Abstract: An experimental product study of the reactions of furfural with the main tropospheric oxidants (Cl, OH and NO$_3$) has been carried out using a Fourier Transform Infrared spectrophotometer (FTIR) and a gas chromatograph–mass spectrometer with a time of flight detector (GC–TOFMS). The main gas-phase products detected were 5-chloro-2(5H)-furanone, maleic anhydride, 2-nitrofuran and CO. Molar yields were quantified for the detected products in these reactions, thus suggesting the existence of nongaseous products that could not be observed with the analytical techniques employed. The formation of Secondary Organic Aerosol (SOA) from the oxidation of furfural with Cl atoms, OH, NO$_3$ and ozone was investigated in a smog chamber in the absence of inorganic seed aerosols. The experimental results show the formation of ultrafine particles (less than 1 µm in diameter) for all of the studied reactions except for the nitrate radical. Given their small size, these ultrafine particles (<1 µm) can easily penetrate into the respiratory tract and reach the alveolar region. These particles, therefore, have the potential to cause severe damage to the respiratory system. The aerosol yield obtained, Y, was low (<0.04) in all cases, which means that the aerosols generated from furfural, under atmospheric conditions, could have little impact.

Keywords: furfural; atmospheric degradation; aerosol; reaction products; mechanism

1. Introduction

Furfural (2-furanaldehyde) is known to be present in the atmosphere as a reaction product of alkylfurans with different tropospheric oxidants [1] and as a biomass combustion product [2]. The main sink for furfural in the troposphere is the reaction with the hydroxyl radical (OH) during daytime [3] and with the nitrate radical (NO$_3$) at night [4]. This compound could also be an important ozone generator in the troposphere due to its high estimated Maximum Incremental Reactivity (MIR) values (22.4 gO$_3$/g COV) [3]. The reactivity of furfural with chlorine and bromine atoms has previously been studied by Cabañas et al. [5] and Bierbach et al. [6], respectively. Furthermore, the photochemistry of furfural has been studied by Hiraoka and Srinivasan [7] and Gandini et al. [8]. Furfural can react with tropospheric oxidants by hydrogen abstraction from the carbonyl group, by electrophilic addition to the double bond of the aromatic ring or by a combination of these two mechanisms. Recent theoretical studies carried out by Huang et al. [9] and Zhao and Wang [10] suggested that furfural reacts with OH and NO$_3$ radicals mainly by C5 addition (~59%). For C2 addition, calculations suggest a ~40% contribution. Hydrogen abstraction seems to make a minor contribution only (~0.05% for nitrate
radicals and 2.8% for OH) [9,10]. To date, experimental studies on furfural reaction products have not been reported in the literature.

Aerosols play an important role in numerous environmental processes. Aerosols can absorb and scatter solar and Earth radiation, influence the generation of clouds and heterogeneous reactions in the atmosphere and thus affect the abundance and distribution of trace gases in it [11,12]. As a result of these interactions, aerosols influence the Earth’s radiation balance, thus playing an important role in climate. It is believed that certain types of organic volatile or semivolatile compounds like cycloalkenes, aromatic hydrocarbons and terpenes favor the generation of Secondary Organic Aerosol (SOA). Moreover, interest in studying heterogeneous reactions involving carbonyl compounds has increased in recent years because of their high SOA-forming potential [13]. Therefore, it is believed that furfural could be a potential aerosol-former because it has two main features for generating SOA: a cyclic aromatic structure and a carbonyl group.

A product study of the gas-phase reactions of furfural with chlorine atoms and hydroxyl and nitrate radicals has been carried out in this work in order to determine the main reaction pathways. SOA formation for the reaction of furfural with Cl, OH and O3 was also investigated using a smog chamber. Data were analyzed using a Fast Mobility Particle Sizer Spectrometer (FMPS) for SOA experiments and a Fourier Transform Infrared spectrophotometer (FTIR) and a gas chromatograph–mass spectrometer with a time of flight detector (GC–TOFMS) for the product study in gas-phase.

