotone in $x$.
- The undirected graph $G$ is connected.

By Assumption 3.1, it is clear that Slater’s condition is satisfied. Besides, compared with [15, 24], the map $F$ is assumed to be strictly monotone rather than strongly monotone.

4 Algorithm Design

In this section, we approximate the parameter uncertainty sets of the game (1) in a proper way and propose a distributed algorithm to find the worst-case solution with the uncertainty in the approximate game.

One of the most common tools for approximating convex sets is by inscribed polyhedrons. Recalling the definition of inscribed polyhedrons, it is a polyhedron with all its vertices on the boundary of the convex set. And it is essentially enclosed by a series of hyperplanes. Denote $\mathcal{M} = \prod_{i=1}^{N} M_i$ and $\mathcal{P}_v = \prod_{i=1}^{N} \mathcal{P}_{v_i}$. Take $\mathcal{P}_{v_i}$ as an inscribed polyhedron of $M_i$ with $v_i$ vertices, it can be expressed as

$$\mathcal{P}_{v_i} = \left\{ \omega_i \in \mathbb{R}^n \mid A_i \omega_i \leq d_i \right\}. \quad (3)$$

Here, for $i \in I$, $A_i \in \mathbb{R}^{q_i \times n}$ are normal vectors of the hyperplanes with normalized rows. They determine the directions of these hyperplanes. $q_i$ is the number of hyperplanes, and $d_i$ are the
distances from the origin point to the hyperplanes.

**Remark 4.1** Here we choose polyhedrons for the approximation because they can be explicitly expressed by linear inequalities, which provide simple mathematical derivation and make the distributed algorithms concise. Furthermore, although the analytical expressions of convex sets with high-dimensional nonlinearities are hard to solve directly, in some situations one can sample exactly a few points on the boundary of the convex set, which naturally form an inscribed polyhedron. This is another important reason for choosing inscribed polyhedrons.

With the help of the approximation by inscribed polyhedrons, the coupled constraint of (1) in the worst case becomes

\[ \sum_{i=1}^{N} \max_{\omega_i \in P_i} \omega_i^T x_i \leq b. \] (4)

Then we can explicitly investigate the worst-case solution with uncertainty based on robust optimization\[^9\] and robust game \[^{15, Theorem 1}\]. Specifically, by introducing a dual variable \( \sigma_i \in \mathbb{R}^{q_i} \), (4) can be equivalently transformed into

\[ \sum_{j=1}^{N} d_j^T \sigma_j \leq b, \quad \forall j \in \mathcal{I}. \] (5)

Moreover, denote \( z_i = \text{col}\{x_i, \sigma_i\} \in \mathbb{R}^{n+q_i}, B_i = [0^T_n, d_i^T] \in \mathbb{R}^{1 \times (n+q_i)}, \) and \( C_i = [-I_n, A_i^T] \in \mathbb{R}^{n \times (n+q_i)}. \) Define \( \Theta_i = \Phi_i \cap \{C_i z_i = 0_n\} \),

\[ \Omega_i = \Theta_i \cap \{C_i z_i = 0_n\}, \] (6)

\( z_{-i} \) as all the vectors except \( z_i \), \( z \triangleq \text{col}\{z_1, \cdots, z_N\} \in \mathbb{R}^{nN+q} \), where \( q = \sum_{i=1}^{N} q_i \). With these notations, the game (1) with approximation is therefore converted into an extended certain game model with resource allocation constraints, that is,

\[ \min_{z_i \in \Omega_i} \tilde{J}_i (z_i, z_{-i}) \]  
\[ \text{s.t.} \sum_{j=1}^{N} B_j z_j \leq b, \quad \forall j \in \mathcal{I}, \] (7)

where \( \tilde{J}_i (z_i, z_{-i}) = J_i (x_i, x_{-i}) \).

Denote the pseudo-gradient of (7) by \( g(z) \triangleq \text{col}\{g_1(z_1, z_{-1}), \cdots, g_N(z_N, z_{-N})\} \in \mathbb{R}^{nN+q} \), where \( g_i(z_i, z_{-i}) \triangleq \text{col}\{\nabla_x J_i (x_i, x_{-i}), 0_{q_i}\} \in \mathbb{R}^{n+q_i} \). Take \( B = \text{Diag} (B_1, \cdots, B_N) \in \mathbb{R}^{N \times (nN+q)} \), \( b = \text{col}\{b_1, \cdots, b_N\} \in \mathbb{R}^N \) with \( \sum_{i=1}^{N} b_i = b \). Then the feasible set of player \( i \) in (7) is defined as

\[ \Xi_i (z_{-i}) \triangleq \left\{ z_i \in \Omega_i \left| \sum_{j=1}^{N} B_j z_j \leq b \right. \right\}. \]
Let $\Xi = \prod_{i=1}^{N} \Xi_i$, $\Omega = \prod_{i=1}^{N} \Omega_i$ and $\Phi = \prod_{i=1}^{N} \Phi_i$. Referring to [3, Proposition 1.4.2] and [27], a strategy profile $z^*$ is said to be a variational equilibrium, or variational GNE, if $z^* \in \text{SOL}(\Xi, g(z))$. Moreover, for a variational GNE of the game (7), $z^*$ together with multiplier $\lambda^*$ satisfy the following first order conditions,

$$0_{nN} \in g(z^*) + B^T \lambda^* + N_B(z^*),$$

$$0 \leq -(Bz^* - b)^T \cdot 1_N, \quad 0 = (Bz^* - b)^T \lambda^*,$$

$$0_N = L\lambda^*,$$

where multiplier $\lambda^* = \text{col}\{\lambda_1^*, \cdots, \lambda_N^*\} \in \mathbb{R}_+^N$, and $L$ is the Laplacian matrix of network $G$.

