Loss of $\pi$-Junction Behaviour in an Interacting Impurity Josephson Junction

Aashish A. Clerk and Vinay Ambegaokar
Laboratory of Atomic and Solid State Physics, Cornell University, Ithaca NY 14853, USA
December 20, 1999

Using a generalization of the non-crossing approximation which incorporates Andreev reflection, we study the properties of an infinite-U Anderson impurity coupled to two superconducting leads. In the regime where $\Delta$ and $T_K$ are comparable, we find that the position of the sub-gap resonance in the impurity spectral function develops a strong anomalous phase dependence—its energy is a minimum when the phase difference between the superconductors is equal to $\pi$. Calculating the Josephson current through the impurity, we find that $\pi$-junction behaviour is lost as the position of the bound-state moves above the Fermi energy.

What is the Josephson current through an interacting Anderson impurity? As this phenomenon involves the coherent transport of pairs of electrons through the impurity, one would expect that a strong on-site repulsion would greatly diminish the effect. Though this intuitive expectation is partially correct, there is a variety of non-intuitive behaviour also associated with this system.

If the on-site repulsion is large and the impurity is singly occupied, a lowest-order perturbative calculation in the impurity-superconductor coupling reveals that the sign of the Josephson coupling can become negative, meaning that the corresponding ground state of the system has a phase difference of $\delta = \pi$ between the two superconductors. An appealing explanation for this behaviour was provided by Spivak and Kivelson, who showed that in the limit of single occupancy, it is impossible to transport a pair across the impurity while preserving its spin ordering, leading to an extra factor of $(−1)$. More generally, $\pi$-junction behaviour is expected whenever spin-flip tunneling processes dominate. Recent work using a Hartree-Fock type procedure indicates this behaviour can survive beyond lowest-order perturbation theory.

Alternatively, in the limit of large impurity-superconductor coupling, the physics of the Kondo effect will also become significant. A resulting enhancement of the Josephson current through the impurity has been predicted in the regime where the superconducting gap $\Delta$ is much smaller than the Kondo temperature $T_K$. Significantly, no $\pi$-junction behaviour is expected here, as the spin of the impurity is completely screened by the Kondo effect.

Given these prior results, it is natural to ask how large the ratio $T_K/\Delta$ must be to see the destruction of $\pi$-junction behaviour, and what the properties of the junction are in this cross-over region; these questions are the motivation for the current paper. We examine the regime where $\Delta$ is comparable in magnitude to $T_K$, a regime in which the effects of both Kondo physics and superconductivity must be treated on an equal footing. Note this parameter range is also of interest as it is more appropriate to mesoscopic quantum dot systems, which would be one possible experimental realization of the model. We find, somewhat surprisingly, that the properties of our system can be understood in terms of another well-studied feature of magnetic impurities coupled to superconductors—the sub-gap bound state. Typically, the position of this state is a function of the ratio $T_K/\Delta$. We find now that this resonance also develops a pronounced dependence on the phase difference as $\delta$ increases from zero, the energy of the bound state decreases. This phase dependence is anomalous in the sense that it indicates an energetic preference away from $\delta = 0$. Interpreting this sub-gap state as a current carrying Andreev bound state, we are led to the conclusion that the system is a $\pi$-junction if the sub-gap bound state is located below the Fermi energy $E_F$. This relation is confirmed by making an explicit calculation of the Josephson current through the impurity.

