(Dated:)

We investigated the magnetoelectric properties of the quasi-one-dimensional spin-1/2 frustrated magnet LiCuVO₄. Longitudinal-magnetoelectric experiments were performed at 1.5 K in high magnetic fields of up to 60 T applied along the a axis, i.e., the spin-chain direction. The magnetoelectric data qualitatively resemble the magnetization results, and saturate at $H_{\text{sat}} \approx 54$ T, with a relative change in sample length of $\Delta L/L \approx 1.8 \times 10^{-4}$. Remarkably, both the magnetoelectric and the magnetization evolve gradually between $H_{c3} \approx 48$ T and $H_{\text{sat}}$, indicating that the two quantities consistently detect the spin-nematic phase just below the saturation. Numerical analyses for a weakly coupled spin-chain model reveal that the observed magnetoelectric can overall be understood within an exchange-striction mechanism. Small deviations found may indicate nontrivial changes in local correlations associated with the field-induced phase transitions.

I. INTRODUCTION

One-dimensional (1D) quantum-spin magnets with competing interactions have been intensively studied for decades to search for unconventional quantum phases that result from the interplay between strong quantum fluctuations and magnetic frustration. As 1D systems generally allow simpler theoretical treatment compared with higher-dimensional ones, they provide an ideal platform for studying quantum phases through a close comparison between experimental and theoretical approaches. One example is the spin-nematic phase, a magnetic analogue of the nematic liquid-crystal phase, where the spin-rotational symmetry is spontaneously broken while translational and time-reversal symmetries are preserved. This new type of quantum phase has been discussed in a variety of 1D spin models, including spin-1/2 [1–4] and spin-1 [5, 6] chains. In the spin-1/2 case, magnon bound states (bimagnons) arise from a competition between ferromagnetic nearest-neighbour $J_1 < 0$ and antiferromagnetic next-nearest-neighbour $J_2 > 0$ interactions, and play a crucial role in the formation of the spin-nematic phase. Upon condensation, bimagnons form a Tomonaga-Luttinger liquid (TLL), which shows dominant spin density wave (SDW) or nematic quasi-long-range correlations at low and high fields, respectively.

One well-studied spin-nematic candidate is the orthorhombic inverse spinel LiCuVO₄, where magnetic Cu²⁺ ions form spin-1/2 chains with two dominant exchange interactions, $J_1$ and $J_2$, along the crystallographic b axis [7–9]. Weak interchain interactions (such as $J_3 < 0$) lead to a three-dimensional (3D) magnetic long-range order below $T_c \approx 2.3$ K with an incommensurate planar spiral structure lying in the ab plane [10, 11]. This spiral structure, which induces ferroelectricity through magnetoelectric coupling, has spurred additional interest in LiCuVO₄ in terms of multiferroicity [12–15].

When applying magnetic fields, a phase transition to an incommensurate collinear SDW phase takes place at $H_{c2} \approx 7.5$ T [16–18]. Such a SDW phase is expected to appear when the SDW correlations of a bimagnon TLL are stabilized by interchain interactions [19, 20]. This picture has been corroborated by neutron scattering [21], nuclear magnetic resonance (NMR) [22], and spin Seebeck effect [23] experiments. With further increasing magnetic field, the SDW correlations are weakened in favor of the nematic correlations, and as a result, a 3D nematic long-range order is stabilized just below the saturation field, as theoretically discussed in Refs. [19, 20, 24, 25]. Remarkably, high-field magnetization [26], NMR [27], magnetocaloric effect (MCE), and ultrasound [28] measurements have reported evidence of this 3D spin-nematic state between $H_{c3}$ and $H_{\text{sat}}$, which are about 40 and 45 T for the magnetic field applied along the c axis, and about 48 and 53 T along the a and b axes.

