ABSTRACT
The thick disc contains stars formed within the first Gyr of Galactic history, and little is known about their planetary systems. The Spitzer MIPS instrument was used to search 11 of the closest of these old low-metal stars for circumstellar debris, as a signpost that bodies at least as large as planetesimals were formed. A total of 22 thick disc stars has now been observed, after including archival data, but dust is not found in any of the systems. The data rule out a high incidence of debris among star systems from early in the Galaxy’s formation. However, some stars of this very old population do host giant planets, at possibly more than the general incidence among low-metal Sun-like stars. As the Solar system contains gas giants but little cometary dust, the thick disc could host analogue systems that formed many Gyr before the Sun.

Key words: planets and satellites: formation – circumstellar matter – infrared: stars.

1 INTRODUCTION
Debris discs are generated by collisions among comets or asteroids, and so are a signpost of planetary systems, indicating that bodies of at least planetesimal size formed. The debris absorbs starlight and re-emits it at longer wavelengths, and observations since 2003 with the Spitzer Space Telescope have yielded many new debris detections in the mid- to far-infrared. The relation between giant planets and planetesimal belts is still uncertain. Bryden et al. (2009) find that the incidence and brightness of cool outer-system debris is not affected by the presence or absence of gas giants in the system, which is not surprising if the formation and evolution of giant planets at a few au and comets at tens of au are decoupled processes. More subtle effects may occur, such as the clearing out of comet belts when giant planets migrate, analogous to the Late Heavy Bombardment (LHB) era in Solar system history. This could result in brief dusty episodes as more planetesimals collide, and subsequent lower dust levels due to the ejection of many comets from the system. However, such LHB events seem to be atypical, as Spitzer has commonly found old star systems that are still very dusty (Booth et al. 2009).

Greaves et al. (2007) argued that the incidence of giant planet and debris systems, and the weak overlap between them, could be explained if the mass of refractory elements at the planet-formation stage controlled the outcome. Young circumstellar discs with a large ‘solid’ mass could quickly form planet cores that go on to accrete gas atmospheres, while less substantial discs only form planetesimals by the time the gas disperses and so evolve into debris systems. This model (see also Wyatt, Clarke & Greaves 2007) addresses the differing metallicity dependences observed – metal-rich discs tend to have a higher solid mass and so a greater probability for building a planet core, while lower solid reservoirs are needed to build comets and so debris has little dependence on metallicity (Beichman et al. 2006; Bryden et al. 2006; Greaves et al. 2007; Trilling et al. 2008).

Here we investigate the formation of planetary systems by observing some of the oldest Galactic stars with Spitzer. A good test of models is to observe old, metal-poor stars. If these proceed only as far as planetesimal growth, a high incidence of debris might be seen, but perhaps modified by the longer time available for collisional grinding and dust removal compared to mid-Galactic-age stars like the Sun (Wyatt 2008). The sample of stars studied here is identified as nearby members of the thick disc – stars that formed within about the first Galactic Gyr (Chiappini, Matteucci & Romano 2001) and have orbits inclined with respect to the Galactic plane. These systems are about twice as old as the Solar system.

2 SAMPLE SELECTION
The targets (Table 1) were initially derived from Karataş, Bilir & Schuster (2005), who identified 22 Galactic thick disc stars near the...
Debris around thick disc stars

Sun. The identification uses criteria of low metallicity and rotation speed, with values centred around [Fe/H] ≈ −0.5 and 180 km s⁻¹, respectively, removing halo stars that have lower vrot for the same metallicity. The sample was then reduced to the 15 stars that lie within 40 pc of the Sun, to make the best use of the sensitivity of the MIPS instrument (Rieke et al. 2004). Four of these stars had been observed in previous Spitzer programs (Beichman et al. 2006; Trilling et al. 2008; Bryden et al. 2009), and the other 11 were observed for our Spitzer programs (Beichman et al. 2006; Mamajek & Hillenbrand 2008) are only for roughly solar activity, and although current calibrations of age versus activity are consistent with this conclusion. We checked for chromospheric membership (Karataş et al. 2005), and independent age estimates well determined (uncertainties of 11.6 Gyr old. This is in very good agreement with the thick disc membership (Karataş et al. 2005), and independent age estimates are consistent with this conclusion. We checked for chromospheric activity, and although current calibrations of age versus activity (e.g. Mamajek & Hillenbrand 2008) are only for roughly solar metallicity, all of our program stars are inferred to have low activity consistent with ages greater than 4 Gyr.