By solving the first order conditions (8) of the variational inequality $\text{VI}(\Xi, g(z))$, we derive a variational GNE of the game (7), which can be regarded as a GNE with equal multipliers, i.e, $\lambda_i^* = \lambda_j^*, \forall i, j \in I$.

Furthermore, by employing an additional variable $\zeta = \text{col}\{\zeta_1, \cdots, \zeta_N\} \in \mathbb{R}^N$, we propose a distributed algorithm for solutions to (8) of the approximate game (7).

**Algorithm 1** For each $i \in I$

**Initialization:**

$z_i(0) \in \Omega_i$, $\lambda_i(0) \in \mathbb{R}_+$, $\zeta_i(0) \in \mathbb{R}$.

**Dynamics renewal:**

$$\dot{z}_i = \Pi_{\Omega_i} \left( z_i - g_i (z_i, z_{-i}) - B_i^T \lambda_i \right) - \dot{z}_i,$$

$$\dot{\lambda}_i = \left[ \lambda_i + B_i z_i - b_i - \sum_{j=1}^{N} a_{ij} (\lambda_i - \lambda_j) - \sum_{j=1}^{N} a_{ij} (\zeta_i - \zeta_j) \right]^+ - \lambda_i,$$

$$\dot{\zeta}_i = \sum_{j=1}^{N} a_{ij} (\lambda_i - \lambda_j),$$

where $a_{ij}$ is the $(i,j)$th element of the adjacency matrix.

Equivalently, a compact form of Algorithm 1 can be written as

$$\begin{cases}
\dot{z} = \Pi_{\Omega} (z - g(z) - B^T \lambda) - z, & z(0) \in \Omega, \\
\dot{\lambda} = [\lambda + Bz - b - L\lambda - L\zeta]^+ - \lambda, & \lambda(0) \in \mathbb{R}_+^N, \\
\dot{\zeta} = L\lambda, & \zeta(0) \in \mathbb{R}^N.
\end{cases}$$

In Algorithm 1, the $i$th player calculates the local decision variable $z_i \in \Omega_i$ based on projected gradient play dynamics. The local variable $\lambda_i \in \mathbb{R}_+$ is to estimate a dual variable associated with the coupled constraints, while the local auxiliary variable $\zeta_i \in \mathbb{R}$ is calculated for the consensus of $\lambda_i$.

**Remark 4.2** Compared with the algorithm in [15], the dynamics (9) is with lower dimen-
sions. Meanwhile, (9) adopts the projection operation to deal with local feasible constraints, which avoids the discontinuous dynamics caused by tangent cones \cite{15, 19}.

The following lemma shows the equivalence between an equilibrium of the algorithm (9) and a solution to VI(\(\mathbf{E}, g(z)\)) satisfying (8).

**Lemma 4.3** Under Assumption 3.1, consider the game (7). If \(\text{col}\{z^*, \lambda^*, \zeta^*\}\) is an equilibrium point of (9), then \(z^*\) is a variational GNE of (7). Conversely, if \(z^*\) is a variational GNE of (7), there exists \((\lambda^*, \zeta^*)\) \(\in \mathbb{R}_+^N \times \mathbb{R}_+^N\) such that \((z^*, \lambda^*, \zeta^*)\) is an equilibrium point of (9).

Next, we analyze the convergence of (9).

**Theorem 4.4** Under Assumption 3.1, the trajectory \((z(t), \lambda(t), \zeta(t))\) of (9) is bounded and converges to an equilibrium point of (9), namely, \(z(t)\) converges to a solution of VI(\(\mathbf{E}, g(z)\)) satisfying (8).

## 5 Equilibrium Analysis

In this section, we show that an equilibrium obtained from Algorithm 1 induces an \(\varepsilon\)-GNE of the original game (1). Moreover, we describe the bound related to \(\varepsilon\).

The following idea is different from that given in \cite{15}. As the estimation of \(\varepsilon\) is actually reflected by solving GNE of the approximate problem dependent on dynamics, we consider establishing the relationship between the approximation accuracy and \(\varepsilon\) from the perspective of the nonlinear perturbed system.

Under Assumption 3.1, the pseudo-gradient \(F\) is strictly monotone with respect to \(x\), which implies that \(z^*\) \(\in\text{SOL}(\mathbf{E}, g(\cdot))\) contains a unique \(x^*\), but the optimal \(\sigma^*\) may not be unique. Moreover, if the form of cost function \(J_i\) is fixed, then different polyhedron approximations result in different variational inequality solutions. Since \(\mathcal{P}_v\) determines \(\mathbf{E}\), we write \(x^* = x^*(\mathcal{P}_v)\), \(z^*(\mathcal{P}_v) = \text{col}\{x^*(\mathcal{P}_v), \sigma^*(\mathcal{P}_v)\}\) for the game (7). Also, denote \(x^*(\mathcal{M})\) as a GNE of the game (1).

