There are good reasons to consider models of low-energy supersymmetry with very light photinos and gluinos. In a wide class of models the lightest $R$-odd, color-singlet state containing a gluino, the $R^0$, has a mass in the 1-2 GeV range and the slightly lighter photino, $\tilde{\gamma}$, would survive as the relic $R$-odd species. For the light photino masses considered here, previous calculations resulted in an unacceptable photino relic abundance. But we point out that processes other than photino self-annihilation determine the relic abundance when the photino and $R^0$ are close in mass. Including $R^0 \leftrightarrow \tilde{\gamma}$ processes, we find that the photino relic abundance is most sensitive to the $R^0$-to-$\tilde{\gamma}$ mass ratio, and within model uncertainties, a critical density in photinos may be obtained for an $R^0$-to-$\tilde{\gamma}$ mass ratio in the range 1.2 to 2.2. We propose photinos in the mass range of 500 MeV to 1.6 GeV as a dark matter candidate, and discuss a strategy to test the hypothesis.

I. INTRODUCTION

In this paper we study the early-Universe evolution and freeze out of light, long-lived or stable, $R$-odd states, the photino $\tilde{\gamma}$ and the gluino $\tilde{g}$. In the type of models we consider, the photino should be the relic $R$-odd particle, even though it may be more massive than the gluino. This is because below the confinement transition the gluino is bound into a color-singlet hadron, the $R^0$, whose mass (which is in the 1 to 2 GeV range when the gluino is very light [1,2]) is greater than that of the photino. Including previously neglected reactions associated with the gluino (more precisely, associated with the $R^0$), we find that light photinos may be cosmologically acceptable; indeed they are an attractive dark-matter candidate.

In the minimal susy model, the mass matrix of the charged and neutral susy fermions (gauginos and Higgsinos) are determined by Lagrangian terms involving the Higgs chiral superfields, $\tilde{H}_1$ and $\tilde{H}_2$, and the SU(2) and U(1) gauge superfields, $\tilde{W}^a$ and $\tilde{B}$, plus soft supersymmetry breaking terms. This leads to a neutralino mass matrix in the basis $(\tilde{B}, \tilde{W}^3, \tilde{H}_1^0, \tilde{H}_2^0)$ of the form

$$
\begin{pmatrix}
M_1 & 0 & -m_Z \cos \beta \sin \theta_W & m_Z \sin \beta \sin \theta_W \\
0 & M_2 & m_Z \cos \beta \cos \theta_W & -m_Z \sin \beta \cos \theta_W \\
-m_Z \cos \beta \sin \theta_W & m_Z \cos \beta \cos \theta_W & 0 & -\mu \\
m_Z \sin \beta \sin \theta_W & -m_Z \sin \beta \cos \theta_W & -\mu & 0
\end{pmatrix}
$$

(1)

Here $m_Z$ is the mass of the $Z$-boson, $\theta_W$ is the Weinberg angle, $\mu$ is the coefficient of a supersymmetric mixing term between the Higgs superfields, and $\tan \beta$ is the ratio of the vacuum expectation values of the two Higgs fields responsible for electroweak symmetry breaking. The susy-breaking masses $M_1$ and $M_2$ are commonly assumed to

---

1$R$-parity is a multiplicative quantum number, exactly conserved in most susy models, under which ordinary particles have $R = +1$ while new “superpartners” have $R = -1$. Throughout this paper we will assume that $R$-parity is exact so the lightest $R$-odd particle is stable.
be of order $m_Z$ or larger, and if the SUSY model is embedded in a grand unified theory, then $3M_1/M_2 = 5\alpha_1/\alpha_2$.

The terms in the Lagrangian proportional to $M_1$ and $M_2$ arise from dimension-3 SUSY-breaking operators. However such SUSY-breaking terms are not without problems. It appears difficult to break SUSY dynamically in a way that produces dimension-3 terms while avoiding problems associated with the addition of gauge-singlet superfields \[\] In models where SUSY is broken dynamically or spontaneously in the hidden sector and there are no gauge singlets, all dimension-3 SUSY-breaking operators in the effective low-energy theory are suppressed by a factor of $\langle \Phi \rangle/m_{PL}$, where $\langle \Phi \rangle$ is the vacuum expectation value of some hidden-sector field. Thus, dimension-3 terms effectively do not contribute to the neutralino mass matrix. This would imply that at the tree level the gluino is massless, and the neutralino mass matrix is given by Eq. (1) with vanishing (00) and (11) entries. However, a non-zero gluino mass, as well as non-zero entries in the neutralino mass matrix are generated through radiative corrections such as the top-stop loop, and for the neutralinos, “electroweak” loops involving higgsinos and/or winos and binos.

The generation of radiative gaugino masses in the absence of dimension-3 SUSY breaking was studied by Farrar and Masiero \[\] From Figs. 4 and 5 of that paper one sees that as $M_0$, the typical SUSY-breaking scalar mass, varies between 100 and 400 GeV, the gluino mass ranges from about 700 to about 100 MeV\[\] while the photino mass ranges\[\]

2See also \[\] for general formulae. Earlier studies \[\] of radiative corrections when tree level gaugino masses are absent included another dimension-3 operator, the so-called “A term,” and did not consider the electroweak loop contributions to the neutralino mass matrix. They also assumed model-dependent relations between parameters.

