Abstract

Background: To understand the gene networks that underlie plant stress and defense responses, it is necessary to identify and characterize the genes that respond both initially and as the physiological response to the stress or pathogen develops. We used PCR-based suppression subtractive hybridization to identify Arabidopsis genes that are differentially expressed in response to ozone, bacterial and oomycete pathogens and the signaling molecules salicylic acid (SA) and jasmonic acid.

Results: We identified a total of 1,058 differentially expressed genes from eight stress cDNA libraries. Digital northern analysis revealed that 55% of the stress-inducible genes are rarely transcribed in unstressed plants and 17% of them were not previously represented in Arabidopsis expressed sequence tag databases. More than two-thirds of the genes in the stress cDNA collection have not been identified in previous studies as stress/defense response genes. Several stress-responsive cis-elements showed a statistically significant over-representation in the promoters of the genes in the stress cDNA collection. These include W- and G-boxes, the SA-inducible element, the abscisic acid response element and the TGA motif.

Conclusions: The stress cDNA collection comprises a broad repertoire of stress-responsive genes encoding proteins that are involved in both the initial and subsequent stages of the physiological response to abiotic stress and pathogens. This set of stress-, pathogen- and hormone-modulated genes is an important resource for understanding the genetic interactions underlying stress signaling and responses and may contribute to the characterization of the stress transcriptome through the construction of standardized specialized arrays.
the development of the systemic response include reactive oxygen species (ROS), SA, JA and ethylene [8-10]. There is evidence for commonalities between plant responses to pathogens (referred to as defense responses) and environmental stresses (referred to as stress responses) [11,12]. Despite similarities, however, a plant's response to each environmental challenge is unique and tailored to increasing the plant's ability to survive the inciting stress [13-16].

A comprehensive understanding of the networks of genes, proteins and small molecules that underlie plant stress and defense responses requires identification and characterization of the molecular components, including the genes that respond both initially and as the physiological response to the stress or pathogen develops. Several groups [17,18] have used existing expressed sequence tag (EST) collections to carry out microarray experiments in initial efforts to identify genes whose expression levels change in response to pathogens and various abiotic stresses. However, existing EST collections are not complete and most were derived from cDNA libraries made from plants grown under normal environmental conditions; hence, ESTs representing stress- and pathogen-induced transcripts are likely to be under-represented in them.

To characterize the stress/defense transcriptome of Arabidopsis more thoroughly, we sought to identify genes whose expression levels change in response to abiotic stress, known second messengers and bacterial and fungal pathogens. We used the bacterial pathogen Pseudomonas syringae and the oomycete pathogen Peronospora parasitica to evoke the pathogen defense response. The availability of both avirulent and virulent strains of these pathogens facilitates identification of genes that are important for resistance, as well as those expressed during disease development [19-21]. Moreover, both of these pathogens cause severe damage to crops of economic importance, such as tomato and crucifers [19]. We also treated plants with SA and methyl jasmonate (MJ) because both are important signaling molecules implicated in plant responses to pathogens, herbivory and wounding and they induce different aspects of the SAR [22].

We used ozone as an abiotic stressor because the plant's response at the biochemical and molecular level shows extensive overlap with the pathogen defense response and includes the production of ROS, as well as induction of HR and SAR [23,24]. At the phenotypic level, acute ozone exposure (high dose for a short interval) causes necrotic lesions similar to those caused by avirulent pathogen infections, whereas chronic ozone exposure (low dose for an extended period of time) accelerates foliar senescence, producing similar symptoms to those caused by virulent pathogen infections [25,26]. There is evidence that elicitor-evoked ROS production, called the oxidative burst, is an essential signaling component of the defense response [27]. Moreover ozone is a component of photochemical smog and itself represents an oxidative stress to living organisms, damaging crops and forests [28].

There are several strategies for identifying differentially expressed transcripts, including differential display (DD), representational difference analysis (RDA), serial analysis of gene expression (SAGE), enzymatic degradation subtraction and subtractive hybridization [29-33]. We chose the PCR-based suppression subtractive hybridization (SSH) procedure for several reasons: it includes a normalization step, it enriches for differentially expressed transcripts, and it yields cDNA fragments that can be used directly for the construction of DNA microarrays. We viewed the normalization step as particularly important because a few stress-activated genes, such as those encoding the pathogenesis-related (PR) proteins, are abundantly induced by a variety of stresses, potentially obscuring important stress-specific transcripts expressed at much lower levels. The SSH procedure developed by Diatchenko et al. [33] has the additional advantage that it exploits the suppression PCR effect, eliminating the need for physical separation of single- and double-stranded cDNAs [34]. We have cloned and sequenced cDNA fragments representing 1,058 stress-induced genes from eight different SSH cDNA libraries. We describe and discuss the stress/defense-induced genes we have identified, many of which have either not previously been associated with stress responses or are not represented in existing cDNA libraries.