Take

\[
\mathcal{P}_{v1} = \prod_{i=1}^{N} \mathcal{P}_{v1,i}, \quad \mathcal{P}_{v2} = \prod_{i=1}^{N} \mathcal{P}_{v2,i}
\]

as two inscribed polyhedrons of \(\mathcal{M}\). With the definition of \(\mathcal{P}_{v1}\) and \(\mathcal{P}_{v2}\), for the \(i\)th player,

\[
\mathcal{P}_{v1,i} = \{\omega_i \in \mathbb{R}^n: A_{1,i} \omega_i \leq d_{1,i}\}, \quad A_{1,i} \in \mathbb{R}^{q_{1,i} \times n}, \quad (11)
\]

\[
\mathcal{P}_{v2,i} = \{\omega_i \in \mathbb{R}^n: A_{2,i} \omega_i \leq d_{2,i}\}, \quad A_{2,i} \in \mathbb{R}^{q_{2,i} \times n}. \quad (12)
\]

Before revealing the \(\varepsilon\)-relationship of \(x^*(\mathcal{P})\) and \(x^*(\mathcal{M})\) in the game (7) and the original game (1), we first investigate the relationship between \(x^*(\mathcal{P}_{v1})\) and \(x^*(\mathcal{P}_{v2})\) (i.e., the approximation accuracy between \(x^*(\mathcal{P}_{v1})\) and \(x^*(\mathcal{P}_{v2})\)) of (7).

Define \(B_t = \text{Diag} (B_1^t, \cdots, B_N^t) \in \mathbb{R}^{N \times (nN + q_1)}\), \(C_t = \text{Diag} (C_{11}^t, \cdots, C_{1N}^t) \in \mathbb{R}^{nN \times (nN + q_1)}\), where \(B_i^t = [0^T_n, d^T_{i,1}] \in \mathbb{R}^{1 \times (n + q_{1,i})}\), \(C_{i1}^t = [-I_n, B_{i1}^T] \in \mathbb{R}^{n \times (n + q_{1,i})}\) and \(q_1 = \sum_{i=1}^{N} q_{1,i}\). \(B_2\) and
C_2 are denoted in a similar way.

Recalling the fact (6) of \( \Omega_i \), with employing a new variable \( \xi = \text{col}(\xi_1, \ldots, \xi_N) \in \mathbb{R}^{nN} \), (8) on \( \mathcal{P}_{v_1} \) is equivalent to

\[
0_{nN} \in g(z^*) + B_1^T \lambda^* + C_1^T \xi^* + \mathcal{N}_\varphi(z^*),
\]

\[
0 \leq -(B_1z^* - b)^T 1_N, \quad 0 = (B_1z^* - b)^T \lambda^*,
\]

\[
0_{nN} = L\lambda^*, \quad 0_{nN} = C_1z^*.
\]

Let \( y = \text{col}(z, \lambda, \zeta, \xi) \), \( R = \Phi \times \mathbb{R}_+^N \times \mathbb{R}^N \times \mathbb{R}^{nN} \). Then Algorithm 1 on \( \mathcal{P}_{v_1} \) is equivalent to

\[
y = D_{\mathcal{P}_{v_1}}(y),
\]

where

\[
D_{\mathcal{P}_{v_1}}(y) = \begin{bmatrix}
\Pi \Phi (z - g(z) - B_1^T \lambda - C_1^T \xi) - z \\
[\lambda + B_1z - b - L\lambda - L\zeta]^+ - \lambda \\
L\lambda \\
C_1z
\end{bmatrix}.
\]

From Theorem 4.4, the whole dynamics of the system (13) is globally asymptotically stable. According to this property, with the converse Lyapunov theorem in [28], there exists a Lyapunov function \( V_{\mathcal{P}_{v_1}}(y) \) satisfying the following inequalities:

\[
\alpha_1(\|y - y^*(\mathcal{P}_{v_1})\|) \leq V_{\mathcal{P}_{v_1}}(y) \leq \alpha_2(\|y - y^*(\mathcal{P}_{v_1})\|),
\]

\[
\dot{V}_{\mathcal{P}_{v_1}} \leq -\alpha_3(\|y - y^*(\mathcal{P}_{v_1})\|),
\]

\[
\left\| \frac{\partial V_{\mathcal{P}_{v_1}}}{\partial y} \right\| \leq \alpha_4(\|y - y^*(\mathcal{P}_{v_1})\|),
\]

where \( \alpha_1, \alpha_2, \alpha_3, \alpha_4 \) are class-K functions, \( y^*(\mathcal{P}_{v_1}) = \text{col}(z^*(\mathcal{P}_{v_1}), \lambda^*(\mathcal{P}_{v_1}), \zeta^*(\mathcal{P}_{v_1}), \xi^*(\mathcal{P}_{v_1})) \) is an equilibrium point of (13).

Analogously, the dynamics on \( \mathcal{P}_{v_2} \) is

\[
y = D_{\mathcal{P}_{v_2}}(y),
\]

where

\[
D_{\mathcal{P}_{v_2}}(y) = \begin{bmatrix}
\Pi \Phi (z - g(z) - B_2^T \lambda - C_2^T \xi) - z \\
[\lambda + B_2z - b - L\lambda - L\zeta]^+ - \lambda \\
L\lambda \\
C_2z
\end{bmatrix}.
\]

Note that (15) can be regarded as a perturbed system of (13). For clarification, let \( \Gamma = \)}
then (15) is converted into
\[
y = D_{\mathcal{P}_{v_1}}(y) + e(y),
\]
where the perturbation term is
\[
e(y) = \begin{bmatrix}
\Pi_{\Phi} (\Gamma - B_2^T \lambda - C_2^T \xi) - \Pi_{\Phi} (\Gamma - B_1^T \lambda - C_1^T \xi) \\
[A + B_2 z]^+ - [A + B_1 z]^+ \\
0 \\
(C_1 - C_2)z
\end{bmatrix}.
\]
Take \(y^*(\mathcal{P}_{v_2})\) as an equilibrium point of (16). After this conversion, we can obtain the upper bound of the approximation accuracy between \(y^*(\mathcal{P}_{v_1})\) and \(y^*(\mathcal{P}_{v_2})\) (i.e., \(x^*(\mathcal{P}_{v_1})\) and \(x^*(\mathcal{P}_{v_2})\)) by investigating \(e(y)\) between (13) and (16).