While a large number of experiments have been performed on LiCuVO₄, there have been only few studies on its magnetoelectric properties. Mourigal et al. have proposed that the magnetoelectric is negligible in LiCuVO₄ based on specific heat and neutron scattering experiments, and that the multiferroicity arises from a purely electronic spin-supercurrent mechanism [14]. In contrast, recent thermal expansion and magnetoelectric experiments in low magnetic fields of up to 9 T by Grams et al. revealed a sizable magnetoelectric coupling in LiCuVO₄ [29].

In this paper, we report longitudinal magnetoelectric measurements of LiCuVO₄ at 1.5 K in high magnetic...
fields of up to 60 T applied along the $b$ axis, i.e., the 1D spin-chain direction. The observed magnetostriction is as large as $\Delta L/L \approx 1.8 \times 10^{-4}$ at high fields, indicating that LiCuVO$_4$ has a sizable magnetoelastic coupling as reported previously [28, 29]. The magnetostriction data qualitatively resemble the magnetization reported in Ref. [27]. In particular, both quantities evolve gradually between $H_{c3}$ and $H_{\text{sat}}$, indicating that the magnetostriction can also probe the 3D spin-nematic state appearing just below the saturation. Furthermore, we analyze the magnetostriction data of LiCuVO$_4$ within an exchange-striction model with exchange interactions modified linearly by the distance between the involved spins. The density matrix renormalization group (DMRG) and exact diagonalization (ED) analyses for the $J_1$-$J_2$(-$J_3$) spin-chain model show an overall agreement with our experimental results. Small deviations found may indicate non-trivial changes in local correlations associated with field-induced phase transitions. A more refined treatment of the interchain coupling or introduction of additional interactions, such as a Dzyaloshinskii-Moriya (DM) term, is needed to explain the magnetoelastic properties of LiCuVO$_4$ in general detail.

II. METHODS

Longitudinal-magnetostriction measurements were performed by the optical fiber Bragg grating (FBG) method [30] in pulsed magnetic fields of up to 60 T with a whole pulse duration of 25 ms at the HLD-EMFL in Dresden. The relative length change, $\Delta L/L$, was obtained from the Bragg wavelength shift of the FBG. A high-quality LiCuVO$_4$ single crystal with a size of 1.9 $\times$ 2.0 $\times$ 0.65 mm$^3$ was used in this study, which is the same one previously used in the magnetocaloric effect and ultrasound experiments by Gen et al. [28]. Magnetic field was applied along the orthorhombic $b$ axis, which is the spin-chain direction ($H \parallel \Delta L/L \parallel b$ axis). Note that the magnetic field was applied along the $c$ axis in Ref. [28].

Numerical analyses were conducted for the $J_1$-$J_2$-$J_3$ model that describes magnetic interactions in the $ab$ plane. We use the ratio $J_1 : J_2 : J_3 = -0.42 : 1 : -0.11$ as obtained from neutron-scattering experiments reported in Ref. [8]. For the Landé $g$-factor, we take the value $g = 2.095$ along the $b$ axis from Ref. [31]. We then set $J_3 = 4.0$ meV so that the theoretical saturation field is adjusted to 48 T, at which the experimental magnetization curve is the steepest; see Appendix B. This value is quite close to $J_3 = 3.8$ meV reported in Ref. [8]. DMRG calculations were performed for the pure 1D $J_1$-$J_2$ model with up to 168 spins (see Appendix A for details). We took into account the interchain coupling $J_3$ in a mean-field manner following Ref. [32]. As a complementary analysis, ED calculations based on TITPACK ver. 2 [33] were performed directly for the $J_1$-$J_2$-$J_3$ model with up to 28 spins on the 2D plane. Both the DMRG and ED results show an overall agreement with the experimental magnetization, as shown in Appendix B.