**Results**

**SSH cDNA library construction**

Plants of the Arabidopsis ecotype Col-0 show disease symptoms when infiltrated with virulent Pseudomonas syringae pv. tomato DC3000 or when sprayed with the oomycete Peronospora parasitica strain Ahc0. The avirulent bacterial strain of P. syringae expressing the avrRpm1 gene elicits a marked HR in Col-0 plants, whereas the P. parasitica strain Emwa elicits a microscopic HR. All treatments, including pathogen infection and treatment with ozone, SA and MJ, were carried out on 3-4-week-old plants. All treatments affect foliar tissue, which was the material used for library construction.

To capture a wide spectrum of differentially expressed genes, leaf tissue was collected at different intervals after the treatment and pooled before RNA extraction (Table 1). Leaves were harvested at 1, 3, 6, 9 and 12 hours after acute ozone treatment and at 1, 8 and 24 hours after bacterial infection and after MJ and SA treatments. Because fungal spores take almost a day to germinate and penetrate the host cell, samples were collected at 12 hours, 2 and 3 days in the incompatible oomycete interaction. In the case of the compatible interaction the host fails to recognize the pathogen early and mounts a response only when the pathogen has proliferated extensively (3-5 days). Samples were therefore collected up to day 5 after inoculation. For the chronic ozone treatment, samples were harvested 2, 4 and 6 days after exposure.
The efficiency of subtraction was evaluated by PCR amplification of a housekeeping gene, that for gyceraldehyde-3-phosphate dehydrogenase (G3PDH), and one of several differentially expressed genes. If subtraction is efficient, transcripts of housekeeping genes should be reduced, while those of differentially expressed genes should be substantially enriched in the population of cDNA fragments used for library construction. Figure 1 shows that the G3PDH fragment is barely detectable even after 30 cycles of amplification in the subtracted sample, while it is clearly detectable in the unsubtracted sample after 20 cycles. To test enrichment for differentially expressed genes, we amplified the PR1 gene for the biotic stressors and SA treatment, the plant defensin gene PDF1.2 for MJ treatment, and the amino-cyclopropane synthase gene (ACS1) for the ozone treatments [9,19,35]. The genes tested showed strong amplification in the subtracted samples after 15 cycles of PCR, whereas in the unsubtracted samples the PCR product was seen only after 10 additional cycles (Figure 1). On the basis of the number of PCR cycles required for equal amplification of the corresponding PCR products from the subtracted and unsubtracted cDNA samples, we estimated that the subtracted libraries were 32-64-fold enriched for differentially expressed genes.

One of the main advantages of SSH is that it normalizes the cDNA abundance so that cDNAs encoded by genes that are expressed infrequently, but nonetheless differentially, can be identified readily [33]. The efficiency of normalization is illustrated in Figure 2. The more uniform distribution of hybridization intensities obtained using the subtracted cDNA probe (Figure 2c) reflects the equalization in the concentrations of individual species present at markedly different concentrations in the initial unsubtracted cDNA populations (Figure 2b).

**Differential expression of genes identified by SSH**

cDNA clones for differentially expressed genes were identified by successively screening new clones first with the unsubtracted driver cDNA (Figure 2a) and tester (Figure 2b) cDNA pools as the probes, then the forward-subtracted (Figure 2c) and reverse-subtracted (Figure 2d) cDNA pools as probes. The first screen identifies cDNAs corresponding to only the most abundant differentially expressed genes, while the second screen identifies genes that are expressed less abundantly, but still differentially. The results from the four hybridizations were recorded for each clone, and those showing the most marked differential expression were selected for sequencing. Although selecting clones that showed strong hybridization only with the forward subtracted pool was straightforward, it was more difficult to select differentially expressed genes when signals were detected in both the forward-subtracted and unsubtracted pools. We endeavored to select those clones that showed 4-5-fold differential hybridization. However, as this was done by visual inspection, such genes constitute a potential source of false positives.

After screening the first three libraries (acute ozone, SA and virulent oomycete infection), we incorporated an additional procedure that permitted us to identify clones already represented in our collection. This was necessary simply because there is significant overlap at the molecular level in plant responses to different stresses and cDNA fragments were being identified and sequenced redundantly. We therefore pooled and labeled aliquots of DNA from sequenced clones, using them to probe each new set of clones. This procedure not only permitted identification of clones representing genes in previous libraries, but also allowed us to monitor the completeness of screening of each library. Figure 3 shows that the yield of new clones decreased as the number of clones examined increased, indicating that by the time several hundred clones had been examined, few new genes remain to be identified in a given library. As the libraries were both normalized and enriched for differentially expressed sequences, it is likely that the recovery of cDNAs