The model we study consists of an infinite-U Anderson impurity coupled to two superconducting leads, each having a different phase. Using a slave-boson representation, we have:

$$H = H_0 + \varepsilon \sum_{\sigma} f_{\sigma}^\dagger f_{\sigma} + W \sum_{\alpha,k,\sigma} (c_{\alpha,ka}^\dagger b_{\sigma}^\dagger f_{\sigma} + h.c.), \quad (1)$$

$$H_0 = \sum_{\alpha,k,\sigma} \varepsilon_{k\sigma} c_{\alpha,ka\sigma}^\dagger c_{\alpha,ka\sigma} + (\Delta_{\alpha} c_{\alpha,k\uparrow}^\dagger c_{\alpha,-k\downarrow} + h.c.). \quad (2)$$

The $c_{\alpha,ka\sigma}$ operators here create band electrons, with $\sigma$ denoting spin and $\alpha = L,R$ labelling the left and right superconducting leads. $\Delta_{\alpha} = |\Delta| \exp(i\phi_{\alpha})$ represents the pair potential in lead $\alpha$, with the phase difference $\delta$ being defined as $\phi_R - \phi_L$. The Anderson impurity has bare energy $\varepsilon_{d\sigma}$ and is represented in the usual manner using auxiliary fermion ($f$) and boson ($b$) operators; the $U = \infty$ constraint of single occupancy takes the form

$$\sum_{\sigma} f_{\sigma}^\dagger f_{\sigma} + b^\dagger b = 1.$$

The NS-NCA. We calculate the impurity spectral function (also called the impurity density of states) for our system using the NS-NCA, an extension of the self-consistent non-crossing approximation (NCA) to superconducting systems. The NCA amounts to an infinite order re-summation of perturbation theory, and has been shown to be quantitatively reliable down to
temperatures below $T_K$. The modification we employ self-consistently includes multiple-Andreev reflection processes in a manner which is formally exact to order $1/N$, where $N = 2$ is the spin degeneracy of the impurity. As the success of the normal NCA is attributed to the fact that it too is exact to order $1/N$ (in the absence of superconductivity), the NS-NCA employed here can be viewed as a natural extension to systems with superconductivity. The graphs determining the $f$-fermion and $b$ slave boson propagators are given in Fig. 1.

Note that the anomalous graphs appearing in Fig. 1 always involve two Andreev reflections. As these Andreev reflection events pick up the phase of the superconductor in which they occur, and each Andreev reflection is free to occur in either of the two superconductors, the phase difference $\delta$ naturally enters the impurity self energies through an interference term. A previous study using the NCA to study the regime $\Delta >> T_K$ neglected these diagrams, and thus omitted the only phase-dependent contribution to the impurity Green function which survives in the limit of a strong on-site repulsion.

The Dyson equations pictured diagrammatically in Fig. 1 lead to a set of coupled integral equations for the $f$-fermion and slave boson propagators. Letting $F(\omega) = (\omega - \varepsilon_d - \Sigma(\omega))^{-1}$ and $B(\omega) = (\omega - \Pi(\omega))^{-1}$ represent the $f$-fermion and slave boson retarded propagators respectively, the equations read:

$$
\Sigma(\omega) = \frac{\Gamma}{\pi} \int d\varepsilon \left( \rho(\varepsilon) B(\omega - \varepsilon) f(-\varepsilon) - \frac{\Pi(\omega)}{\pi} \int d\varepsilon' \tau(\varepsilon) \tau(\varepsilon') B(\omega + \varepsilon) F(\omega + \varepsilon + \varepsilon') B(\omega + \varepsilon') \right) - \frac{\Gamma}{\pi} \int d\varepsilon' \tau(\varepsilon) \tau(\varepsilon') B(\omega + \varepsilon) F(\omega + \varepsilon + \varepsilon') B(\omega + \varepsilon')
$$

$$
\Pi(\omega) = \frac{2\Gamma}{\pi} \int d\varepsilon \left( \rho(\varepsilon) F(\omega + \varepsilon) f(\varepsilon) + \frac{\Gamma}{\pi} \int d\varepsilon' \tau(\varepsilon) \tau(\varepsilon') F(\omega + \varepsilon) B(\omega + \varepsilon + \varepsilon') F(\omega + \varepsilon') \right).
$$

In these equations, $\rho(\varepsilon)$ is the electronic density of states, $\Gamma = \pi W^2 \rho(0)$ the bare tunneling rate, $f$ the Fermi distribution function, and $\tau(\varepsilon)$ is an effective electron-hole coherence parameter defined by:

$$
\tau(\omega) = \sum_{k,\alpha}^{} u^*_{k,\alpha} v_{k,\alpha} \delta(|\omega| - \varepsilon_n) f(\omega)
$$

where $u_{k,\alpha}$ and $v_{k,\alpha}$ are the usual BCS coherence factors.