III. RESULTS AND DISCUSSION

A. Magnetostriction measurements and exchange-striction mechanism

Figure 1(a) shows the longitudinal magnetostriction, $\Delta L/L$, of LiCuVO$_4$ in magnetic fields of up to 60 T ($H \parallel \Delta L/L \parallel b$ axis) with the normalized magnetization, $M/M_{\text{sat}}$, taken from Ref. [27]. Note that the LiCuVO$_4$ sample used in magnetization measurements was from the same batch as that used in the present magnetostriction study. The magnetostriction data qualitatively resemble the magnetization up to the saturation, except that no transition was detected at around 10 T (labelled as $H_{c2}$ in the magnetization). At saturation, the observed magnetostriction is as large as $\Delta L/L \approx 1.8 \times 10^{-4}$, indicating a sizable magnetoelastic coupling in LiCuVO$_4$ as also reported recently [28, 29].

To highlight the anomaly in high magnetic fields, the derivative of the longitudinal magnetostriction, $d(\Delta L/L)/dH$, is shown in Fig. 1(b). Notably, the magnetostriction still grows above 48 T ($H_{c3}$), at which a clear peak in $d(\Delta L/L)/dH$ is observed, and it saturates around 54 T ($H_{\text{sat}}$). Similar behavior has also been observed in magnetization and NMR experiments, as reported previously in Refs. [26, 27]; in these works, evidence for the existence of a 3D spin-nematic phase between $H_{c3}$ and $H_{\text{sat}}$ was given. The observed similarity indicates that the magnetostriction can consistently detect the 3D spin-nematic phase as well.

To understand the microscopic origin of the magnetostriction, we adopt the following exchange-striction model for a 1D frustrated $J_1$-$J_2$ spin-chain system [34, 35]

$$H_{\text{es}} = \sum_{n=1,2} \sum_j (J_n - f_n \epsilon) \langle S_j \cdot S_{j+n} \rangle + N_{1D} k' \epsilon^2 - g \mu_B H \sum_j S_j^z,$$

(1)

where $\epsilon = \Delta L/L$, $f_n$ is the magnetoelastic coupling coefficient, $k'$ is the elastic constant per Cu$^{2+}$ ion, and $N_{1D}$ is the number of Cu$^{2+}$ ions in the chain. For a fixed field $H$ or a fixed magnetization $M$, $\epsilon$ can be determined from minimizing the expectation value of $H_{\text{es}}$. To compare with the experimental data, we set $\epsilon$ to zero for $M = 0$, obtaining

$$\epsilon(M) = \frac{1}{k'} \sum_{n=1,2} f_n \left( \langle S_j \cdot S_{j+n} \rangle_M - \langle S_j \cdot S_{j+n} \rangle_{M=0} \right),$$

(2)

where $\langle \cdots \rangle_M$ denotes the expectation value at the magnetization $M$ and $\langle \cdots \rangle_{M=0}$ indicates the spatial average (i.e., the average over $j$). This expression indicates that the magnetostriction $\epsilon = \Delta L/L$ is a useful probe to detect local spin correlations $\langle S_j \cdot S_{j+n} \rangle_M$, although there are unknown coefficients $f_n$. For the sake of simplicity, we
have neglected the contribution of the interchain coupling $J_0$; by including it, the change in the local spin correlation on the $J_0$ bond will be added to Eq. (2) with a coefficient $2f_0/k'$.

As Eq. (2) is similar to the expression of the spin-interaction energy $E_{\text{int}}$ (i.e., the expectation value of the Heisenberg interaction part of the Hamiltonian), it is interesting to compare $E_{\text{int}}$ with the measured $\Delta L/L$. Exploiting the thermodynamic relation $\frac{\partial E}{\partial M} = H$, the spin-interaction energy relative to the zero-field case can be obtained from the magnetization data ($M$ versus $H$) via

$$\Delta E_{\text{int}}(M) = E_{\text{int}}(M) - E_{\text{int}}(0) = \int_0^M H(M')dM'. \quad (3)$$

$\Delta L/L$ and $\Delta E_{\text{int}}$ are shown in Fig. 2, where both quantities are normalized to 1 at saturation. As seen in Fig. 2(a), the two curves exhibit an overall similar field dependence. A small deviation is found in the intermediate SDW phase between $H_{c2}$ and $H_{c3}$. This indicates that the exchange-striction model, Eqs. (1) and (2), is a good approximation to describe the magnetoelastic properties of LiCuVO$_4$. We note that both $\Delta L/L$ and $\Delta E_{\text{int}}$ show a kink around $H_{c3}$; The kink in $\Delta E_{\text{int}}$ is consistent with the theoretical picture of Ref. [24].