2. Experimental

2.1. Materials

The chemicals were obtained commercially: furfural (Aldrich, St. Louis, MO, USA, 99%), 2-nitrofuran (Aldrich, 99%), maleic anhydride (Aldrich, 99%), nitric acid (65%, Fluka), hydrochloric acid (37%, Fluka), 2-(5H)-furanone (98%, Aldrich), CO (99.998%, Praxair, Danbury, CT, USA), Cl2 (Praxair, >99.8%), air (Praxair, 99.999%) and NO (Praxair, 99%). OH radicals were synthesized by continuous photolysis of CH3ONO in the presence of NO in air at a wavelength of 360 nm. CH3ONO was generated in the laboratory as described elsewhere [14]. NO3 radicals were obtained by thermal decomposition of N2O5, which was synthesized in the laboratory [15]. Ozone was obtained from an ozonizer (OG Ozogas model TRCE–5000, ORSIS, Moscow, Russia) with a maximum production rate of 5 g O3/h.

2.2. Methods

2.2.1. Gas-Phase Product Study

The experimental system used in this study has been described in previous works [4,16] and thus it will be only briefly described here. Product experiments were carried out at room temperature (297 ± 2 K) and atmospheric pressure (700 ± 1 Torr) with synthetic air in two different reaction chambers: (1) a 50 L Pyrex® glass cell with in situ FTIR equipment (Nicolet 6700, Thermo Fisher Scientific, Waltham, MA, USA) equipped with six actinic fluorescent lamps (λmax = 360 nm), (2) Teflon® (Wilmington, DE, USA) reactor of 150 or 500 L, the latter was employed for the study with the nitrate radical. These Teflon® reactors were surrounded by UV–Vis lamps and equipped with ports for sampling onto a 30/50 μm solid-phase microextraction (SPME) fiber of divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS). The fiber was exposed in the reactor during 60 s and then thermally desorbed during 15 min at 250 °C in the injection port of the gas chromatograph. The compounds were separated by a capillary column (30 m × 0.3 mm × 1 μm, Tracsci TRB–1701 Teknokroma, Barcelona, Spain). Detection was performed by mass spectrometry in electron ionization mode (EI) with a time of flight analyzer, GC–TOFMS (AccuTOF GCv Jeol, Tokyo, Japan). For the study of each reaction at least 2 sets of experiments were performed following the reaction at about 45 min.

For GC–TOFMS analysis, products were identified according to their retention time and/or by comparison of their mass spectra with the database. In the quantitative product analysis previous
calibrations were carried out by introducing a known concentration of a commercial sample into the reactor (S1: Annex I in Supplementary Materials). For FTIR analysis, a spectral subtraction procedure was used to obtain the concentrations of furfural and products as a function of the reaction time. Identification was carried out by comparing reaction samples with calibrated reference IR spectra. Quantification of species was carried out by calibrated reference procedure (S2: Annex II in Supplementary Materials). For each experiment, over 30–45 spectra were recorded with a spectral resolution of 1 cm$^{-1}$.

The initial concentrations of reactants in this set of experiments were as follows: (in parts per million, ppm): furfural, 10–40 for FTIR and 2–8 for GC–TOFMS; Cl$_2$, 20 for FTIR and 2–7 for GC–TOFMS; CH$_3$ONO and NO 7–10 for FTIR and 3–5 for GC–TOFMS; N$_2$O$_5$, 10 for FTIR and 20 for GC–TOFMS experiments.

2.2.2. SOA Formation Study

Experiments were carried out in the 500 L Teflon® reactor mentioned above. Experiments were performed at room temperature and atmospheric pressure. An FMPS 3091, TSI equipment was employed to obtain the size distribution. The decay of furfural was monitored by GC–TOFMS, following the same procedure described for the study of gas-phase products. The aerosol mass concentration, $M_0$, was calculated by FMPS from the mobility diameters determined by this instrument on assuming spherical shape and a density of the aerosol of 1 g cm$^{-3}$.