| **Treatments used for generating stress cDNA libraries** |
| Age (weeks) | Treatment | Control | Time points | Library/clone designation |
| 4 | 350 ppb of O₃ for 6 h | Clean air | 1, 3, 6, 9, 12, 24 h | Aoz |
| 3 | 150 ppb of O₃ for 6 h/day for 6 days | Clean air | 2, 4 and 6 days | Coz |
| 4 | 1 mM SA in water | Water | 1, 8 and 24 h |  |
| 4 | 50 μM of MJ in 0.01% ethanol | 0.01% ethanol | 1, 8, 24 and 48 h | MJ |
| 4 | Pst DC3000 5x10⁷ CFU/ml | 10 mM MgCl₂ | 1, 8, 24 and 24 h | DC |
| 4 | Pst DC3000 (avrRpm1) 5x10⁷ cfu/ml | 10 mM MgCl₂ | 1, 8, and 24 h | RPM |
| 3 | P. parasitica Ahco 2 x 10⁴ spores/ml | Water | 1, 3 and 5 days | VPP |
| 3 | P. parasitica Emwa 2 x 10⁴ spores/ml | Water | 12 h, 1, 2 and 3 days | APP |

Aoz, acute ozone; APP, avirulent P. parasitica infection; Coz, chronic ozone; DC, virulent P. syringae infection; MJ, methyl jasmonate; RPM, avirulent P. syringae infection; SA, salicylic acid; VPP, virulent P. parasitica infection.
for differentially expressed genes is reasonably complete. It should be noted, however, that because we screened each new library for clones we had already identified in previous libraries, the libraries are not independent of each other. This procedure might also lead us to miss highly homologous members of multigene families.

We cloned and sequenced the reverse-subtracted cDNAs for just two libraries, those prepared from ozone-treated plants and those infected with a virulent strain of the oomycete pathogen. Although we screened almost 600 clones in these two libraries, we identified cDNAs for only 48 differentially expressed genes, most of which encode proteins involved in photosynthesis. Thus it appears that a relatively small number of genes is downregulated by stress and suggests that different kinds of stress downregulate the same genes.

Although differential expression of every gene has not yet been tested under every stress condition, of the more than 700 genes tested to date, roughly 90% have exhibited differential expression by either northern blotting or DNA microarray analysis (see Additional data files), each of which has different sensitivity limitations. Some representative northern blot results are shown in Figure 4. Because these tests have been carried out under a more limited set of conditions than those represented by the treatments used for library construction, it appears likely that most of the cDNA clones described here represent differentially expressed genes.
Sequence analysis of stress ESTs

We sequenced 1,461 clones selected for differential expression as described above from among more than 6,000 clones in the eight stress cDNA libraries. On average, 12% of the sequences in each library were redundant (Table 2). The frequency with which identical cDNA fragments were isolated and sequenced was low (approximately 2%), in large part because of the prescreening to eliminate such redundancy. Most of the redundancy within libraries (10%), as well as between libraries (25%), resulted from the use of Rsal-restricted cDNA fragments in the SSH procedure. Because of the restriction step, two or more different cloned cDNA fragments can represent a single transcript. This type of redundancy was rapidly identified using coincidence of the Munich Information Center for Protein Sequences (MIPS) identifiers. Thus the 1,461 different fragments sequenced identified a total of 1,058 different genes (Table 2).

With the information gathered from the MIPS Arabidopsis database [36] and InterPro protein domain searches [37] we were able to identify or assign putative functions to about three-quarters (764) of the genes in the stress cDNA collection. More than 290 SSH clones encoded proteins with insufficient similarity to proteins of known function to assign a function with confidence, and we therefore classified them as being of unknown function. The genes of known function were

Representative northern blot analyses of stress-modulated genes using cloned cDNA fragments from the SSH libraries. (a) Acute ozone treatment; (b) comparison of treatment with salicylic acid, virulent bacteria or avirulent bacteria; (c) chronic ozone treatment; (d) treatment with virulent oomycete. Control leaves (C) were infiltrated with 10 mM MgCl₂. Tissue for RNA isolations was harvested at the indicated time points post-treatment.
sorted into the 12 primary functional categories [38]. The distribution of the genes with known or predicted functions is represented as a pie chart in Figure 5. The largest set of genes (15%) was assigned to the metabolism category, while genes involved in cell growth/division constituted the smallest group, comprising less than 2% of the genes. Genes involved in signal transduction and protein destination/storage formed the second (13%) and third largest groups (12%), respectively. Genes implicated in stress/defense response and genes involved in transcription together constituted 20% of the stress cDNA collection (Figure 5).

Digital northern analysis

EST datasets have been used recently to extract information on gene-expression levels [39-41]. The underlying assumption of such a ‘digital northern’ analysis is that the number of EST clones is proportional to the abundance of the mRNA used for constructing the library [42]. Most Arabidopsis EST collections are derived from non-normalized cDNA libraries, making them useful for this purpose [43]. We recorded the number of EST hits from the MIPS summary report link or by BLAST searches with the Arabidopsis EST database for each clone in our stress collection. Using 1/20,000 as the definition of a rare message [44-46] and knowing that there are more than 100,000 Arabidopsis ESTs in GenBank, we consider genes with fewer than six ESTs to represent rarely transcribed genes.