3 OBSERVATIONS AND DATA REDUCTION

The 11 new stars were observed between 2006 August and 2007 October, using MIPS at 24 and 70 μm (Table 2). Exposure times were 3 and 10 s at these wavelengths, respectively, multiplied by the number of repeats given in Table 1. The data reduction and instrument calibration procedures are described in Engelbracht et al. (2007) and Gordon et al. (2007). The initial data reduction was done by aperture photometry as described in Trilling et al. (2008). Subsequently, these observations plus the archival data for the other stars were re-reduced homogeneously as part of a Spitzer program number 30339. Since the survey was proposed, Reddy, Lambert & Allende Prieto (2006) identified further thick disc stars, several of which were observed in various Spitzer programs, as was one of the more distant stars of Karataş et al. (2005), HD 101259. The total number of stars discussed here is 22, of which 19 have data at two Spitzer wavelengths.

The (logarithmic) metallicities in this sample are −0.23 to −1.03, considerably lower than the mean of −0.06 with standard deviation of 0.25 for local thin disc stars (Valenti & Fischer 2005). For nine of the volume-limited objects, Takeda et al. (2007) have calculated the ages based on isochrone fitting, a method that is most accurate for old stars that have evolved off the main sequence. Where the age is well determined (uncertainties of <0.30 per cent for HD 3795, 30649, 68017, 114729, 218209 and 221830), these stars are dated at 9.6–11.6 Gyr old. This is in very good agreement with their thick disc membership (Karataş et al. 2005), and independent age estimates are consistent with this conclusion. We checked for chromospheric activity, and although current calibrations of age versus activity (e.g. Mamajek & Hillenbrand 2008) are only for roughly solar metallicity, all of our program stars are inferred to have low activity consistent with ages greater than 4 Gyr.

Table 1. Properties of the thick disc stars. The first two sets of stars form the volume-limited sample and the third set includes those outside the complete volume or more recently identified as thick disc objects (see text). Metallicities are for Fe except HD 19034 and 101259, which are combined metals. The last columns are the observed date and number of exposures for the new data (see text).

Table 2. Observed fluxes F and errors, and excesses E, R derived from observed fluxes compared to the photospheres. E24 is expressed in magnitudes while R70 is the ratio of the observed and photospheric fluxes, with a significance for any dust of X70, i.e. excess flux above the photosphere divided by its error.
4 RESULTS

4.1 Survey limits

From Table 2, we find no dust excess towards any of the stars. At 24 $\mu$m, the differences between observed and photospheric fluxes vary between $-0.05$ and 0.06 magnitudes, so there are no positive outliers. The standard deviation of the excesses is 0.03 mag and the mean is $-0.01$ mag. At 70 $\mu$m, there is one candidate excess of $+2.6\sigma$, but the most negative value is at $-2.3\sigma$, so there are again no notably positive outliers.

About half the stars were not detected at all at 70 $\mu$m. This is mainly attributable to larger distances of rare thick disc objects compared to thin disc stars. For example, the median target distance is 28 pc compared to 20 pc in Trilling et al. (2008), while the average 70-$\mu$m noise level is about 5 mJy in both cases. Three of the stars (HD 29587, 30649 and 218209) observed here also had high sky backgrounds that can increase the noise. Fig. 1 assesses the sensitivity achieved within the thick disc sample. Survey stars are binned here according to the minimum excess that could be detected with $3\sigma$ confidence. The fraction of thick disc stars where only excesses above three times the photosphere can be detected (i.e. bins from 301 to 350 per cent upwards) is rather large. In the general stellar surveys, the sensitivity attained was generally better than this (light blue bins). However, many excesses above 300 per cent were seen in those studies (dark blue bins), suggesting that our survey could be adequately deep if the thick disc stars have typical debris. The biases in comparing the incidence of debris for the thin and thick disc stars are discussed further below.