Results. We use a Gaussian density states for the band electrons having half-width $D$. For the results shown here, we choose model parameters $\varepsilon_d = -0.67D$ and $\Gamma = 0.15D$, which yields an approximate $T_K = 0.0005D$. We have solved numerically via iteration the NS-NCA equations in equilibrium for various temperatures, gap sizes and phase differences. Within the NCA, the impurity spectral function $A_d(\omega)$ can be directly related to the $f$-fermion and slave boson spectral functions:

$$
A_{ds}(\omega) = \int d\varepsilon [e^{-\beta \varepsilon} + e^{-\beta(\varepsilon - \omega)}] A_{fs}(\varepsilon) A_b(\varepsilon - \omega)
$$

where the auxiliary particle spectral functions are defined by $A_f = -\frac{1}{2} \text{Im} F, A_b = -\frac{1}{2} \text{Im} B$. Note that the equality in equation (6) reflects a neglect of vertex corrections which is consistent with the large-$N$ nature of the NCA.

**FIG. 2.** Position of sub-gap bound state as a function of $\Delta/T_K$ for a fixed $T/\Delta = 0.5, T_K = 0.0005D$. The vertical dashed line indicates the approximate value of $\Delta$ for which the bound state resonance crosses the Fermi energy. Inset: plots of the impurity density of states $A_d(\omega)$ for $\Delta/T_K = 0.66$ at various phase differences. From right to left, we have $\delta = 0$ (solid curve), $\delta = \pi/4, \delta = \pi/2, \delta = \pi$ (dash-dot curve).

The solid curve in Fig. 2 (with points indicated by circles) shows the position $y$ (in units of $\Delta$) of the sub-gap resonance in the impurity density of states as a function of $\Delta/T_K$ at $\delta = 0$ and at a constant ratio $T/\Delta = 0.5$; this resonance corresponds to the sub-gap bound state. As has been observed in earlier studies, we find that as $\Delta/T_K$ decreases, the position of the bound state increases, with the transition across the Fermi energy occurring when $\Delta$
is on the order of \( T_K \). Note that as we are not using a model with particle-hole symmetry, we only have a single sub-gap state.

A cogent interpretation of this behaviour was provided in Ref. 3, where the position of the sub-gap bound state was suggested to result from the competition between two possible ground states. For \( T_K > \Delta \), the ground state of the system is the Kondo singlet, and the excited sub-gap state is a spin doublet. Recall that in the Kondo singlet ground state of the infinite-\( U \) Anderson model, there is a small probability of finding the impurity empty, despite the fact that the bare site energy \( \varepsilon_d \) is well below \( E_F \); this is not true for the doublet state, where the impurity is expected to be singly occupied. Thus, the fact that the bound state is located above \( E_F \) in this limit (i.e. \( y > 0 \)) reflects the fact that one must add a particle at the impurity to the singlet ground state to reach the doublet state. The magnitude of \( y \) indicates the energy splitting between these two states:

\[
y = \frac{E_{\text{excited}} - E_{\text{ground}}}{\Delta} = \frac{E_{\text{doub}} - E_K}{\Delta} > 0 \tag{7}
\]

where \( E_{\text{doub}} \) is the energy of the doublet state and \( E_K \) is that of the Kondo singlet state. Similarly, for \( \Delta > T_K \), the ground state is the fully-paired doublet favoured by the superconductivity; the bound state is located below \( E_F \) as one must remove a particle from the doublet ground state to reach the excited singlet state. An identical expression holds for \( y \):

\[
y = -\frac{(E_{\text{excited}} - E_{\text{ground}})}{\Delta} = -\frac{(E_K - E_{\text{doub}})}{\Delta} < 0 \tag{8}
\]

The crossing of \( E_F \) by the sub-gap state is thus seen to indicate a substantial change in the nature of the ground state.