By the foregoing criteria, 577 (55%) of the stress-inducible genes are in the rarely transcribed category and 178 of these (17%) are not represented by an EST in the Arabidopsis EST database. Only 2 (0.0018%) of the genes in the stress cDNA collection are represented by more than 200 ESTs and can be classified as abundantly transcribed. These are the Rubisco activase (AozUP12, At2g39730) and a polyubiquitin gene (APP-FD09, At5g05320). The remaining 479 (45%) cDNAs correspond to genes transcribed at moderate rate (7-200 ESTs) in unstressed plants. This analysis does not, of course, reflect the stress-altered levels of these transcripts. Nonetheless, it reveals that a significant fraction of stress-modulated genes is not represented in existing EST collections and that many are infrequently transcribed in normal plants, underlining the need to construct specialized libraries.

Promoter analysis

The number, order, and type of protein-binding sequences present in promoters are major determinants of the differences in expression patterns of genes. Because the transcript levels of the genes represented in the present collection change in response to stress, protein-binding motifs associated with stress-inducibility should be over-represented in the promoters of the stress collection when compared with the total complement of Arabidopsis promoters. We compared the frequency of occurrence of 16

![Figure 5](image-url)

A pie chart showing the fraction of stress-modulated genes in each of the functional categories described in Bevan et al. [38].
different stress-related motifs in the total collection, and in each library individually, with their frequencies in the total population of *Arabidopsis* promoters (see Materials and methods).

We found that six of the 16 stress-related motifs analyzed were over-represented in the promoter sequences of the stress collection as a whole (Table 3a), and four additional motifs were over-represented in the promoters of at least one of the libraries (Table 3b). The ABRE-like motif, W-box motif, W-box-like motif, SA-inducible motif, the G-box and the TGA motifs were significantly over-represented in the promoters of the stress collection as a whole, compared with the total population of *Arabidopsis* promoters (Table 3a). The H-box factor (HBF) motif was over-represented in the promoters of genes represented in the virulent bacterial library, heat-shock element (HSE) and Myb4 motifs were over-represented in the avirulent bacterial library, and the Myc motif was over-represented in the SA library (Table 3b). We also looked for combinations of motifs that had been reported to function together [47]. The G-box and H-box motifs occur together in 31 promoters in our collection (p = 0.00587). Over all, more than half of the tested stress motifs are over-represented in the promoters of the genes in the stress cDNA collection, reflecting its enrichment for stress-responsive genes. The two ethylene-related motifs (GCC-box and EIN3), and the drought-response element (DRE), AtMyb1, AtMyb2 and AtMyb3 motifs were not statistically significantly over-represented in the promoters of genes identified by the stress cDNA collection.

### Discussion

#### Analysis of the total SSH library

To assess the contribution of the present stress cDNA collection to characterizing the *Arabidopsis* stress transcriptome, we examined five recent reports of *Arabidopsis* stress/defense-modulated genes that used either commercial or investigator-constructed cDNA microarrays [7,17,18,48,49]. Using the accession numbers provided in each publication, we retrieved each sequence from the GenBank database. We then used BLAST at the TAIR site to search the AGI genome database and identified the MIPS code for the differentially expressed genes reported in each of these studies. Once the MIPS code had been identified, we were able to estimate the number of genes differentially expressed in each of these studies and determine the overlap between each group and the stress cDNA collection (Table 4).

The extent of overlap between the stress cDNA collection and the subset of stress- or defense-modulated genes ranged from a low of 16% with the 308 genes identified by Maleck *et al.* [7] to a high of 32% with the 507 genes reported by Schenk [17]. Thus almost 70% of the genes in the stress cDNA collection have not previously been identified as stress/defense modulated. Conversely, a significant number of genes reported to be induced or repressed in the stress/defense response is not represented in the stress cDNA collection. This may be attributable in part to the stringency of the differential expression criterion (4-5-fold difference between experimental and control expression levels) we used in selecting clones to sequence. As the criterion for differential expression in the microarray studies analyzed was 1.5-2.5-fold over control

levels, many genes identified as differentially expressed in these studies would not have been included in our libraries.