3. Results and Discussion

3.1. Gas-Phase Products

In order to facilitate the identification of the generated products, a general mechanism has been proposed for hydrogen abstraction and double bond addition. The presence of the –CHO group in C2 leads to the deactivation of the C3 and C5 positions of the aromatic ring due to its negative inductive effect. However, according to the number of resonance forms generated by the attack of the oxidant X (Cl, OH or NO$_3$; Scheme S1, Supplementary Materials), the most favored positions seem to be C2 and C5. This assumption was confirmed by theoretical calculations [9,10]. Of these two positions, C2 and C5, the first is hindered due to the presence of the carbonyl group in the same position. As a consequence, it is expected that the C5 attack will be preferred. Similar double bond addition mechanisms have been proposed for the reactivity of alkylfurans [1,17]. Moreover, the furfural can react by aldehydic hydrogen abstraction but, according to the bibliographic data, the abstraction of hydrogen from the aromatic ring is less likely [18]. This behavior has also been described in previous theoretical works regarding the reactivity of furfural with OH [10] and NO$_3$ [9]. According to these works, a similar reaction mechanism for the reactions with chlorine atoms has been proposed (see Scheme 1).

The formation of maleic anhydride (P2) and 5-chloro-2-(5H)-furanone (P1) as reaction products was evidenced by GC–TOFMS. The presence of maleic anhydride was confirmed by comparing the retention time and mass spectrum with those of the commercial compound. Furthermore, 5-chloro-2-(5H)-furanone is not commercially available so its formation was confirmed by comparison with the El mass spectrum obtained in previous works [17]. The formation of this compound was also observed in the experiments performed by FTIR spectroscopy. An example of the IR bands due to the reaction products generated in the reaction of furfural with Cl atoms is shown in Figure 1.

The bands centered at 2890, 2351 and 2100 cm$^{-1}$ (Figure 1b) are assigned to HCl, CO$_2$ and CO, respectively. CO may be generated by the decarboxylation of the CHO group and HCl is a coproduct of the hydrogen abstraction process. However, the concentrations of these compounds must be treated with caution since they are also present in the chamber when air and Cl$_2$ are exposed to visible light. The absorption band at 1829 cm$^{-1}$ is assigned to 5-chloro-2-(5H)-furanone, which has been proposed as a product from the C5 addition. This type of furanone has also been detected in previous works as a product of the reaction of alkylfurans with Cl atoms [17]. There is a very good agreement
between the residual product spectrum and the bibliographic spectra of 5-chloro-2(5H)-furanone [17] (Figure 1d), which strongly supports the finding that the residual FTIR features are mainly attributable to 5-chloro-2(5H)-furanone.

![Scheme 1](image_url)

**Scheme 1.** General C5 addition mechanism in the reaction of furfural with atmospheric oxidants X (Cl atoms, OH or NO3 radicals). The secondary route for C2 addition is shown in blue. Confirmed products are shown in bold.

**Figure 1.** (a) FTIR spectra of furfural. (b) Furfural with chlorine atoms after 30 min of reaction. (c) Furfural with chlorine atoms in the presence of NO after 20 min of reaction. (d) 5-chloro-2-(5H)-furanone.

In the residual product spectrum, the formation of maleic anhydride was not observed, possibly due to overlap with the chlorofuranone bands (Supplementary Materials Figure S2). However, the formation of a broad band at around 1797–1760 cm⁻¹ suggests the presence of one or more compounds with a lactone-like structure. This fact, along with the band observed at 3750 cm⁻¹ (νO–H), could indicate the formation of 5-hydroperoxy-2(5H)-furanone (P3), which could be generated from the chlorine addition in C2—as proposed in the literature for NO3 [9] and OH [10] radicals (blue route in Scheme 1). In the latter case, ring-opening products have also been theoretically proposed in the literature, although this route is only expected to be minor. Moreover, maleic anhydride, which was detected in our experiments, can also be formed in the H abstraction route (Scheme 2), albeit to a lesser extent.

Product formation for the reaction of furfural with chlorine atoms in the presence of NO was also studied. Two analogous mechanisms have been proposed by considering the reaction with NOx. The same products were detected as in the absence of NOx. Besides, the presence of NOx leads to the formation of nitrate and peroxyacylnitrate products.
The formation of 5-chloro-2(5H)-furanone is evidenced in Figure 1c along with sets of IR bands at 792, 1262 and 1744 cm$^{-1}$ and 890, 1163 and 1700 cm$^{-1}$, which are absorption patterns attributed to –OONO$_2$ and –ONO$_2$ groups, respectively. Moreover, the band at 1798 cm$^{-1}$ may be due to the presence of a substituted lactone and the band at 1843 cm$^{-1}$ may be due to the presence of a carbonyl group of a nitrate compound.

