Abstract—With constant technological advances, flight simulation has increasingly resembled a real flight. The use of motion platforms together with a virtual simulation is what is most recent in this field, due to its global approach to a flight. However, these flight simulators generate a great added value, so that for trivial trainings and entertainment their use becomes impracticable. With this in mind, in this work was presented a low cost project of a new model of flight simulator containing both simulations, visual and motion. More specifically, this work aims to demonstrate an analytical method for calculating the drives of the designed simulator, so that it supports the loads of the structure and user, in addition to the dynamic torque required by the simulation platform. Furthermore, it was shown how to obtain the inertia of a complex structure as designed using SolidWorks software and also how to acquire magnitudes such as acceleration and angular velocities using Flight Simulator X and Link2FS Multi software. Finally, with the torque and power values required to perform the pitch and roll movements, a commercial selection of the motors was made for platform so that these drives would supply the demand of both torque and power.

Keywords—Analytical Calculation, Flight Simulation, Links2FS Multi, Power, Torque.

I. INTRODUCTION

Since the dawn of aviation, pilots training has been the subject of many studies seeing that they should achieve a high level of efficiency without risk being taken during the training phase. In military aviation, for example, pilot skill was of paramount importance, as precision in combat maneuvers could ensure the success of the mission [1].

Flight simulators have been developed for more than a century, seeking to achieve the highest possible realism and safety for the user. Currently, flight simulators have been widely used for both professional training and entertainment. Generally, the use of a simulator is always superior to the use of real equipment in three aspects: safety, cost of equipment and experimental control [1][2][3].

According to Dourado [1], when used for training, the flight simulator should have a reduction in the time between land training and real flight due to mistakes made by beginners, the simulation must be safe, cost and pollution must also be smaller.

Many authors have discussed themes or subsystems related to the simulation of a flight, but few have discussed this as a whole, that is, from virtual simulation to simulation of aircraft movements. For example, Shahal discussed this as a whole, that is, from virtual simulation to simulation of aircraft movements. For example, Shahal treated only the influence of visual parameters such as brightness and contrast on the visual simulation of a fixed-base simulator, while Pool presented a cybernetic approach to evaluate the flight simulator's motion fidelity [4][5].

Due to that reason, the authors elaborated a project considering the required subsystems in order that a simulation with a global fidelity of a real flight can be acquired[6]. These subsystems are a view of the environment outside the cockpit of an airplane, a motion system which supports the movements done by an
aircraft, and the main controllers of an airplane, in this case the joystick, the rudder pedals and the accelerators. A flight simulator with 2 degrees of freedom (2DOF) containing both the visual and control simulation made by Flight Simulator X (FSX) software and controller replicas of an aircraft, as well as simulation of airplane movements, made through a motion platform composed of structural parts and electrical drives.

However, owing to the complexity of the platform and the calculations involved, in addition to all programmatic control, this work aims to present the final design of the flight simulator and the analytical procedure to calculate the power and torque of the electric motors of the simulator and also the computational method used to obtain the moment of inertia of the simulation platform. In addition, an effort has been done to select the appropriate commercial electric motors for each movement.

II. METHODS

2.1 Project of the Flight Simulation Platform

During the initial phase of the project several factors were defined in order to delimit the peripherals and drives to be used. The relevant factors for this project were the final cost, the interaction of the user with the simulator and, the most relevant, the fidelity of the simulation provided by the precision of the movements. For the platform modeling, SolidWorks 2016 software was used.

2.2 Determination of the Drive type

Before determining the type of drive to be used on the platform, the initial factors were again considered on the choosing. The main types of drives are hydraulic, pneumatic and electric. Pneumatic drives were the first to be discarded because they can achieve low power and torque, which would not match the demand of this project. The hydraulic drive would be the one that would present greater precision of the movements, besides high powers that could be reached, but the needed cost would be very high compared to the electric drives, for this reason the hydraulic drive was also discarded [7]. Amongst the electric drives, stand out the conventional motors AC and DC, besides the servomotors. Of these types of electric motors, the one that fit better was the AC motor, although this one needs an inverter of frequency for the control of the speed, would still be a cheaper option than the others. However, this motor has less control accuracy when compared to the servomotor, but by establishing a certain precision tolerance, the AC motor would comply with the demand.