Note that \(e(y)\) reflects the difference in continuous-time projected dynamics on \(\mathcal{P}_{v_1}\) and \(\mathcal{P}_{v_2}\), respectively. Recalling the definition of inscribed polyhedrons in (3), \(e(y)\) is basically affected by different hyperplanes (their corresponding normal vectors and displacement terms) in \(\mathcal{P}_{v_1}\) and \(\mathcal{P}_{v_2}\), where the distance between hyperplanes can be measured by angular metric.

As defined in (10)–(12), without losing generality, consider \(q_{1,i} \leq q_{2,i}\). Let \(A_{2,i}^l\) be any row of matrix \(A_{2,i}\), \(\forall i \in I, 0 \leq l \leq q_{2,i}\), and \(A_{1,i}^{l(i)}\) be the corresponding row of matrix \(A_{1,i}\). Accordingly, denote \(\tau_i^l \in [0, \pi/2)\) as the angular metric of \(A_{2,i}^l\) and \(A_{1,i}^{l(i)}\), where \(\tau_i^l = \psi \left( A_{2,i}^l, A_{1,i}^{l(i)} \right)\). The following lemma gives an upper bound of \(\|e(y)\|\).

\textbf{Lemma 5.1} Under Assumption 3.1, on \(\overline{I} = I \cap \{ \|y - y^*(\mathcal{P}_{v_1})\| < r \}\), the perturbation term \(e(y)\) of (16) satisfies
\[
\|e(y)\| \leq \delta = r \sum_{i=1}^{N} q_i c_i \theta_i,
\]

where \(c_i\) is a finite positive constant, \(q_i = q_{2,i}\) is the number of hyperplanes in \(\mathcal{P}_{v_2,i}\), \(\theta_i = \max_{0 \leq l \leq q_{2,i}} \tau_i^l\) for \(i \in I\).

The next lemma explains that \(\|y^*(\mathcal{P}_{v_1}) - y^*(\mathcal{P}_{v_2})\|\) is ultimately bounded by a small bound if \(e(y)\) is small enough, referring to [28].

\textbf{Lemma 5.2} Take \(V_{\mathcal{P}_{v_1}}(y)\) as a Lyapunov function satisfying (14) in set \(\overline{I}\). Suppose that \(\|e(y)\| \leq \delta < \mu \alpha_3 \left( \alpha_2^{-1}(\alpha_1(r)) / \alpha_4(r) \right)\), with a constant \(\mu \in (0, 1)\). Then, for all \(\|y(t_0) - y^*(\mathcal{P}_{v_1})\| \leq \alpha_2^{-1}(\alpha_1(r))\), the equilibrium \(y^*(\mathcal{P}_{v_2})\) of the perturbed system (16) satisfies
\[
\|y^*(\mathcal{P}_{v_1}) - y^*(\mathcal{P}_{v_2})\| \leq \rho(\delta) = \alpha_1^{-1} \left( \alpha_2 \left( \alpha_3^{-1} \left( \frac{\delta \alpha_4(r)}{\mu} \right) \right) \right).
\]
a finite \( r \) to satisfy (18). Clearly, a lower metric yields a lower bound. It can be regarded as the robustness of the nominal system with a stable equilibrium, since arbitrarily small perturbations will not cause a significant deviation. Moreover, it follows from (18) that

\[ \| \mathbf{x}^*(P_{v_1}) - \mathbf{x}^*(P_{v_2}) \| \leq \rho(\delta). \]

Since \( \rho(0) = 0 \) and \( \rho \) is strictly increasing in \([0, \infty)\), \( \| \mathbf{x}^*(P_{v_1}) - \mathbf{x}^*(P_{v_2}) \| \) tends to zero as \( \delta \) vanishes.

**Remark 5.3** Compared with the analysis in [15], Lemma 5.1 does not rely on the Hausdorff metric, which leads to technical difficulties in estimating the parameter changes of different polyhedrons, and thus can not describe the relationship between the approximate accuracy of different polyhedrons and the difference between the corresponding equilibria. Instead, by introducing angular metric, these difficulties are solved, and the upper bound of the difference between equilibria can be obtained, which extends the result in [15] and ensures the estimation of \( \epsilon \) in the sequel.

With Lemma 5.2, we finally show that an equilibrium \( \mathbf{x}^*(P_v) \) obtained from Algorithm 1 induces an \( \epsilon \)-GNE of the original game (1) and estimate the approximation accuracy of \( \epsilon \).

**Theorem 5.4** Under Assumption 3.1,

(i) the variational GNE \( \mathbf{x}^*(\mathcal{M}) \) of the game (1) in the worst case exists and is unique;

(ii) \( \mathbf{x}^*(P_v) \) of the equilibrium in Algorithm 1 induces an \( \epsilon \)-GNE of the game (1) in the worst case;

(iii) the value of \( \epsilon \) satisfies

\[ \epsilon \leq 2\varsigma_1 \alpha_1^{-1} \left( \alpha_2 \left( \alpha_3^{-1} \left( \frac{\delta \alpha_4(r)}{\mu} \right) \right) \right), \]

where the constant \( \mu \in (0, 1) \), \( \alpha_1, \alpha_2, \alpha_3, \alpha_4 \) are class-\( K \) functions in (14), \( \varsigma_i \) is the Lipschitz constant of \( J_i \). Specifically,

\[ \delta = r \sum_{i=1}^{N} \frac{q_i c_i}{\sqrt{2 h_i \nu_i} - 1} \]

where \( h_i = H(P_{v_i}, \mathcal{M}_i) \) is the Hausdorff distance between \( P_{v_i} \) and \( \mathcal{M}_i \), \( q_i \) is the number of hyperplanes in \( P_{v_i} \), \( \nu_i \) is a constructive curvature related merely to the structure of \( \mathcal{M}_i \), \( c_i \) is a finite constant.