For GC–TOFMS experiments, four product peaks were observed at 10.03, 12.02, 13.23 and 23.73 min in the gas chromatogram (see Figure 2). Peaks at 10.03 and 13.23 min were assigned to maleic anhydride and 5-chloro-2-(5H)-furanone (P1), respectively. The peak at 12.02 min was identified as being due to 2-nitrofuran. The assignment was confirmed by comparing the retention times and mass spectra with those of commercial samples: 2-nitrofuran and maleic anhydride. For the identification of 5-chloro-2-(5H)-furanone, the IR and MS spectra obtained for the synthesized products in our previous work were employed [17].

Matches were not found in the database for the peak observed at 23.73 min, but according to the FTIR data, one would expect the formation of a nitrate compound containing a carbonyl group. Therefore, taking in account the FTIR data, the m/z value (141) and pattern observed (Figure S2), this peak is tentatively assigned to 2-furylnitroketone (P4, Scheme 2). However, the presence of this product was not confirmed because it is not commercially available.

The formation of 2-furylnitroketone and 2-nitrofuran (P5) can be explained by the reaction between the intermediate radicals generated and NO$_2$, which is present in the NOx mixture (red route in Scheme 2). These radicals react slowly with O$_2$ since it is a slightly exothermic and highly reversible reaction, but, alternatively, they would react with other species such as O$_3$, NO$_2$ and RO$_2$ [10].

Analogous mechanisms were proposed for the reaction of furfural with OH radicals. According to the literature, 2-oxo-3-pentene-1,5-dialdehyde, 5-hydroxy-2-(5H)-furanone, 4-oxo-2-butenic acid and maleic anhydride are the main products expected for the OH oxidation of furfural [10]. From this list of proposed products, only the formation of maleic anhydride was observed in our experiments by GC–TOFMS. The FTIR spectra are in this case more difficult to analyze due to the overlap of the OH precursors employed (CH$_3$NO + NO) and the decomposition products (formaldehyde, CO and NO$_2$). However, the IR bands observed in the product spectra after 30 min of photolysis (see Figure S3, Supplementary Materials) have been associated with the presence of –ONO$_2$ and –OONO$_2$ groups, as described previously. These bands may correspond to the products P4 and P5, which may be formed when certain levels of NOx are present in the gas mixture.
For NO were obtained using IR absorption cross-sections found in the literature [19]. In the case of which could be assigned to the formation of 2-furylcetone mentioned above. The band at 1840 cm$^{-1}$ proposed in work by Huang et al. [9]. Once again, the presence of these products was not confirmed because they are not commercially available.

The formation of 5-nitrate-2-(5H)-furanone and maleic anhydride have also been suggested in the literature [9]. The IR absorption bands observed are also consistent with the formation of 5-hydroperoxy-2-(5H)-furanone and 3-nitrate-2-hydroperoxy-3(2H)-furanone, which were theoretically proposed in work by Huang et al. [9]. Once again, the presence of these products was not confirmed because they are not commercially available.

The quantification of the identified products was only possible in certain cases. The product concentrations were estimated using calibration curves obtained previously by introducing into the reactor a set of samples of known concentration.

For some products, such as 5-chloro-2(5H)-furanone and NO$_2$, the concentration profiles were obtained using IR absorption cross-sections found in the literature [19]. In the case of 5-chloro-2-(5H)-furanone, the concentration was estimated using the IR absorption coefficient of the 2-(5H)-furanone [19] because of their structural similarity and since the former is not commercially available. A value for this coefficient of $(1.65 \pm 0.27) \times 10^{-3}$ ppm V$^{-1}$ m$^{-1}$ for the band of 1811 cm$^{-1}$ was used. For NO$_2$, a value of $(1.46 \pm 0.04) \times 10^{-3}$ ppm V$^{-1}$ m$^{-1}$ for the band at 1630 cm$^{-1}$ was taken for the quantitative analysis. In addition to these two products, the concentrations of maleic anhydride,

CO, HCl, HNO₃ and 2-nitrofuran were obtained. An example of the concentration–time profiles for the reaction of Cl atoms and furfural is shown in Figure 3.

![Figure 3](image-url)

**Figure 3.** FTIR concentration–time profiles for the reaction of furfural with chlorine atoms. • Furfural, ■ HCl, ○ CO, ▲ 5-chloro-2-(5H)-furanone.