Although we do not have the information to determine all of the reasons for the limited overlap between previous studies and the present one, we can identify several contributing factors. A major factor is the ability of the SSH procedure to identify genes that are expressed differentially, but at low levels. As noted earlier, more than half of the differentially expressed genes in the present collection can be classified as rare but differentially transcribed genes. Therefore, the SSH procedure would not have been included in our libraries. Maleck et al. [7] studied a custom array containing 2,375 ESTs with a biased representation of putative defense-associated and regulatory genes. From our estimate of redundancy (approximately 30%), this array contains 1,662 distinct genes. The study of Cheong et al. [48] involved the Affymetrix Arabidopsis GenomeChip array representing 8,200 genes. Desikan et al. [18] studied Arabidopsis Functional Genomics Consortium microarrays containing 11,000 EST clones representing approximately 7,800 distinct genes. The custom array of Swidzinski et al. [49] contains 75 ESTs previously implicated in programmed cell-death responses such as senescence and hypersensitive response.

Table 4
Comparison of the present stress-inducible cDNA collection with stress/defense genes identified in other large-scale studies

| Study | Cut-off | Induced/repressed clones | MIPS id | Represented in stress cDNA collection | Treatment |
|-------|---------|--------------------------|---------|--------------------------------------|-----------|
| [7]   | 2.5-fold| 413                      | 308     | 50 (16%)                             | Benzothiadiazol treatment, bacterial and oomycete pathogen |
| [17]  | 2.5-fold| 705                      | 507     | 160 (32%)                            | Fungal pathogen, SA, Mj, ethylene |
| [48]  | 2-fold  | 657                      | 281     | 73 (26%)                             | Mechanical wounding |
| [18]  | 1.5-fold| 175                      | 114     | 32 (28%)                             | Hydrogen peroxide |
| [49]  | 1.5-fold| 75                       | 69      | 16 (23%)                             | Heat treatment and senescence |

Maleck et al. [7] studied 10,000 EST clones obtained from the Arabidopsis Biological Resource Center representing approximately 7,000 genes. Schenk et al. [17] studied a custom array containing 2,375 ESTs with a biased representation of putative defense-associated and regulatory genes. From our estimate of redundancy (approximately 30%), this array contains 1,662 distinct genes. The study of Cheong et al. [48] involved the Affymetrix Arabidopsis GenomeChip array representing 8,200 genes. Desikan et al. [18] studied Arabidopsis Functional Genomics Consortium microarrays containing 11,000 EST clones representing approximately 7,800 distinct genes. The custom array of Swidzinski et al. [49] contains 75 ESTs previously implicated in programmed cell-death responses such as senescence and hypersensitive response.

Genes encoding proteins involved in stress/defense signaling comprise 13% of the genes in the collection. They include genes encoding proteins involved in signal perception (several types of receptor kinases) and signal transmission (G proteins, protein kinases, protein phosphatases, calcium-binding proteins) (see Additional data files). About 10% of the genes (79) in the collection were classified as stress/defense response genes. This includes genes encoding proteins of the antioxidant response (GSTs, peroxidases), the SAR response (pathogenesis-related genes) and cell rescue [50]. Genes induced in response to other stresses, such as drought [51], heat shock [52], dehydration [53-55], and elicitors such as Avr9 [56], avrRpt2 [57] and harpins [58,59], were also identified in the stress cDNA collection, underscoring the overlap between the different stress responses.

Genes encoding proteins involved in moving, modifying, storing and degrading proteins constituted the third largest group (12%) in the stress cDNA collection. Nearly half of the genes (45) in this category (92) are involved in proteolysis (see Additional data files). Proteolysis of important regulatory proteins is a key aspect of cellular regulation in eukaryotes [60,61] and there is evidence that the ubiquitin-proteasome pathway is important in implementation of the plant defense response [62-64]. Proteosome subunit genes are induced in response to stresses [65,66] and several regulatory subunits were identified in the stress cDNA collection. The F-box-containing proteins of the SCF complex constitute a family of E3 ligases, key components of the ubiquitin-proteasome pathway [67], as

Functional classification of genes represented in SSH libraries
We were able to assign nearly three-quarters of the genes to functional groups based on sequence similarities with known genes or motifs (see Additional data files). Although functional assignment based only on sequence homology needs experimental verification, it nonetheless provides a measure of the diversity of the genes in the stress cDNA collection. Genes from all the major functional categories are represented in the collection (Figure 5, and see Additional data files).

Maleck et al. [7] studied 10,000 EST clones obtained from the Arabidopsis Biological Resource Center representing approximately 7,000 genes. Schenk et al. [17] studied a custom array containing 2,375 ESTs with a biased representation of putative defense-associated and regulatory genes. From our estimate of redundancy (approximately 30%), this array contains 1,662 distinct genes. The study of Cheong et al. [48] involved the Affymetrix Arabidopsis GenomeChip array representing 8,200 genes. Desikan et al. [18] studied Arabidopsis Functional Genomics Consortium microarrays containing 11,000 EST clones representing approximately 7,800 distinct genes. The custom array of Swidzinski et al. [49] contains 75 ESTs previously implicated in programmed cell-death responses such as senescence and hypersensitive response.

are many RING finger proteins [68]. The RING finger motif is thought to mediate protein-protein interactions and E3 ligase complex assembly. Certain RING finger proteins are rapidly induced by elicitors in Arabidopsis and may be involved in the rapid degradation of regulatory proteins during early stages of pathogen attack [69]. Four genes encoding proteins with an F-box domain and seven different genes encoding RING/RING-H2-finger proteins, including the elicitor-induced ATL6-like gene [69], were identified in the stress cDNA collection. In summary, the stress cDNA collection comprises a broad repertoire of stress-responsive genes encoding proteins that are involved in both the initial and subsequent stages of the physiological response to abiotic stress and pathogens.