While the behaviour of the bound state at \( \delta = 0 \) has received much attention, the effects of having a phase difference has not, to our knowledge, been previously studied. The triangles in Fig. 2 indicate the bound state positions \( y \) for the same values of \( T_K/\Delta \) as the solid curve, but now with a phase difference of \( \delta = \pi \) between the superconductors. We find that for all values tested, \( y \) decreases as we increase \( \delta \) to \( \pi \) – the sub-gap bound state has an anomalous phase dependence. This behaviour is seen more explicitly in the inset of Fig. 2, where we plot the sub-gap resonance for various values of \( \delta \).

The phase dependence of the sub-gap state can also be interpreted in terms of a competition between the Kondo singlet and the fully paired doublet states. The Kondo state is again expected to be the ground state for \( T_K > \Delta \), while the the doublet state will be the ground state in the opposite regime. Significant now however is the fact that the phase dependence of these two states is quite different. In the doublet state, the impurity can be viewed as a local moment and we thus expect a negative Josephson coupling and that \( E_{\text{doub}} \) will be a minimum at \( \delta = \pi \). In the Kondo singlet state, the impurity spin has been screened and thus we do not expect any anomalous Josephson coupling – \( E_K \) will be a maximum at \( \delta = \pi \). With these associations, it follows from Eqs. (7) and (8) that \( y \) is minimized at \( \delta = \pi \), meaning that the sub-gap state has an anomalous phase dependence. Note that for small values of \( \Delta/T_K \), it is possible to make the sub-gap state cross \( E_F \) and thus change markedly the nature of the system ground state by only changing \( \delta \).

At this point, it is natural to attempt to make a connection to the Josephson effect. Recall that for a non-interacting system, it is possible to discuss the Josephson current as being at least partially carried by Andreev bound states existing in the weak link between the two superconductors.\( ^4 \) These states have a phase-dependent energy, and thus contribute to the current through the relation \( I = \frac{\hbar}{2e} dF/d\delta \), where \( F \) is the free energy of the junction. For the simple case where a non-interacting impurity couples the two superconductors, there are always two Andreev bound states with energies \( \pm |\varepsilon(\delta)| \); as the lower-energy state – \( |\varepsilon(\delta)| \) has a “normal” phase dependence \((dE/d\delta > 0)\), the Josephson current is always positive.

In the present case, matters are quite different due to the strong on-site interaction. We have only one apparent Andreev bound state, and its phase-dependence is anomalous \((dE/d\delta < 0)\). We would thus naively expect that the Josephson current would both become negative and enhanced in magnitude as the bound state crosses below \( E_F \) and becomes “occupied”. Of course, this picture is oversimplified, as there are other possible contributions to the Josephson current – due to interactions, the impurity contribution to the free energy \( F \) is not just a simple function of the impurity density of states.

The conjecture made above can be tested by making an explicit calculation of the DC Josephson current through the impurity. Using a technique similar to that used in Ref. 4 to calculate the normal current through an interacting impurity, we arrive at the following exact expression for the Josephson current:

\[
I_J = \frac{4e}{h} \Gamma \sin(\delta/2) \sum_k W_{k,2}^* \int d\omega f(\omega) \times \frac{-Im}{\pi} \left( g_{k,12}(\omega) C_{d,21}(\omega,\delta) \right). \tag{9}
\]

Here, \( g_{k,12}(\omega) \) indicates an anomalous BCS propagator, and \( C_{d,21}(\omega,\delta) \) is the anomalous impurity propagator; without loss of generality, we have chosen \( \delta_L + \phi_R = 0 \).