The profiles are typical of primary products that undergo a progressive increase in the concentration from the early stages of the reaction. Similar time–concentration profiles were obtained for 5-chloro-2-(5H)-furanone, CO and HCl in the case of the reaction of furfural with chlorine atoms in the presence of NOₓ. In the cases of maleic anhydride and 2-nitrofuran, the curves obtained after 4–6 min of reaction and using GC–MS/TOF suggest the loss of these products through secondary reactions (Figure S5, Supplementary Materials). As mentioned before, chlorofuranone has a typical primary product profile while the nitro-2-furylketone (P7) has a secondary product profile (Figure S6, Supplementary Materials). This may indicate that high levels of NO₂ are required for the generation of this product (P7).

The yields of the primary products were obtained from the slopes of plots of the amounts of consumed furfural. The product yields obtained for the reaction of furfural with different oxidants are provided in Table 1.

**Table 1.** Product yields confirmed by FTIR and GC–TOFMS analysis for the reaction of furfural with different oxidants.

| Compound                          | Molar Yield (%) |
|-----------------------------------|-----------------|
|                                   | Cl ± NOₓ        | OH ± NOₓ |                             |
| HCl                               | (72.9 ± 0.9) a  | (56.6 ± 2.1) a | –                           |
| CO                                | (22.9 ± 0.4) a  | (11.4 ± 0.4) a | –                           |
| 5-chloro-2-(5H)-furanone          | (6.8 ± 0.1) a   | (6.0 ± 0.2) a | (23.8 ± 0.3) a               |
| Maleic anhydride                  | (6.1 ± 0.5) b   | (6.7 ± 0.2) b | –                           |
| 2-nitrofuran                      | (10.8 ± 0.5) b  | (8.8 ± 0.6) b | (20.0 ± 3.0) b               |

Products identified by a FTIR and b GC–TOFMS; Unconfirmed X. The yield error is 2 times the standard deviation calculated from the least–square fit.
For the reactions of furfural with chlorine atoms in the absence and presence of NOx, the molar yields obtained for 5-chloro-2-(5H)-furanone were similar for both reactions, although the levels of HCl and CO quantified were lower for the reaction in the presence of NOx. Yields of HCl and CO are overestimated due to wall secondary reactions and traces of humidity.

For the reaction of furfural with the OH radical, only the levels of CO (using FTIR) and maleic anhydride (using GC–MS/TOF) were confirmed. Both products lead to primary concentration–time profiles, as in the case of chlorine reactions. In this case, the yield obtained for the anhydride was slightly higher than that obtained for the reaction with chlorine atoms.

For the reaction with NO3 radicals, only the levels of NO2, CO and HNO3 were confirmed by FTIR analysis. A progressive increase in the concentration of NO2 during the reaction can be seen (Figure S7 Supplementary Materials), but this began to decay over time as a result of secondary reactions. The high concentrations detected initially are attributable to the thermal decomposition of the precursor (N2O5). The yield was estimated to be (78.3 ± 6.6)%. In this case, the high levels of NO2 detected could be of great importance since it can react with the reaction intermediates generated. The concentration profiles for CO and HNO3 are more or less constant, with a slight decay observed for the latter throughout the reaction. This trend can be attributed to the deposition of nitric acid on the reactor walls. However, HNO3 levels are difficult to evaluate since, as mentioned before, they are strongly influenced by the existence of secondary reactions. Molar yields of (58.6 ± 8.6)% and (20 ± 3)% for 2-nitrofuran and maleic anhydride, respectively, were quantified by GC–TOFMS. As can be seen from the results in Table 1, this yield is considerably higher than in the case of the other oxidants, which suggests in this case an extra route for the generation of maleic anhydride (Scheme 1).

As mentioned above, the curve contours observed for maleic anhydride after 2 h of reaction suggest loss due to secondary reactions. The molar yield for the 2-furylnitroketone could not be obtained since it is not commercially available.