Transcription factors and regulatory elements in the promoters of genes in the stress cDNA collection
The WRKY transcription factors are involved in defense, wounding, senescence and plant development [7,16,70-73]. There are 70 genes with a WRKY domain in the Arabidopsis genome and six of them (WRKY15, 25, 33, 46, 62, 70) are in the stress cDNA collection. These WRKY transcription factors modulate gene expression by binding to W-boxes and W-box-like motifs, which are significantly over-represented in the promoters of the genes in the stress cDNA collection (Table 3a). The bZIP transcription factors are important in the regulation of genes activated by light, UV radiation, pathogen attacks, elicitors, wounding, abscisic acid (ABA) treatment, and SA treatment [47,71,74-81]. We identified two basic zipper (bZIP) transcription factors and basic helix-loop-helix (bHLH) transcription factors in the stress cDNA collection. The promoters of a subset of genes in the stress cDNA collection are enriched in G-box and TGA motifs, suggesting that they may be regulated by these bZIP and bHLH transcription factors. Identifying insertional knock-outs or creating antisense lines for these transcription factor genes and using them for expression profiling with microarrays constructed from the stress cDNA collection will facilitate identification of the targets for these transcription factors.

Abscisic acid response elements (ABREEs) are important during the plant’s response to abiotic stresses such as dehydration, salinity and cold, all of which are ABA-mediated [82,83]. There is evidence that ROS are involved in ABA signaling [84]. The enrichment of the ABRE motif in the promoter sequences of the genes in the stress cDNA collection may reflect crosstalk among stress signaling pathways mediated by common second messengers, such as H2O2. The over-representation of the SA-inducible element in the promoter sequences of the genes in the stress cDNA collection, especially those in the SA library, further validates the enrichment of the stressor-specific genes using the SSH technique and suggests that these genes may be regulated by the changes in the levels of SA that occurs in stress responses [85].

The motifs associated with the hormone ethylene (GCC-box and EIN3) were not significantly over-represented in the promoters of genes represented in the stress cDNA collection. A plausible reason is that SA and ethylene act antagonistically to each other [5]. The over-representation of the SA-inducible genes in the collection may be correlated with the reduced representation of the ethylene-responsive genes in the stress cDNA collection. The Myb1 motif was identified in Antirrhinum [86], the Myb2 and Myb3 motifs in Petunia [87]. These sequences have not been verified as valid Myb binding motifs in Arabidopsis. The under-representation of the DRE-like element suggests that genes whose expression is modulated by pathogen attacks and oxidative stress signaling may have minimal overlap with genes involved in dehydration and cold responses.

There is evidence that the H-box motif is involved in developmental regulation of flowering, but there is no report of its involvement in stress/defense responses [88,89]. However, a combination of the H-box motif and the G-box motif has been shown to be important for binding of bZIP transcription factors to rapidly induce defense-related genes [47,90,91]. The significant over-representation of these two motifs together in the promoter sequences of the stress cDNA collection suggests that combinatorial interactions between these two cis-elements may also be important in the regulation of stress-responsive genes. It is becoming increasingly evident that a major theme underlying euukaryotic transcriptional regulation is combinatorial control [92]. Identifying the cis-elements and the cognate transcription factors that bind to them during stress or defense responses is the first step towards characterization of higher-order nucleoprotein complexes.

Materials and methods
Plant materials and growth conditions
A. thaliana ecotype Col-0 plants were grown in soil (Scotts-Sierra Horticultural Products Company, Marysville, OH) in 5 cm pots (50 per flat) under fluorescent light 30 W/m2/s with a 14 h light/10 h dark photoperiod for 3-4 weeks.

Ozone treatment
Plants were transferred to growth chambers for ozone (O3) fumigation (clean air control plants were transferred to an adjacent chamber under identical conditions except for the O3 treatment). For acute O3 treatment, plants were transferred to the experimental chambers 4 weeks after germination, allowed to acclimate for 1-2 days, and then maintained in clean air (controls) or treated with 0.35-0.4 µl/liter O3 for up to 6 h. For chronic O3 treatment, plants were transferred to the experimental chambers 3 weeks after germination, allowed to acclimate 1-2 days, and then maintained in clean air (controls) or treated with 0.15 µl/liter O3 for 6 h per day for up to 9 days. For SSH experiments, 4-10 leaves were harvested, avoiding the most immature leaves,
cotyledons, and the first two true leaves. Leaves from 1, 3, 6, 9, 12 and 24 h time points were pooled for the acute ozone library and leaves from plants exposed for 2, 4 and 6 days were pooled for the chronic ozone library. RNA was isolated as described below.