To analyze further the slightly different behavior of $\Delta L/L$ and $\Delta E_{\text{int}}$, we plot them as a function of $M/M_{\text{sat}}$ in logarithmic scales in Fig. 2(b). Our motivation for this plot stems from the fact that the power-law relation $\Delta L/L \propto M^p$ has been observed in a variety of magnetic materials: with $p = 2$ in conventional antiferromagnets, $p = 1$ in spin-dimer systems [36, 37], and $p = 1.3$ in the distorted kagome-lattice magnet volborthite, Cu$_3$V$_2$O$_7$(OH)$_2$·2H$_2$O [35]. Here, $p = 2$ can be understood from a classical canted antiferromagnetic order, in which $\mathbf{S}_i = S(\sin \theta \cos \mathbf{q} \cdot \mathbf{r}_i, \sin \theta \sin \mathbf{q} \cdot \mathbf{r}_i, \cos \theta)$, with $\theta$ and $\mathbf{q}$ being the canting angle and the propagation.
vector, respectively. This gives

$$S_i \cdot S_j = S^2 \left( \sin^2 \theta \cos \mathbf{q} \cdot \mathbf{r}_{ij} + \cos^2 \theta \right) = (S^2 - m^2) \cos \mathbf{q} \cdot \mathbf{r}_{ij} + m^2,$$

with $m = S_i^z = S \cos \theta$ and $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$. $p = 1$ in spin-dimer systems is also comprehensible from the fact that the magnetization $M$ and the change in the intradimer correlations $(S_i \cdot S_j)_M$ are both proportional to the number of triplons. The unusual power $p = 1.3$ in volborthite could, thus, be interpreted as a result of strong quantum fluctuations in a low-dimensional frustrated magnet. As shown in Fig. 2(b), our data fit well to the relations $\Delta L/L \propto M^{1.32}$ and $\Delta E_{\text{int}} \propto M^{1.55}$ in the SDW phase. We will use these power-law relations as a guide to compare the experimental and numerical results. The exponents $p = 1.32$ and $1.55$ are significantly different from that of conventional antiferromagnets; the former agrees with that for volborthite. This indicates a crucial role of quantum fluctuations in LiCuVO$_4$ due to its quasi-1D nature.

**B. Comparison with numerical results**

In Fig. 3, we compare the spin-interaction energy $\Delta E_{\text{int}}$ per spin extracted from the experimental data with the DMRG results with and without the interchain coupling $J_5$. Here, the DMRG calculations were carried out for the pure 1D $J_1$-$J_2$ model, and the effect of $J_5$ is taken into account in a mean-field manner by simply adding $2J_5 (M/2M_{\text{sat}})^2$ to the energy per spin [32]. The DMRG results modified by $J_5$ show a very good agreement with the experiments even without normalization for the vertical axis. The agreement is expected since $\Delta E_{\text{int}}$ is related to the magnetization via Eq. (3), and we have adjusted the value of $J_2$ in such a way that the DMRG result modified by $J_5$ can best reproduce the experimental magnetization (Appendix B).