It was noted that some stars have 70-$\mu$m fluxes well below the photospheric prediction, although with large errors. Since the MIPS calibration is reliable over a wide range of fluxes (Gordon et al. 2007), we considered whether the stars could be underbright for reasons related to metallicity. However, for a wide sample of stars observed at 24 $\mu$m, there is a mild trend of enhanced flux at low [Fe/H], contributing about 0.02 mag at our median metallicity of $-0.6$ (Fig. 2). If the 24-$\mu$m fluxes are normal or slightly high, it would be surprising if metal-poor stars switched to being under-

Figure 2. $K-[24]$ colour against [Fe/H] (from NSTARS, at http://nstars.nau.edu) and linear fit. Data are from various Spitzer surveys, re-reduced homogeneously.

Figure 3. Co-added 70-$\mu$m data, showing the flux range 5–95 per cent. The averaged star signal is visible at the centre.

4.2 Dust excesses

To search more deeply for cool excess among the ensemble, frames for the 11 new 70-$\mu$m observations were stacked about the stellar positions, taking the resulting mean per pixel signals. In Fig. 3, the mean photosphere is now faintly visible at centre, although background structures from individual frames are also present. Aperture photometry gives a mean flux of $4.6 \pm 1.2$ mJy, consistent with minimal debris given the mean 70-$\mu$m photospheric flux of 5.2 mJy.

A better estimate of the net cool dust within the whole thick disc sample can be found from a weighted average of the 70-$\mu$m bright somewhat longwards, at 70 $\mu$m. Since stars observed with good signal-to-noise ratio tend not to be underbright, an optimal scaling test was carried out to check the observed to predicted flux ratio. The scale factor is found to be 1.08 $\pm$ 0.06, so we conclude that there is no general 70-$\mu$m flux deficit and the faint results are by chance. Also, the distribution of significance values $\chi_{70}$ (Table 2) is a slightly broadened Gaussian ($\sigma = 1.15$) centred close to zero, indicating the 70-$\mu$m results are not anomalous.

1 The stars HD 65583, 68017, 144579 and 157214 have also been observed with Spitzer IRS and have no excesses out to 34 $\mu$m (Lawler et al. 2009).
excesses (Table 2). We define E70 = R70−1 and weight the values by 1 error−2, where the error in E70 can be written as E70/γ 70. The net excess for the 19 stars with 70-μm data is 0.07 ± 0.34, i.e. ≲40 per cent above the photosphere at the 1σ upper bound. This result is however dominated by five stars with low-noise data. For a stellar effective temperature of around 5600 K and dust peaking in brightness at 70 μm, i.e. of temperature around 50 K, an excess of <40 per cent gives an upper limit on fractional dust luminosity L_dust/L_* of 4 × 10−6 (Beichman et al. 2006).

Table 3: Debris incidence in the thick disc.

| stars | debris incidence |
|-------|------------------|
| 19    | low              |
| 20    | normal           |
| 21    | high             |

Approximately 80 per cent of nearby Sun-like stars are also dust free at this level individually (Greaves & Wyatt 2010). Hence, if the thin and thick disc populations have similar debris incidence and levels, the null result here for only 19 stars is not surprising. In more detail, the expected number of debris detections at 70 μm can be estimated from Fig. 1, taking into account the limiting depths of the thick disc data. The number of detection per 50 per cent wide excess bin is then the fraction in the general (T+B) surveys, scaled to 19 stars, and multiplied by the fraction of thick disc targets where such an excess was detectable. This yields a cumulative 2.1 expected detections, with a Poisson error of ±1.5, so finding no debris systems is within the errors. Similarly, there is a 5 per cent incidence of 24-μm excess for Sun-like stars in general (Koerner et al. 2009), so finding none among 22 stars here is consistent with similar populations. Studying trends by age, Gáspár et al. (2009) found a 24-μm debris incidence of approximately 4.1 ± 1.5 per cent at 3–10 Gyr. In theoretical models, some slow fading is expected, with fractional dust luminosity decreasing e.g. by 25 per cent by 11 Gyr compared to typical mid-age Galactic systems at about 5 Gyr (Löhne, Krivov & Rodmann 2008).

Statistics are ultimately limited by the small numbers of thick disc stars actually passing through the solar vicinity at the present time, and in our volume-limited sample we have already searched for debris among the nearest 15, or 70 per cent, of objects catalogued by Karakas et al. (2005). Fainter levels of debris or cooler dust may be accessible to the Herschel satellite, now observing at wavelengths of 70–500 μm.