From Theorem 5.4, the upper bound of \( \epsilon \) is proportional to the bound of \( \delta \). With the expression of \( \delta \) in (20), when constructing polyhedrons with more vertices, we obtain more hyperplanes enclosed the polyhedrons (more rows of matrix \( A_i \) and vectors \( d_i \)), which results in a lower metric and higher accuracy of \( \epsilon \). Actually, there are developed investigations on how to construct a proper inscribed polyhedron\[25, 26\]. When the vertices or faces are constructed successively, we can find a proper inscribed polyhedron by the iterative algorithms based on
Hausdorff metric. The main idea of iterative algorithms is to construct a polyhedron $P_{v(k+1)} = \text{conv}(P_{v(k)} \cup \{w_{k+1}\})$ every iteration, where $v(k)$ is the number of vertices in $P_{v(k)}$, $w_{k+1}$ is a point from $\partial M$ (i.e., the boundary of $M$). The Hausdorff metric satisfies $H(P_{v(k)}, M) \leq C_M \cdot v(k)^{(n-1)/2}$, where $C_M$ is a constant related with the curvature of $M$. One of the methods of constructing point $w_{k+1}$ is as follows. For $u \in \mathbb{R}^n$, denote $g_M(u) = \max\{(u, x) : x \in M\}$ as the support function of $M$ on the unit sphere of directions $S^{n-1} = \{u \in \mathbb{R}^n : \|u\| = 1\}$. The additional point $w_{k+1} \in \partial M$ belongs to the support plane parallel to the hyperplane in $P_{v_k}$, for which the quantity $g_M(u) - g_{P_{v(k)}}(u)$ attains its maximum on the set of external normals $u \in S^{n-1}$ to the hyperplanes of $P_{v(k)}$. The initial polyhedron could be constructed by the method[29]. In addition, since the parameter set constraint of each player is private information to itself, different players can approximate their parameter sets through different construction methods separately, in advance and offline.

6 Numerical Experiments

In this section, we examine the approximation accuracy of Algorithm 1 on demand response management problems under uncertainty as in [30, 31].

Consider a game with $N = 10$ electricity users with the demand of energy consumption. For $i \in I = 1, \cdots, 10$, $x_i \in \Theta_i$ is the energy consumption of the $i$th user, where $\Theta_i = \{x_i \in \mathbb{R}^2 : c_1 \mathbf{1}_2 \leq x_i \leq c_2 \mathbf{1}_2\}$ with $c_1 = -15$, $c_2 = 20$. In this network game, each user needs to solve the following problem given the other users profile $x_{-i}$,

$$
\min_{x_i \in \Theta_i} \frac{1}{2}(x_i - \omega)^T(x_i - \omega) - x_i^T p(Q(x))
$$

s.t. $\sum_{j=1}^N \omega^T x_j \leq b$, $\omega \in E_{(3,2)}(2,2)$, $\forall j \in I$, \hspace{1cm} (21)

where $\omega_i = (5-i)\mathbf{1}_2 \in \mathbb{R}^2$ is the nominal value of energy consumption, and $p = N(1_2 - Q(x))$ is the pricing function with $Q(x) = \frac{1}{N} \sum_{j=1}^N x_j$ as an aggregate term. All electricity users need to meet the coupled inequality constraint with the parameter $a \in \mathbb{R}^2$ satisfying an elliptical region

$$
E_{3,2}(2,2) = \\left\{ \omega \in \mathbb{R}^2 : \frac{(\omega_1 - 2)^2}{3^2} + \frac{(\omega_2 - 2)^2}{2^2} \leq 1 \right\}.
$$

Take a ring graph as the communication network $\mathcal{G}$,

$$
1 \rightleftarrows 2 \rightleftarrows \cdots \rightleftarrows 10 \rightleftarrows 1.
$$

Meanwhile, we set tolerance as $t_{tol} = 10^{-4}$ and the terminal criterion as $\|\dot{y}(t)\| \leq t_{tol}$. We employ inscribed rectangles to approximate $E_{(3,2)}(2,2)$, where the trajectories of one dimension of each $x_i$ are shown in Figure 1. Then we verify the approximation accuracy of Algorithm 1. We approximate $E_{(3,2)}(2,2)$ with inscribed triangles, rectangles, hexagons, octagons, decagons, and dodecagons, respectively. Figure 2 presents different strategy trajectories of one fixed player.
with different approximations. The vertical axis represents the value of the convergent $\varepsilon$-GNE and the horizontal axis represents the real running time of Algorithm 1. The results imply that when we choose a more accurate approximation, equilibria with different polyhedrons get closer to the exact solution.