The studied oxidants led to the formation of the common product maleic anhydride. This compound may be generated by hydrogen abstraction of the –CHO group (via I), since the formation of its coproduct (5-hydroxy-2-(5H)-furanone) via II has not been confirmed. For reactions with chlorine atoms and the OH radical, the yield for maleic anhydride obtained is between 6 and 9%. However, this yield is underestimated because it is suspected that this compound undergoes a photolysis process [20]. However, in the case of the nitrate radical, as mentioned above, the anhydride has an extra contribution by the additional pathway. Its yield (~20%) is approximately 2–3 times greater than for other reactions. The results obtained in this study confirm that for reactions with chlorine atoms and the OH and NO3 radicals, furfural reacts by both mechanisms, namely C5 addition and aldehydic hydrogen abstraction. According to the estimated yield for 2-nitrofuran, it is believed that the abstraction process occurs to a greater extent for nitrate radicals. The reaction with NO3 radicals led to the formation of various nitrated products such as 2-nitrofuran (P5) and unconfirmed products such nitro-2-furylketone (P4), which are common products to those obtained in the reaction with chlorine atoms in the presence of NOx. This may be due to high levels of NO2, which make furfural react by following a parallel path (marked in red in the proposed reaction mechanism). This behavior was not observed with the OH radical, where the concentrations of NO2 due to the decomposition of methyl nitrite employed as the precursor is lower.

3.2. SOA Size Distributions

The few products identified in the gas-phase study and their low yields lead us to believe that some of the reaction products generated are not being observed in the gas-phase. This may be because many of the furfural reaction products are in a condensed phase, and therefore, they are not being correctly sampled. For this purpose, a series of experiments was performed under atmospheric pressure and room temperature (similar experimental conditions to those used in the products’ experiments) to study the formation of aerosols in the reaction of furfural with Cl, OH and O3. The same set of experiments was performed to study the reaction with NO3, but particle formation was not observed.
The decay of furfural versus the variation of SOA mass ($M_0$) for the reaction with chlorine atoms is represented in Figure 4. The steady state for aerosol production was observed after 30 min, with a maximum mass of around $9 \times 10^2$ µg m$^{-3}$ for the reaction with chlorine atoms. A typical concentration profile, as described in the literature [21], was observed in this experiment, thus suggesting a strong relationship between the concentration of furfural and aerosol generation.

![Figure 4. Profile of furfural and aerosol mass under chlorine degradation conditions.](image)

As SOA wall loss was observed, the aerosol mass concentration ($M_0$) was corrected by using the wall deposition coefficient rate obtained in this work ($kw = (2.95 \pm 0.46) \times 10^{-5}$ s$^{-1}$).

A significant amount of particulate matter, i.e., between 60 and 950 µg m$^{-3}$, was observed in the oxidation of furfural with chlorine atoms, OH radicals and ozone at the stationary state. This state is rapidly reached after 30 min for the chlorine and ozone reactions and after 5 min for the OH reaction. The furfural concentration was monitored by offline SPME sampling and analyzed by GC–TOFMS. The fiber was exposed in the reactor during 60 s and then thermally desorbed during 15 min at 250°C in the injection port of the gas chromatograph. The reactor was filled with purified air, a quantity of reactant (2.5–3.5 µg m$^{-3}$) and oxidant (~2.5 × 10$^{14}$ molecule cm$^{-3}$). For the study with chlorine atoms and OH radicals, six visible lamps were employed to start the reaction. Ozone was obtained from an ozonizer as mentioned above. Prior tests were performed to confirm the absence of particle generation from the exposure of furfural to light.

All of the experiments were carried out in the absence of inorganic seed aerosol. The initial concentrations employed for the oxidant ([Ox.]0) and furfural or reactive organic gas ([ROG]0) are listed in Table 2 together with the reacted furfural (Δ[ROG]) and aerosol yield, Y. The overall organic aerosol yield was determined by employing Equation (1):

$$Y = \frac{M_0}{\Delta[ROG]}$$

where $M_0$ is the organic aerosol mass concentration and Δ[ROG] is the reacted furfural, both in µg m$^{-3}$.

It can be seen from the results that atmospheric degradation of furfural leads to the formation of low vapor pressure products (particulate matter), as previously proposed in the gas-phase study.