5 DISCUSSION

The debris incidence in the thick disc is either low or normal; we can rule out a particularly high incidence of excess in these metal-poor systems. Recent theoretical work by Johansen, Youdin & Mac Low (2009) has suggested that low-metal systems could have late planetesimal formation as the gas disc is dispersed, in which case more collisional debris might have been expected around the thick disc stars, but this is not seen here. In contrast, some thick disc stars do host giant planets – an outcome thought to reflect more efficient planetesimal building at early stages. In our sample, HD 114729 has a gas giant (Butler et al. 2003), and four other good planet candidates exist for thick disc stars (Gonzalez 2009). The M sin i of these planets range from 0.5 to 7 Jupiter masses and the semimajor axes from 0.15 to 2 au.

Fig. 4 shows the predictions of our model (Greaves et al. 2007) based on the mass of solids available at the planetesimal formation stage. The model is based on a threshold of solid material needed for a successful outcome such as building a gas giant core, and with the solid mass within the disc scaling by the metal fraction in common with the star. The M_solid distribution is obtained by multiplying the lognormal distribution of overall disc masses (Andrews & Williams 2005) by the lognormal distribution [Fe/H] for the population of interest, here with mean and standard deviation of −0.6 and 0.2, respectively. The thresholds for forming detectable debris discs and gas giants are around 0.02 and 0.1 Jupiter masses in solids, respectively (Greaves et al. 2007). For simplicity we neglect systems with both planets and debris, since the two phenomena appear uncorrelated (Bryden et al. 2009), and so this is a small subset of Sun-like stars.

Fig. 4 then predicts that 15 per cent of thick disc stars should form giant planets, with a further 9 per cent forming comet belts. Around the general local population of Sun-like stars, the corresponding numbers are 21 and 20 per cent. The differences are modest because the availability of solid material is largely dictated by the disc mass, which have a very broad distribution of σ = 1.15 dex, compared to the standard deviations around 0.2 dex for the metallicities. Hence, while the peaks of the solid-mass distributions do shift for differing metals (Fig. 4), the upper tails associated with forming planetesimals are broad and do not have greatly different numbers of stars.

These values are compatible with survey data, taking into account that not all systems of planets and debris have yet been discovered. In the general stellar population, the extrapolated planet total is 17–20 per cent (Cumming, Marcy & Butler 2009) and the debris disc count at 70 μm is around 14–20 per cent (Trilling et al. 2008; Greaves & Wyatt 2010), which agree well with the predictions of 21 and 20 per cent, respectively. For the thick disc stars, the debris incidence is ≲5 per cent versus the 9 per cent predicted, and the planet count is estimated at ∼6–11 per cent, versus 15 per cent predicted. It has been noted that lower-metal discs may disperse faster (Yasu et al. 2009), and this could reduce the efficiency of growing planetesimals compared to our simple model.

The thick disc planet frequency is poorly known, with our 6 per cent estimate derived from three planetary systems among 52 thick disc objects that have [Fe/H] < −0.2 and [α/Fe] > 0.2 (Valenti & Fischer 2005; Reid et al. 2007), while the 11 per cent is for two out of 18 systems in the Fe-, Mg-selected, volume-limited, thick disc sample of Fuhrmann & Bernkopf (2008). These planet frequencies are actually higher than for low-metal stars in general, such as the incidence of 1 per cent for periods of less than 3 yr found in a recent survey by Sozzetti et al. (2009). Conditions that...
could promote the formation of more gas giants in the old thick
disc population compared to younger low-metal thin disc stars are
at present unclear.

6 CONCLUSIONS

While the scarcity of nearby thick disc stars makes it difficult to
study the population, there are examples of disc and planet systems
around some comparably old stars. A gas giant is known around the
post-main-sequence star V391 Peg of age $\geq 10$ Gyr (Silvotti et al.
2007); the $\approx 10$-Gyr old G8 V star τ Ceti has a debris disc (Greaves
et al. 2004) and the oldest known star with both a planet and debris
is 70 Vir at $\approx 9$ Gyr (Bryden et al. 2009). These discoveries point
to some of the first stars in the Galaxy having had the potential
to form planetary systems akin to those around typical stars seen
today. If some thick disc stars have minimal cool debris but do host
gas giants orbiting at a few au, these would be analogues to the
Solar system formed many Gyr before the Sun.