![Figure 1](image1)

**Figure 1** Trajectories of all players’ strategies

![Figure 2](image2)

**Figure 2** Trajectories of approximation by different inscribed polyhedrons

Additionally, recalling the definition of $\varepsilon$-GNE, the numerical values of $\varepsilon$ under different types of approximation are listed in Table 1. Obviously, the value of $\varepsilon$ decreases with the increase of the vertices of polyhedrons and the decrease of Hausdorff distances, which is consistent with the approximation results.
Table 1  Performance of different approximations

| Polyhedrons     | Triangle | Rectangle | Hexagon  | Octagon  | Decagonal | Dodecagonal |
|-----------------|----------|-----------|----------|----------|-----------|-------------|
| Values of $\varepsilon$ | 16.0416  | 11.8262   | 6.6113   | 3.9556   | 1.5406    | 0.7054      |

We further verify the effectiveness of our algorithm by comparing it with the algorithm of [15]. Figure 3 shows comparative results for our algorithm and the method proposed in [15]. The results imply that both of them are convergent, and (9) is with a faster convergence rate because (9) has lower dimensions and less complexity.

Figure 3  The comparison of the performance of our algorithm and the algorithm in [15]

7 Conclusion

A distributed game with coupled inequality constraints has been studied in this paper, where parameters in constraints are from general uncertain convex sets. By employing inscribed polyhedrons to approximate parameter sets, a distributed algorithm has been proposed for seeking an $\varepsilon$-GNE in the worst case, and the convergence of the algorithm has been shown. With the help of convex set geometry and metric spaces, the approximation accuracy affected by different inscribed polyhedrons is analyzed. Moreover, with the proof that the equilibrium point of the algorithm is an $\varepsilon$-GNE of the original problem, an upper bound of the value of $\varepsilon$ has been estimated by analyzing a perturbed system.

Appendix A  Proof of Lemma 4.3

(i) Consider $(z^*, \lambda^*, \zeta^*)$ as an equilibrium point of (9). By properties of normal cones to nonempty closed convex sets, at the equilibrium point, $\dot{z} = 0_{N, N}$ implies that $H_B(z^* - g(z^*)) = B^T \lambda^* = 0_N$. Then it follows from Lemma 2.38 of [32] that $-g(z^*) - B^T \lambda^* \in H_B(z^*)$.

Moreover, we set $\dot{\lambda} = 0_N$ and $\dot{\lambda} = 0_N$, which obtain $L \lambda^* = 0_N$ and $Bz^* - b - L \zeta^* \in H_B(z^*)$. It implies that $Bz^* - b - L \zeta^* \leq 0_N$. Because the graph $G$ is undirected and connected, $1_N^T L = 0_N^T$, and $1_N^T (Bz^* - b) \leq 0$. Also, take $\gamma^* \in H_B(z^*)$. Then we have $Bz^* - b - L \zeta^* \leq 0_N$. When $\lambda^* > 0_N$, $\zeta^* = 0_N$. Then it derives that $(Bz^* - b)^T \lambda^* = 0_N$. When $\lambda^* = 0_N$, $\zeta^* \in -R_N^N$, and $(Bz^* - b)^T \lambda^* = 0_N$ is still hold. Thus, $z^*$ is a variational GNE of the game (7).

(ii) When $z^*$ is a variational GNE of game (7), there exists $\lambda^* \in R_+$ such that the first order conditions (8) are satisfied. It is clear that $-g(z^*) - B^T \lambda^* \in H_B(z^*)$ is equivalent to $H_B(z^* - g(z^*)) = B^T \lambda^* = 0_N$. Furthermore, since $0 \geq (Bz^* - b)^T 1_N$, there exists an $\gamma^* \in R_+$ such that $0 = (Bz^* - b + \gamma)^T \cdot 1_N$. Note that $L 1_N = 0_N$ implies $\ker(L) = \text{span} \{1_N\}$.
\( \mathbb{R}^N = \ker(L) \oplus \text{Im}(L), \) there exists \( \zeta^* \in \text{Im}(L) \) such that \( L \zeta^* = Bz^* - b + \gamma, \) which implies \( Bz^* - b - L \zeta^* \in N_{\mathbb{R}_+^N}(\lambda^*). \) Therefore, \( (z^*, \lambda^*, \zeta^*) \) is an equilibrium point of (9).

**Appendix B** Proof of Theorem 4.4

Let \( \hat{\Omega} \triangleq \Omega \times \mathbb{R}_+^N \times \mathbb{R}_+^N \) and \( s = \text{col}(z, \lambda, \zeta). \) Define

\[
\hat{F}(s) \triangleq \begin{pmatrix}
g(z) + B^T \lambda \\
-Bz + b + L \lambda + L \zeta \\
-L \lambda
\end{pmatrix}, \quad U(s) \triangleq \Pi_B(s - \hat{F}(s)).
\]

Take the following Lyapunov function

\[
V(t) = -\langle \hat{F}(s), U(s) - s \rangle - \frac{1}{2} \|U(s) - s\|_2^2 + \frac{1}{2} \|s - s^*\|_2^2,
\]

where \( s^* = \text{col}(z^*, \lambda^*, \zeta^*). \) It follows from [33] that \( -\langle \hat{F}(s), U(s) - s \rangle - \frac{1}{2} \|U(s) - s\|_2^2 \geq 0. \) Thus, \( V(t) \geq \frac{1}{2} \|s - s^*\|_2^2 \geq 0, \) and \( V(t) = 0 \) if and only if \( s = s^*. \) Moreover, referring to [6],

\[
\dot{V}(t) \leq -\langle \hat{F}(s) - \hat{F}(s^*) \rangle^T (s - s^*) = - (z - z^*)^T (g(z) - g(z^*)) - \lambda^T L \lambda.
\]

Due to the monotonicity of \( g(z), \) it derives that \( \dot{V}(t) \leq 0. \) Hence, the trajectory of algorithm (9) is bounded and any finite equilibrium point of (9) is Lyapunov stable.