In Fig. 4, we compare the experimental magnetostriction data with the DMRG results of the local spin correlations $(S_i \cdot S_j)_M$ on the $J_1$ and $J_2$ bonds and the spin interaction energy $\Delta E_{\text{int}}$ (see Appendix A for details of the DMRG analysis). Here, the spatial average $\langle \cdots \rangle$ is taken over the concerned bonds $(i, j)$ for each interaction, and all the quantities are normalized between 0 and 1, which correspond to the zero-field case and the saturation, respectively. We also present the DMRG and ED results on the local spin correlations without normalization in Fig. 5. Notably, in Fig. 4, the normalized spin correlations on the $J_1$ and $J_2$ bonds show quite similar behavior. This is remarkable as $J_1$ and $J_2$ are ferromagnetic and antiferromagnetic, respectively, and the correlations have opposite signs at low fields, as seen in Fig. 5. While we do not have a physical explanation for this behavior, it has the convenient consequence that any linear combination of the two local correlations shows similar behavior if normalized. Indeed, in Fig. 4, the DMRG data for the spin-interaction energy $\Delta E_{\text{int}}$ also behave similarly to the local spin correlations although it contains the small mean-field contribution of the interchain coupling $J_5$. In contrast, the experimental magnetostriction data, $\Delta L/L$, which is also expected to be described by the local spin correlations according to Eq. (2), show a clear deviation in the SDW phase between $H_{c2}$ and $H_{c3}$. This deviation cannot be explained even if we consider a linear combination of the spin correlations on $J_1$, $J_2$, and also $J_5$ bonds, as we explain in the following.
be sensitive to the field-induced phase transitions as described by Eqs. (1) and (2). The spin Hamiltonian and in the exchange-striction mechanism, such as exchange anisotropy and DM interactions in the system, it would be important to investigate the effects of additional terms to the scaling of the magnetostriction $\Delta L/L \propto M^{1.82}$ for $J_1$ and $M^{1.74}$ for $J_2$. Solid lines show the scaling [Eq. (5)] with $p = 1.82, 1.74$, and 2 for the $J_1$, $J_2$, and $J_3$ bonds, respectively [38]. In the ED results, symbols with small, medium, and large sizes correspond to the cases of 20, 24, and 28 spins, respectively [a screw boundary condition $\mathbf{c}_3$ with $(L_x, L_y) = (5, 4), (6, 4), \text{ and } (7, 4)$ as described in Appendix B].

The calculated data in Fig. 5 are described well by the relation

$$\langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle_M - \langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle_{M=0} \propto M^p,$$

with $p = 1.82, 1.74$, and 2 for the $J_1$, $J_2$, and $J_3$ bonds, respectively. Note that the relation with $p = 2$ for the $J_3$ bond is automatically satisfied in the mean-field treatment of $J_5$, and it is confirmed well in the ED result for the 2D model. If we assume that the contribution of the $J_3$ bond is an order of magnitude smaller, a linear combination of the correlations (Fig. 5) cannot lead to the scaling of the magnetostriction $\Delta L/L \sim M^{1.32}$ in the SDW phase [Fig. 2(b)]. Furthermore, such a linear combination cannot explain the kink-like features of the magnetostriction around the field-induced transition points $H_{c2}$ and $H_{c3}$ (Fig. 4).

The above consideration indicates a missing contribution in the magnetostriction. Such a contribution should be sensitive to the field-induced phase transitions as observed experimentally. A more refined treatment of the interchain coupling $J_3$ might be required. It would also be important to investigate the effects of additional terms such as exchange anisotropy and DM interactions in the spin Hamiltonian and in the exchange-striction mechanism described by Eqs. (1) and (2).

IV. SUMMARY

Magnetostriction measurements of LiCuVO$_4$ in high magnetic fields up to 60 T applied along the $b$ axis show monotonous increase of $\Delta L/L$ reaching a sizable value $\Delta L/L \approx 1.8 \times 10^{-4}$ at the saturation field $H_{sat} \approx 54$ T. Both the magnetostriction and the magnetization [27] evolve in a similar way between $H_{c2} \approx 48$ T and $H_{sat} \approx 54$ T, which indicates that both quantities consistently detect the 3D spin-nematic phase just below saturation. Our results were discussed within the exchange-striction mechanism. The DMRG and ED analyses for the $J_1$-$J_2$(-$J_5$) spin-chain model show a good agreement with the experimental observations. A more refined treatment of the interchain coupling or additional interactions such as DM interactions would be needed to explain the magnetoelastic properties of LiCuVO$_4$ in more detail. As our results reveal the importance of the magnetoelastic coupling, it would be interesting to reconsider the contribution of the lattice to the multiferroic properties of LiCuVO$_4$, which is under debate [14, 29].