**Bacterial infections**

*Pseudomonas syringae* pv. *tomato* (*Pst* DC3000), which causes bacterial speck disease in Col-0 plants, was used to infect plants for construction of the virulent bacterial library. The *Pst* DC3000 expressing *avrRpm1* gene induces hypersensitive cell death in Col-0 plants and was used to infect plants for constructing the avirulent bacterial library. The bacteria were grown on King’s agar plates at 28°C. Bacterial cultures were prepared by resuspending the cells from overnight cultures in 10 mM MgCl₂ to the required optical density (OD₆₀₀ = 0.05; 1 OD₆₀₀ = 10⁷ colony-forming units (CFU)/ml). A titer of 5 x 10⁷ CFU/ml was used for infiltrations. Leaves were infiltrated on the abaxial side using a 1-ml syringe. The inoculated leaves were harvested 1, 8 and 24 h after inoculation. Equal amounts of tissue were pooled from each time point for library construction.

**Inoculations with Peronospora parasitica**

The Ahco strain of *P. parasitica* was maintained on Col-0 plants and the Emwa strain on Ws plants in a growth chamber with 10-h day at 16°C and 14-h dark period at 20°C. Fresh spores were collected in water and the inoculum was adjusted to 2 x 10⁴ conidiosporangia per milliliter and applied as a fine mist to the seedlings using an airbrush sprayer (Paasche Air Brush Company, Harwood Heights, IL). The sprayed plants were placed in a tray containing water-soaked paper towels, covered with a lid sprayed on the inside with a fine mist of water, and sealed using plastic wrap to maintain the humidity. The sprayed plants were transferred to the growth chamber in which the pathogen is regularly maintained. Control plants were sprayed with water using the airbrush sprayer and were maintained under the same conditions. Seedlings were harvested 1, 3 and 5 days after inoculation and pooled for RNA extraction and identification of genes induced in the compatible interaction between Col-0 plants and the Ahco strain of the pathogen. Seedlings were harvested 12 h, 1, 2 and 3 days after inoculation for the incompatible interaction between Col-0 plants and the Emwa strain of *P. parasitica*.

**Salicylic acid (SA) and methyl jasmonate (MJ) treatments**

Four-week-old plants were sprayed with 1 mM sodium salicylate dissolved in water (Sigma, St. Louis, MO) and control plants were treated with water. Leaves were harvested 1, 8 and 24 h after the treatment. Equal amounts of tissues were pooled from each time point for RNA isolations. Four-week-old plants were sprayed with 50 mM methyl jasmonate (MJ) (Sigma) in 0.001% ethanol and control plants were treated with 0.001% ethanol. Leaves were harvested 1, 8, 24 and 48 h after the treatment. Equal amounts of tissue were pooled from each time point for RNA isolation.

**RNA isolation**

Total RNA was isolated from frozen leaf tissue using Trizol (Life Technologies, Carlsbad, CA) according to the manufacturer’s instructions. Briefly, tissue was ground to a fine powder in liquid N₂ and homogenized in Trizol (1 ml reagent/0.1 g fresh weight tissue), then allowed to stand at room temperature for 5-10 min. Chloroform:isoamyl alcohol (24:1) was added using 0.2 ml/ml Trizol. Samples were mixed by vortexing and allowed to stand at room temperature for 2-5 minutes more, then centrifuged for 15 min at 10,000g. The upper aqueous layer was removed to a clean tube and RNA was precipitated with an equal volume of isopropanol. After 10 min at room temperature, samples were centrifuged for 15 min at 10,000g to pellet the RNA. The pellet was washed with 75% ethanol and resuspended in RNase-free water. The typical yield of total RNA was 50-80 µg/100 mg leaf tissue. Poly(A)⁺ RNA was purified from total RNA using PolyTract oligo(dT) columns (Promega, Madison, WI).