We calculate the anomalous impurity propagator within the NCA using the lowest-order contributing graph,\( ^7 \) without making any further approximation. To calculate an approximate value of the 0 temperature Josephson current, we use Eq. (9) with the Fermi function taken at \( T = 0 \), but with all spectral functions calculated at \( T = 0.5\Delta \) (the NCA is unreliable at \( T = 0 \)). This is a reasonable procedure, as we expect no qualitative changes in the spectral functions as the temperature is further lowered; the sub-gap resonances will only be
sharpened. Retaining a finite $T$ Fermi function would smear the contribution of the sub-gap resonances, and thus obscure the behaviour we are interested in.

![Graph](image)

**FIG. 3.** Approximate $T = 0$ phase-derivative of the Josephson current $(dJ/d\delta)$ at $\delta = 0$ for various values of $\Delta/T_K$. Note the transition from negative to positive current (indicated by the vertical dashed line) coincides with the sub-gap bound state crossing the Fermi energy (see Fig. 2).

Plotted in Figure 3 is the approximate 0 temperature phase derivative of the Josephson current $(dJ/d\delta)$ thus obtained as a function of $\Delta/T_K$, taken at $\delta = 0$. Comparison to Fig. 4 indicates that $\pi$-junction behaviour is indeed lost when the bound state crosses above the Fermi energy, as expected from a non-interacting picture. Similar results hold at other values of $\delta$; $(dJ/d\delta)$ changes sign at roughly the same value of $\Delta/T_K$ at which the bound state crosses the Fermi energy. It would thus appear that the sub-gap bound state is the entity responsible for carrying the reversed-sign Josephson current associated with $\pi$-junction behaviour.

Note that in some respects, our conclusion here resembles what was found in a study of the Josephson current through a non-interacting magnetic insulating layer. There also, the transition to $\pi$-junction behaviour is accompanied by an anomalous Andreev bound state crossing below the Fermi energy. We stress again that the present situation is quite different due to the strong on-site repulsion – there is no a priori reason guaranteeing that the general non-interacting theory relating $I_J$ to Andreev bound states should be applicable to the interacting system studied here. We find only a single sub-gap state in the impurity density of states, whereas in the non-interacting case bound states always occur in pairs, with one member of each having $dE/d\phi < 0$.

Also of interest in the present system is the behaviour of the superconducting phase of the impurity itself. We find that this phase undergoes a shift by $\pi$ as the bound state passes through the Fermi energy. When the bound state is above $E_F$, the impurity simply has the average phase of the two superconducting leads – at low energies, the signs of both the real and imaginary parts of the anomalous impurity Green function $(G^R,d)$ are the same as those of the average anomalous Green functions of the superconductors. However, when the bound state moves below $E_F$, we find that the anomalous impurity Green function changes sign. We interpret this to mean that the impurity has acquired an additional phase of $\pi$. This behaviour is shown Fig. 4. It is clear from Eq. 10 that this additional factor of $(-1)$ will cause a sign change in the Josephson current. A similar phase shift was found in earlier work involving a single superconductor, though a transition was not observed.

**FIG. 4.** Anomalous impurity spectral function $ImG^R,d$ for various values of the phase difference $\delta$ with fixed $\phi_L + \phi_R = 0$, $\Delta = 0.66T_K$, $T = 0.5\Delta$. Note that as $\delta$ increases, the spectral function changes sign; this coincides with the bound state crossing below the Fermi energy (see inset of Fig. 3).

Conclusions.- Using an extension of the NCA, we have studied the properties of an infinite- $U$ Anderson impurity coupled to two superconductors. We find that the sub-gap bound state develops an anomalous phase dependence, and that $\pi$-junction behaviour is lost when the bound state crosses above $E_F$.