Appendix A: DMRG calculations

We performed DMRG calculations for the pure 1D $J_1$-$J_2$ Heisenberg model with the Hamiltonian given by

$$\mathcal{H}_{1D} = J_1 \sum_j \mathbf{S}_j \cdot \mathbf{S}_{j+1} + J_2 \sum_j \mathbf{S}_j \cdot \mathbf{S}_{j+2}. \quad (A1)$$

We set $J_1 : J_2 = -0.42 : 1$ as explained in Sec. II. The number of spins was up to $N_{1D} = 168$ and open boundary conditions were imposed.

Using DMRG, we calculated the lowest-energy state in each subspace characterized by the $z$ component of the total spin, $S_{tot}^z = \sum_j S_j^z$. We then computed the lowest energy $E_{1D}^{tot}(m)$ and the local spin correlations $\langle \mathbf{S}_j \cdot \mathbf{S}_{j+n} \rangle_{m}$ ($n = 1, 2$), where $m = S_{tot}^z / N_{1D}$ and $\langle \cdots \rangle_{m}$ denotes the expectation value with respect to the lowest-energy state in the subspace with $S_{tot}^z = N_{1D} m$ in the system under the open boundary conditions. Note that $m$ relates to the magnetization $M$ in the main text as $M = Ng \mu_B m$, where $N$ is the number of Cu$^{2+}$ ions. The
FIG. 6. (a) Local spin correlations $\langle S_j \cdot S_{j+n/m} \rangle^{(o)}$ for $N_{1D} = 168$ and $m = 48/168$. Open and solid symbols respectively represent the DMRG data and fits using Eqs. (A2) and (A3). Solid lines connecting the fits are guides to the eye. (b) The DMRG data of $\langle S_j \cdot S_{j+n/m} \rangle^{(o)}$ for $m = 0$. The data for $N_{1D} = 96$ are shown to demonstrate oscillations with four-site period. We observed similar four-site period oscillations also for $N_{1D} = 120$ and 168. Dashed lines connecting the data points are guides to the eye.

number of density matrix eigenstates kept in DMRG that is required for achieving a sufficient accuracy depends on $N_{1D}$ and $S_{tot}^z$. In our calculation, we kept up to 600 states in the most severe case and the truncation error (the sum of the density matrix weights of discarded states averaged over the last sweep) was, at most, $6 \times 10^{-7}$. We, thereby, confirmed that the calculation was accurate enough for our argument.

The magnetization, which will be discussed in Appendix B, was obtained from the data of $E_{\text{tot}}^{1D}(m)$ by finding $m$ that minimizes $E_{\text{tot}}^{1D}(m) - hN_{1D}m$ for each $h = q\mu_B H$. We found that $S_{tot}^z$ appearing in the magnetization curve was all even except for the single case of $S_{tot}^z = 1$. This observation indicates the formation of bound magnon pairs for $S_{tot}^z \geq 2$. We note that this is consistent with the known result that the $J_1$-$J_2$ Heisenberg chain with $J_1 < 0$, $J_2 > 0$, and $J_1/J_2 \lesssim -1$ exhibits the Haldane dimer phase for $m = 0$ and the bimagnon TLL phase for $0 < m < 1/2$, while the range of the vector-chiral phase inbetween them, if any, is too narrow to be detected in the numerical calculation [2, 3, 40, 41]. We consider only the states with even $S_{tot}^z$ in the following analysis of the local spin correlations.

In Fig. 6, we present the DMRG data of the local spin correlations $\langle S_j \cdot S_{j+n/m} \rangle^{(o)}$ for $N_{1D} = 96, 120, \text{and } 168$ with Eqs. (A2) and (A3) as shown in Fig. 6(a).