2.3 Torque Analytical Calculation

The motion platform was designed to describe the pitch and roll movements of an aircraft, each movement being described by an electric motor. Thus, the calculation procedure was done using the Euler equations of motion for the dynamic torque, where each component of the torque represents one of the movements of the aircraft. However, if this analytical method were not used, the computation could be done by systematic computation using a generic technique such as Euler-Newton [8].

So, the minimum torque required by the motors can be calculated as proposed, analytically, by equation 1:

\[ M_{\min} = M_{\text{dynamic}} + M_{\text{static}} \]  

(1)

Where \( M_{\text{dynamic}} \) can be calculated by Euler equations from 2 to 4[9]:

\[ M_x = I_{xx} \alpha_x + \omega_y \omega_z (I_{zz} - I_{yy}) \]  

(2)

\[ M_y = I_{yy} \alpha_y + \omega_x \omega_z (I_{zz} - I_{xx}) \]  

(3)

\[ M_z = I_{zz} \alpha_z + \omega_x \omega_y (I_{yy} - I_{xx}) \]  

(4)

Where \( I \) is the inertia for the part of the motion platform and \( \alpha \) and \( \omega \) are respectively the maximum angular acceleration and velocity described by the structure.

Using the parallel-axis theorem, also called the Steiner's theorem, the rotational inertia of a body with respect to an axis parallel to the center of mass axis can be calculated by equation 5 [10]:

\[ I = I_o + M d^2 \]  

(5)

Where \( I_o \) is the inertia about to the center of mass and \( d \) is the distance between the parallel axes.

However, this inertia calculation is usually done manually for bodies with simple geometry as shown by Abdulghany [10]. Therefore, to calculate the inertia of three-dimensional bodies and complexes, software is commonly used to this calculation and it express the result as an inertia tensor as shown in equation 6 [10]:

\[ I = \begin{pmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{pmatrix} \]  

(6)

Where the elements of the diagonal refer to the moments of inertia on the three orthogonal axes \( x \), \( y \) and \( z \).

In order to obtain this tensor a tool of the software SolidWorks 2016 was used, which shows the mass properties of the selected bodies in the project, so that inertia can be obtained for both pitch and roll.

The angular acceleration was obtained empirically using two programs, Flight Simulator X (FSX) and Link2FS Multi. A flight simulation was done using the FSX with Cessna 172 model as aircraft, one of the most used aircraft for pilot training. During the simulation,
forced maneuvers were made to simulate extreme flight situations, where critical accelerations would be imposed on the aircraft. Using the Link2FS Multi software, the critical accelerations imposed on the aircraft were collected and the maximum acceleration obtained was used for the calculation, as this would be the situation where a higher torque would be required. Then, the dynamic torque was calculated using the Euler equations.

As well as the minimum torque, the dynamic torque could have been computationally calculated according to the dynamic analysis done by Herrero [11] for a mechanism with 3DOF. But, as a simplification to calculate the static torque, the equation 5 [12] was used.

\[ M_{\text{static}} = r \times F = \begin{vmatrix} i & j & k \\ r_x & r_y & r_z \\ F_x & F_y & F_z \end{vmatrix} \] (7)

Where \(r_x, r_y\) and \(r_z\) represent the orthogonal distances, according to the coordinate system, up to the axis of rotation and \(F_x, F_y\) and \(F_z\) represent the force vectors according to the coordinate system.

However, for this calculation both mass and distance were obtained using SolidWorks 2016 software to evaluate these quantities, where \(m\) would be the mass of the selected platform part added to an arbitrary mass given to the user which multiplied by gravity would promote the force weight would generate the static torque considering a \(r\) that would be the orthogonal distance from the center of mass to the axis of rotation of the motors. Then, the static torque was calculated, disregarding its sense since at times the torque would be favorable to the movement and now would be contrary. Finally, the minimum torque required for each of the motors can be calculated.

2.4 Power Analytical Calculation

The motors are commercially found according to their power and in their datasheet can be found the value of the nominal torque. The electric motor must supply both the required power and torque. Thus, the analytical power calculation was done using equation 8 [13]:

\[ P = M_{\text{min}} \times \omega \] (8)

Where \(M_{\text{min}}\) was previously calculated and \(\omega\) is the maximum angular velocity achieved by the Cessna 172 aircraft during the simulated flight in FSX. As well as the angular acceleration, the maximum angular velocity was obtained using Link2FS Multi.