Furthermore, denote the set of points satisfying \( \dot{V}(t) = 0 \) by \( E_v \triangleq \{(z, \lambda, \zeta) : \dot{V}(t) = 0\}. \)

From (23), there holds

\[
E_v \subseteq \{(z, \lambda, \zeta) : z = z^*, L \lambda = 0\}.
\]

Then we claim that the maximal invariance set \( R \) within the set \( E_v \) is exactly the equilibrium point of (9). It follows from the invariance principle (Theorem 4.4 of [28]) that \( (z(t), \lambda(t), \zeta(t)) \to R \) as \( t \to \infty, \) and \( R \) is a positive invariant set. Consider a trajectory \( \bar{z}(t), \bar{\lambda}(t), \bar{\zeta}(t) \) in \( R. \) Note that (24) implies \( \bar{z} = 0, \bar{\zeta} = 0, \) and \( \bar{\lambda} = \) constant. Due to the boundedness of the trajectory, it leads to a contradiction if \( \bar{\lambda} \neq 0. \) Hence, any point in \( R \) is an equilibrium point of the algorithm (9). By Corollary 4.1 in [28], the system (9) converges to its equilibrium point. Therefore, based on Lemma 4.3, \( z(t) \) converges to a solution of \( \text{VI}(\bar{z}, g(z)) \) satisfying (8).

**Appendix C** Proof of Lemma 5.1

We will prove the conclusion of Lemma 5.1 in two steps.

**Step 1** Denote \( P_{v_1}^1 = \{\in R^n : A_1 \omega \leq d_1\} \) as an inscribed polyhedron of a convex and compact set \( \mathcal{M} \subseteq \mathbb{R}^n \) with \( V_1 \) as the set of vertices on the boundary of \( \mathcal{M}. \) Take \( P_{v_2}^2 = \{\in R^n : A_2 \omega \leq d_2\} \) as another inscribed polyhedron whose vertices consist of \( V_2 = V_1 \cup \{v_0\}, \) with \( v_0 \) as an additional vertex on the boundary of \( \mathcal{M}. \) We first prove that for \( A_2 \) as any row of matrix \( A_2, \) there exists a corresponding row \( A_1^{(l)}(l) \) of matrix \( A_1 \) such that \( \|A_2 - A_1^{(l)}(l)\| \leq c \varepsilon^l, \)

\[ \square \]
where $\tau^l = \psi(A^l, A^{(l)}) \in [0, \pi/2)$ is the angular metric between $A^l$ and $A^{(l)}$, $c$ is a finite positive constant.

Suppose that there are $q_1$ rows of $A_1$ and $d_1$, $q_2$ rows of $A_2$ and $d_2$, the first $q_1 - 1$ rows of $A_1$ are the same as the first $q_1 - 1$ rows of $A_2$. Thus, we only need to investigate the difference between $A_1^{q_1}$ and the last $q_2 - q_1 + 1$ rows of $A_2$.

Note that the dimension of each hyperplane is $n - 1$, and normalized vectors $A^l_2$ (or $A^{(l)}_1$) represent normal vectors of hyperplanes enclosing the polyhedron $P^{q_2}_v$ (or $P^{q_1}_v$). It follows from Lemma 2.1 that the angle between two hyperplanes uniquely equals to that between their normal vectors. Then there exist a derived angular metric and a corresponding scalar $\tau^l \in [0, \pi/2)$ for $q_1 \leq l \leq q_2$.

Additionally, referring to [34, Theorem 2.21], there exists a derived gap metric $v(A^l_2, A^{q_2}_v)$ such that

$$\|A^l_2 - A^{q_2}_v\| \leq \frac{1 + \|A^{q_2}_v\|^2}{\sqrt{1 + \|A^{q_2}_v\|^2 - 1}} \cdot v(A^l_2, A^{q_2}_v).$$

According to the definition of the gap metric in [20] and [35], there holds

$$v(A^l_2, A^{q_2}_v) = \sin \tau^l.$$

Since $A_1$ and $A_2$ are with normalized rows, with the fact $\sin \tau^l \leq \tau^l$, there exists a constant $c$ such that $\|A^l_2 - A^{q_2}_v\| \leq c \tau^l$.

**Step 2** Take $P_v$ and $P_{v_i}$ defined in (11) and (12) as two arbitrarily inscribed polyhedrons of $\mathcal{M}$. Without losing generality, consider $q_{1,i} \leq q_{2,i}$, $\forall i \in \mathcal{I}$. If $q_{1,i} < q_{2,i}$, then we increase the number of the hyperplane in $P_{v_{1,i}}$, successively. The newly added hyperplanes are the same as the $q_{1,i}$-th hyperplane. Continue this process until $q_{1,i} = q_{2,i}$.

According to the Lipschitz continuous of the projection,

$$\|e(y)\| \leq \|B_1 - B_2\| (\|A\| + \|z\|) + \|C_1 - C_2\| (\|\xi\| + \|z\|).$$

For $i \in \mathcal{I}$, since $B^1_{v_i} - B^2_{v_i} = [0^T, (d_{1,i} - d_{2,i})^T] \in \mathbb{R}^{1 \times (n+q_{2,i})}$ and $C^1_{v} - C^2_{v} = [-0_{n \times n}, (A_{1,i} - A_{2,i})^T] \in \mathbb{R}^{n \times (n+q_{2,i})}$, we only need to investigate $\|A_{1,i} - A_{2,i}\|$ and $\|d_{1,i} - d_{2,i}\|$.