**Suppression subtractive hybridization (SSH)**

SSH was carried out using the PCR-Select Subtractive Hybridization kit (Clontech, Palo Alto, CA). Experimental and control samples for each treatment were processed simultaneously to reduce false positives. We increased the amount of mRNA to 3-4 µg from the 2 µg recommended by the manufacturer to compensate for the loss of mRNA during the phenol chloroform extractions. cDNA prepared from the treated samples was used as the ‘tester’ and that from the control sample as ‘driver’ for the forward subtraction to isolate fragments corresponding to genes whose expression level was increased following the treatment. The reverse subtraction was carried out with the control sample as tester to isolate fragments corresponding to genes whose expression level decreased following the treatment. The PCR-based enrichment of differentially expressed sequences depends on the number of tester molecules with adaptors ligated to their ends. If the fraction of tester cDNA with the adaptors was less than 25%, ligations were repeated. We designed plant-specific glyceraldehyde-3-phosphate dehydrogenase (*G3PDH*) primers to test the ligation efficiency as recommended by the manufacturer. A *G3PDH* gene fragment of approximately 300 bp was amplified with *G3PDH* 3’ and 5’ primers (GAPA-F: GGTAGGATCGGGAGGAAC; GAPAR: GATAACCTTCTTGGCACCAG) using the adaptor-ligated cDNA as template. The tester cDNA was also amplified with *G3PDH* 3’ primer and an adaptor-specific primer, which yields a fragment that is 200 bp bigger than the fragment generated with the gene-specific primers. Samples from the *G3PDH* gene fragment amplifications using the subtracted and unsubtracted cDNA pools were analyzed after 15, 20, 25 and 30 cycles of PCR. Primers to amplify regions without an *Rsa*I site were designed for two stress-induced genes, the
**Cloning and differential screening**

Secondary PCR products were cloned into the T/A cloning vector pCR2.1TOPO (Invitrogen; acute O2 library) or the Advantage PCR cloning vector (Clontech; all the other libraries) according to manufacturer’s instructions. About 500-1000 colonies were picked and grown in 96-well microtiter plates in LB medium with 100 mg/l ampicillin. The clones were amplified using the nested primers 1 and 2R (Clontech manual) to check for the presence and size of individual inserts. The PCR products were run on high-density (Clontech manual) to check for the presence and size of individual inserts. The PCR products were run on high-density agarose gels in duplicate (200 wells/gel) and transferred to nylon filters. The membranes were hybridized under stringent conditions with equivalent amounts of 32P-labeled cDNAs.

**Sequencing and sequence analysis**

Cycle sequencing reactions were prepared using BigDye dye terminator, modified for smaller reactions with Half-term (GenPak, Stony Brook, NY) to conserve reagents. Sequencing electrophoresis was carried out by the PSU Nucleic Acid Facility using the nested 1 or 2R adaptor primers. Each sequence was edited to correct sequencing ambiguities and remove the primer sequence. The edited sequences were sequenced from the 5’ end using the ReadyPrime random primed DNA labeling kit (Amersham-Pharmacia) with [5-32P] (ICN Biomedicals, Irvine, CA). Blots were hybridized and washed according to standard procedures [94].

**Stress motifs for promoter analysis**

Sixteen stress-related cis-elements were selected on the basis of their identification in other studies on Arabidopsis stress/defense-modulated genes [7,16,71]. The frequency of W-box (TTGACY) and W-box-like (BBWGACYT) elements was tested as these are binding sites for plant-specific WRKY transcription factors involved in plant development and plant responses to environmental stresses [7,16,70–73]. G-boxes (CACGTG), H-boxes (CCTACC) and TGA motifs (TGACG) are binding sequences for bZIP transcription factors, which have an important role in the regulation of genes activated by environmental cues [71,74–81]. We also tested some of the well-characterized stress hormone-responsive motifs, including the ABA-response element (BACGTGKM) [95], SA-inducible motif (ACGTCGA) [96], two ethylene-related motifs, GCC-box (GCCGCC) [97] and the EIN3 motif (GGATGTA) [98]. The Arabidopsis Myc and Myb homologs are important in the plant’s responses to pathogens, low temperatures and dehydration [82,99,100]. We tested for the frequency of occurrence of the Myc-element (CACATG) and four different Myb motifs (ATMyb1, MTCWACC; ATMyb2, TAAACGTT; ATMyb3, TAACCTAC; ATMyb4, ACMWAMC) [71,101] in the promoters of genes identified by cDNAs in the stress collection. We also tested the frequency of occurrence of two other known stress promoters, the DRE (DRCCGACNW) [95], and the HSE (CTNGAANNTTCNA) [102] to determine the extent of overlap in genes activated during different stresses.

**Probability and significance calculations for promoter analysis**

To determine whether a particular motif is over-represented among the promoters of a given SSH library, we first determined the frequency of each motif in the total complement of Arabidopsis promoters using the 1,000 bp upstream promoter files from TAIR [103]. We then calculated the probability of finding m promoter regions having one or more motifs in the set of n promoters in each SSH library, as well as in the total SSH library collection. We considered a motif to be significantly over-represented if this probability was less than 0.05. These calculations were implemented using Perl scripts that are available from the StresDB [104].

**Additional data files**

Additional data files including a table of the digital northern data showing the number of ESTs for each clone in the SSH library, the microarray data for the response to 1 hour of ozone treatment and five days after virulent oomycete infection, and details of how the microarrays were printed and hybridized are available as with the online version of this paper.

**Acknowledgements**