2.5 Selection of motors and gear units

The selection of suitable motors was consulted catalogs from one of the largest electric motor companies, the WEG [14]. In addition, catalogs of gears were also consulted, so that the drives meet the required torque[15].

III. RESULTS

3.1 Flight Simulator Platform

Fig.1: Motion Flight Simulator Platform shows the isometric view of the finished and rendered project. The platform was designed in an attempt to obtain the maximum possible structural symmetry. As seen in Fig.1: Motion Flight Simulator Platform, the roll is described by the internal structure, the gear and motor assembly being located on a support in the outer ring, where movement would be imposed on the structure by a coupling. In the meantime, the pitch movement would be imposed on the structure as a whole by means of the gear and motor assembly arranged in one of the support tripods of the structure. The platform is designed to describe angles of maximum 40°, and in commercial flights the maximum pitch and roll values are 15°. In this way, the platform would attend both for pilot training and entertainment.
3.2 Torque Analytical Calculation

Fig.2: Other view of the Flight Simulator shows another view of the simulation platform, which can be seen interface devices with a replica of the joystick used in the Cessna 172 as well as accelerators, in addition to a 32” TV for visual simulation.

The relevant properties for the torque calculation are the distance from the center of mass to the center of rotation of the roll motor and the inertia of the structure relative to the axis of rotation. Equation 9 shows the inertia tensor of the selected bodies and shown in Fig. 3:

\[
I = \begin{pmatrix} 51.55 & 5.25 & -0.59 \\ 5.25 & 73.27 & -0.47 \\ -0.59 & -0.47 & 106.95 \end{pmatrix}
\] (9)

The units of the inertias shown in equation 9 are in kg.m². Fig.3: Internal Structure and its Mass Centers shows that the dynamic torque for the roll is the \(M_x\), so the inertia to be considered for the calculation should be the \(I_{xx}\) which is equal to 51.55 kg.m². The acceleration obtained using the software FSX and Link2FS was 0.5 rad/s². From this data can be calculated the dynamic torque using the equation 2 and considering that there is no initial velocity, because the motor would have interrupted cycles, that is, with each movement that was carried out, soon after if it was not necessary to continue the movement, the motor would stop the movement. In this way, the second part of equation 2 would be null. Thus, the dynamic torque obtained was 17.44 N.m.

The orthogonal distances from the center of mass to the axis of rotation were also obtained through the mass properties in order to calculate the static torque. Table.1: Mass Center from Internal Structure shows the data from the center of mass to the internal structure.

| Mass Center (m) | X    | Y    | Z    |
|----------------|------|------|------|
| X              | -0.08|      |      |
| Y              | -0.13|      |      |
| Z              | 0.01 |      |      |

Therefore, the distance considered for the calculation of the torque was the distance in Z, since this is perpendicular both the force weight (Fy) and the axis X, already the distance ry although it is orthogonal to the X axis at the same time is parallel the force weight, for this reason does not generate a static torque. Using equation 7, the static torque was calculated. The mass of the internal structure considering the mass of a user of 100 kg was 284 kg. The static torque for distance Z was 27.8604 N.m. Thus, using equation 1, the minimum torque for the motor running the roll was 45.3 N.m.

The same procedure was used to calculate static and dynamic torques for pitch motion. Equation 10 below shows the inertial tensor for the platform considering the internal and external structures.
reductions rates in 1 stage and motors with 1750 rpm of nominal speed.

Table 4: Reducer and its output properties

|   | Reduction | Power (hp) | Torque (N.m) |
|---|-----------|------------|--------------|
| Pitch | 1.80 | 0.65 | 208 |
| Roll  | 1.60 | 0.40 | 96 |

For the selected reduction and to obtain these values of torque and output power, the electric motors required for pitch and roll were respectively 2 hp and 1 hp. According to the gearbox catalog of WEG-Cestari, MAGMA type gear units for pitch and roll were size 7 and 5 respectively.

IV. CONCLUSION

From the analysis of the results, it can be concluded that the flight simulation platform, despite having a high torque demand, at the same time showed a low power requirement due to the low displacement velocity. It may also be noted that as proposed, the analytical method of calculating dynamic quantities was very simple, even for a complex structure as projected.

Finally, it is possible to simply specify the torque and power calculation to specify commercial devices that would support with a certain safety factor the torque and power values found. In future works, this article will be compared another approach calculation which will be done using an assistance of software like Adams and Ansys.