The yield of the reaction with chlorine atoms is between 6 to 10 times greater than in the cases of ozone and OH. The particle size obtained is also larger for the reaction with chlorine (diameters 107–523 nm) and this suggests that the reaction of furfural with this oxidant leads to a more effective formation of aerosols.
Table 2. Experimental conditions employed for SOA study. Aerosol mass (M0), aerosol yield (Y) and SOA size distribution (diameter) obtained at the end of each studied reaction.

| Precursor Oxidant | [Precursor Oxidant]0/1014 Molecule cm−3 | t/min | Δ[ROG]0/10−4 µg m³ | Δ[ROG]/10−4 µgm³ | M0/µg m³ | Y | Size/nm |

In the reaction of furfural with the OH radical, particles were formed by irradiation of the precursor mixture (CH₃ONO and NO) with visible lamps in air. The concentration and particle size observed under the same experimental conditions were lower than those obtained in the reaction with chlorine atoms. In this reaction, due to the formation of preexisting ultrafine particles from the degradation of the OH precursor, it is believed that these act as condensation nuclei that promote the growth of the particles in this process. However, the existence of a nucleation process cannot be dismissed.

For the study of the SOA formation in the reaction of furfural with ozone, several individual additions of a small quantity of an O₂/O₃ mixture were carried out, but only after the addition of a large excess of O₃, and particle formation was observed. A similar evolution of the size distribution as in the case of chlorine atoms was observed. The SOA distribution for the reaction of furfural with chlorine atoms is shown in Figure 5.

![Figure 5. Size distribution of SOA particles formed in the reaction of furfural with chlorine atoms at different times, t = 1 min, t = 2 min, t = 4 min, t = 8 min, t = 18 min, t = 43 min. Variation of furfural concentration during the reaction. Solid line.](image)

A set of experiments at different furfural/oxidant concentrations were carried out in order to study its influence of this parameter on the aerosol yield for the reaction with chlorine atoms. The results are summarized in Table 3.

In most experiments, aerosol yields in the 5–7% range were obtained. The lowest aerosol yield was obtained in Experiment 5, in which a concentration ratio <1 was employed. Reaction 2, with a ratio close to one, also gave a low value of Y.

The aerosol yields obtained in this work for the photooxidation and ozonolysis of furfural are low, but these values are of the same order of magnitude as those reported in the literature for isoprene [22,23] and pinene [24] oxidations. Nevertheless, these values may represent lower limits.
4. Conclusions

The main products detected were 5-chloro-2-(5H)-furanone and maleic anhydride for the reaction with chlorine atoms. 2-nitrofuran was observed in the presence of NOx. The formation of 2-furylketone and 5-nitrate-2-(5H)-furanone has also been tentatively proposed for the reactions with nitrate radicals and chlorine atoms in the presence of NOx. A general mechanism for the atmospheric oxidation of furfural has been proposed. The attack of the oxidants occurs mainly by a double bond addition at the C5 position. Hydrogen abstraction is also observed for all of the studied oxidants. Furthermore, the high maleic anhydride yield obtained for nitrate reactions suggests a contribution from an extra route. When oxidation of furfural takes place under high NOx conditions, an alternative route with NO/NO2 has been proposed. This behavior has been observed for nitrate and Cl/NOx reactions.

The low yields obtained for the gas-phase products identified (~13–23% for chlorine and ~9% for OH in terms of total carbon) suggest the formation of furfural products in a condensed phase. This statement was confirmed in our experiments, where secondary organic aerosol was observed for the reaction of furfural with chlorine atoms, OH radicals and ozone.

The formation of particulate matter in the reaction of furfural with chlorine atoms, OH radicals and ozone was observed. The aerosol yields obtained for these reactions varied in the 0.3–3% range, with the reactions with chlorine atoms giving the highest yield, Y. In this reaction, the influence of the oxidant:furfural ratio was studied and an average yield of 6% was obtained for most of the reactions. When [Cl2]/[ROG] ≤ 1, lower yields of around 2–3% were obtained. Although the aerosol yields obtained in this work are not particularly high, the generation of an aerosol is expected to have greater relevance in coastal areas, where the concentrations of chlorine atoms are higher and these reactions become more important. The presence of organic aerosols in the atmosphere can influence the terrestrial radiative balance since they absorb and disperse solar and terrestrial radiation and influence the generation of clouds and heterogeneous reactions [11,12]. In addition, the particulate matter observed is made up of ultrafine particles, in the order of nanometers, and they can easily penetrate the airways and reach the alveolar region. However, more experiments are required to better understand the atmospheric oxidation of furfural.