It follows from Step 1 that $\|A_{1,i} - A_{2,i}\| \leq c_{A_{1,i}} \leq \theta_{i} c_{A_{1,i}}$, $\forall i \in \mathcal{I}$, where $c_{A_{1,i}}$ is a constant for $i \in \mathcal{I}$. Then, $\|A_{1,i} - A_{2,i}\| \leq q_i c_A \theta_i$, where $q_i = q_{2,i}$ is the number of hyperplanes in $P^i_{v_{2,i}}$.

Correspondingly, $\|d_{1,i} - d_{2,i}\| \leq q_i c_d \theta_i$, where $c_{d,i}$ is a constant for $i \in \mathcal{I}$. The analysis of other players is similar to that of player $i$. To sum up, there exists a finite constant $c$ such that $\|e(y)\|$ can be bounded by $\delta$ on $\overline{\mathcal{I}}$, that is,

$$\|e(y)\| \leq r (\|B_1 - B_2\| + \|C_1 - C_2\|) \leq r \sum_{i=1}^{N} \|A_{1,i} - A_{2,i}\| + \|d_{1,i} - d_{2,i}\| = r \sum_{i=1}^{N} q_i (c_{A_{1,i}} + c_{d,i}) \theta_i = r \sum_{i=1}^{N} q_i c_i \theta_i.$$

The proof is finished.
Appendix D  Proof of Theorem 5.4

We first verify the existence and uniqueness of \( x^*(\mathcal{M}) \).

Referring to [29], for a convex set \( \mathcal{M} \), there exists an inscribed polyhedron \( \mathcal{P}_v \) of \( \mathcal{M} \) such that the upper bound of the Hausdorff metric between \( \mathcal{M} \) and \( \mathcal{P}_v \) satisfies \( H(\mathcal{P}_v, \mathcal{M}) \leq C_{\mathcal{M}} v^{(n-1)/2} \), where \( C_{\mathcal{M}} \) is a constant related with the curvature of \( \mathcal{M} \), and \( v \) is the number of vertices in \( \mathcal{P}_v \). That is to say, \( \lim_{v \to \infty} H(\mathcal{P}_v, \mathcal{M}) = 0 \). Meanwhile, following from [36, Lemma 4], there holds

\[
\tau_i^l \leq \theta_i \leq \frac{1}{\sqrt{\frac{2}{h_i n_i} - 1}}, \tag{25}
\]

where \( h_i = H(\mathcal{P}^1_{v_{1,i}}, \mathcal{P}^1_{v_{2,i}}) \) represents the Hausdorff distance between \( \mathcal{P}^1_{v_{1,i}} \) and \( \mathcal{P}^1_{v_{2,i}} \), \( n_i \) is a constructive curvature related merely to the structure of \( M \), and \( \theta_i \) is the upper bound of the Hausdorff metric between \( \mathcal{M} \) and \( \mathcal{P}_v \).

Next, we prove that \( x^*(\mathcal{P}_v) \) of the approximate game (1) and estimate \( \varepsilon \). Rewrite \( \delta \) as \( \delta(\mathcal{P}_{v_1}, \mathcal{P}_{v_2}) \). When \( \mathcal{P}_{v_2} \) is fixed, \( \delta(\mathcal{P}_{v_1}, \mathcal{P}_{v_2}) \) is continuous in \( \mathcal{P}_{v_1} \). By substituting \( \delta(\mathcal{P}_{v_1}, \mathcal{P}_{v_2}) \) into (17) and (18), \( \|x^*(\mathcal{P}_{v_1}) - x^*(\mathcal{P}_{v_2})\| \to 0 \) as \( H \to 0 \), which means that \( x^*(\mathcal{P}_v) \) is continuous in \( \mathcal{P}_v \) under Hausdorff metric. Therefore, there exist a unique \( x^*(\mathcal{M}) \) such that

\[
\lim_{v \to \infty} x^*(\mathcal{P}_v) = x^*(\mathcal{M}). \tag{26}
\]

Finally, based on the definition of \( \varepsilon \)-GNE in Definition 3.1, we analyze the difference between \( J_i(x^*(\mathcal{P}_v)) \) and \( J_i(x^*_{i,0}(\mathcal{P}_v)) \), the \( i \)th players equilibrium strategy is \( x^*_{i}(\mathcal{P}_v) \) with respect to \( \mathcal{P}_v \), and \( x^*_{i,0} \) is arbitrarily chosen from \( X_i \). Meanwhile, other players strategies remain the same \( x^*_{-i}(\mathcal{P}_v) \).

\[
J_i(x^*(\mathcal{P}_v)) - J_i(x^*_{i,0}(\mathcal{P}_v)) \leq \|J_i(x^*(\mathcal{P}_v)) - J_i(x^*_{i,0}(\mathcal{P}_v))\| + \|J_i(x^*(\mathcal{P}_v)) - J_i(x^*(\mathcal{M}))\| + \|J_i(x^*(\mathcal{M})) - J_i(x^*_{i,0}(\mathcal{M}))\| \leq \varepsilon_i \|x^*(\mathcal{P}_v) - x^*(\mathcal{M})\| + \varepsilon_i \|x^*_{i,0}(\mathcal{M}) - x^*_{i,0}(\mathcal{P}_v)\| \leq 2\varepsilon_i\alpha_i^{-1} \left( \alpha_2 \left( \frac{\delta \alpha_i(r)}{\mu} \right) \right),
\]

where the third term in the first inequality is due to the definition of GNE. From this definition, the upper bound of the last term is zero. This yields the conclusion.