FIG. 7. Uniform parts of the local spin correlations, $c_1$ and $c_2$, as functions of $m$. These were obtained from the fitting of the DMRG data of $\langle S_j \cdot S_{j+n/m} \rangle^{(o)}$ for $N_{1D} = 96, 120, \text{and } 168$ with Eqs. (A2) and (A3) as shown in Fig. 6(a).

that were derived as the expressions of the local energy density of the bimagnon TLL under open boundary conditions [2, 42, 43]. The wave number $Q$ relates to $m$ via the density of bimagnons $\rho$ as

$$Q = \frac{2\pi N_{1D}}{N_{1D} + 1} \left( \rho - \frac{1}{2} \right),$$

$$\rho = \frac{1}{2} \left( \frac{1}{2} - m \right).$$

We performed the least-square fitting of the DMRG data of $\langle S_j \cdot S_{j+n/m} \rangle^{(o)}$ for $N_{1D}/4 + 1 \leq j \leq 3N_{1D}/4 - n$ with Eqs. (A2) and (A3) by taking $c_n$, $c'_n$, and $K$ as fit parameters. We, thereby, determined the uniform parts.
The data exhibit a smooth behavior and the dependence on the system size $N_{1D}$ is negligibly small. We, thus, used the data of $c_1$ and $c_2$ for $N_{1D} = 168$ as the estimates of the local spin correlations $\langle S_i \cdot S_j \rangle_M$ on the $J_1$ and $J_2$ bonds in the thermodynamic limit.

Appendix B: Magnetization

The magnetization was calculated using the DMRG and ED methods for the $J_1$-$J_2$-$J_5$ spin-chain model with $J_1 : J_2 : J_5 = -0.42 : 1 : -0.11$, $J_2 = 4.0$ meV, and $g = 2.095$. The model can conveniently be defined on an approximate rectangular lattice with the primitive vectors $\mathbf{u} = (b/2, 0)$ and $\mathbf{v} = (0, a)$. The $J_1$, $J_2$, and $J_5$ interactions connect spins separated by the vectors $\mathbf{u}$, $2\mathbf{u}$, and $\pm \mathbf{u} + \mathbf{v}$, respectively. The DMRG calculations were performed for the pure $1D$ $J_1$-$J_2$ model with $N_{1D} = 168$ spins, and the interchain coupling $J_5$ was taken into account in a mean-field manner [32]. Namely, at fixed $m = \frac{N_{1D}}{2}$, the ground-state spin-interaction energy per spin, $E_{\text{int}}(m)/N_{1D}$, is modified by an additive correction of $2J_5m^2$. Correspondingly, in the magnetization $(m$ versus $h = g\mu_B H = \frac{1}{N_{1D}} \frac{\partial E_{\text{int}}(m)}{\partial m}$), $h$ is modified by an additive correction of $4J_5m^2$. In contrast, the ED calculations were performed directly for the 2D model with 28 spins. To reduce finite-size effects in ED, we adopted a screw boundary condition [39], in which spins separated by $L_x \mathbf{u} + \mathbf{v}$ and $L_y \mathbf{v}$ with $(L_x, L_y) = (7, 4)$ were identified.

In Fig. 8, the measured magnetization [27] and the DMRG and ED results are shown together. Here, the numerical results are presented for the cases with and without the interchain coupling $J_5$ to highlight its effect. We find a good agreement between the experimental data and the numerical results with $J_5$ coupling, which supports the present model. Furthermore, the agreement between the DMRG and ED results demonstrates the effectiveness of the mean-field treatment of $J_5$ in the DMRG calculations.

[34] The exponents $p$'s for the correlations on the $J_1$ and $J_2$ bonds were determined from the least-square fitting of the DMRG data with Eq. (5) using the data for $0.4 \leq \langle \langle S_i \cdot S_j \rangle \rangle \leq 0.7$. On the other hand, the solid line for the correlations on the $J_1$ bond simply shows the relation $\langle S_i \cdot S_j \rangle = (M^2/2M_{sat})^2$ expected in the mean-field treatment.