3Actually, larger values of $M_0$ are not considered in order to keep the gluino mass greater than about 100 MeV. Otherwise an unacceptably light pseudoscalar meson would be produced \[\].

4Upon diagonalization of the mass matrix, the physical neutralino states are a linear combination of $\tilde{B}^0$, $\tilde{W}^3$, $\tilde{H}_1^0$, and $\tilde{H}_2^0$. When the gaugino submatrix elements are small, the lightest neutralino is
from around 400 to 900 MeV, for \( \mu \gtrsim 40 \) GeV. This estimate for the photino mass should be considered as merely indicative of its possible value, since an approximation for the electroweak loop used in Ref. \[4\] is strictly valid only when \( \mu \) or \( M_0 \) are much larger than \( m_W \). The other neutralinos are much heavier, and the production rates of the photino and the next-lightest neutralino in \( Z^0 \) decay are consistent with LEP bounds \[4\].

Using the results of Ref. \[4\], but additionally restricting parameters so that the correct electroweak symmetry breaking is obtained, Farrar \[2\] found \( M_0 \sim 150 \) GeV and estimated the \( R^0 \) lifetime. This allowed completion of the study of the main phenomenological features of this scenario, which was begun in Ref. \[1\]. The conclusion is that light gluinos and photinos are quite consistent with present experiments, and result in a number of striking predictions \[2\]. However models with light gauginos have been widely thought to be disallowed because it has been believed that the relic density of the lightest neutralino, usually referred to as the \text{LSP}, exceeds cosmological bounds unless \( R \)-parity is violated \[8–9\].

In this paper we point out that previous considerations of the relic abundance have neglected the rather important interplay between the photino and the gluino which can determine the final neutralino abundance if the photino and gluino are both light, as they must be in models without dimension-3 explicit \text{susy}-breaking terms. We find that when gluino–photino interactions are included, rather than being a cosmological embarrassment, these very light photinos are an excellent dark matter candidate. In this paper we discuss the decoupling and relic abundance of light photinos, and the sensitivity of the result upon the parameters of the \text{susy} models.

\[ a \text{ linear combination of } \tilde{W}^3 \text{ and } \tilde{B}^0 \text{ that is almost identical to the } SU(2) \times U(1) \text{ composition of the photon, and thus is correctly called “photino.”} \]

\[ ^5 \text{In this scenario, LSP is an ambiguous term: the gluino is lighter than the photino, although the photino is lighter than the } R^0. \text{ A more relevant term would be LRÖCS—lightest } R \text{-odd color singlet.} \]
For the light masses studied here, freeze-out occurs well after the confinement transition so the physical states must be color singlets. Since $\tilde{g}$ is not a color singlet, below the confinement transition the relevant state to consider is the lightest color-singlet state containing a gluino, which is believed to be a gluon-gluino bound state known as the $R^0$. The other light $R$-odd states are more massive than these, and decay to the two light ones with lifetimes much faster than the expansion rate at freeze out. The only other possible state of interest is the $S^0$, which is the lightest $R$-odd baryon, consisting of the color-singlet, flavor-singlet state $uds\tilde{g}$ [12]. The masses for the states we consider will be assumed to be in the range [24]

$$
\begin{align*}
\tilde{g} & (\text{gluino}) : \quad m_{\tilde{g}} = 100 - 600 \text{ MeV} \\
\tilde{\gamma} & (\text{photino}) : \quad m = 100 \text{ MeV} - 1400 \text{ MeV} \\
R^0(\tilde{g}\tilde{g}) & : \quad M = 1 - 2 \text{ GeV} \\
S^0(uds\tilde{g}) & : \quad M_{S^0} = 1.5 - 2 \text{ GeV}. 
\end{align*}
$$

(2)

Since it is the lightest color-singlet $R$-odd state, the $\tilde{\gamma}$ is stable, and $R^0$ decays to a final state consisting of a photino and typically one meson: $R^0 \rightarrow \tilde{\gamma}\pi; \tilde{\gamma}\eta$, etc. The lifetime is very uncertain, but probably lies in the range $10^{-4}$ to $10^{-10}$s, or even longer [2].

The reaction rates that determine freeze out will depend upon the $\tilde{\gamma}$ and $R^0$ masses, the cross sections involving the $\tilde{\gamma}$ and $R^0$, and possibly the decay width of the $R^0$ as well. In turn the cross sections and decay width also depend on the masses of the $\tilde{\gamma}$, $\tilde{g}$ and $R^0$, as well as the masses of the squarks and sleptons. We will denote the squark/slepton masses by a common mass scale $M_{\tilde{S}}$ (expected to be of order 100 GeV). Even if the masses were known and the short-distance physics specified, calculation of the width and some of the cross sections would be no easy task, because one is dealing with light hadrons. Fortunately, our conclusions are reasonably insensitive to individual masses, lifetimes, and cross sections, but depend crucially upon the $R^0$-to-$\tilde{\gamma}$ mass ratio.
When we do need an explicit value of the photino mass $m$ or the masses of squarks and sleptons, we will parameterize them by the dimensionless ratios

$$\mu_8 \equiv \frac{m}{800 \text{ MeV}}; \quad \mu_S \equiv \frac{M_{\tilde{\gamma}}}{100 \text{ GeV}}.$$  

(3)

Although there are several undetermined parameters in our calculation, as mentioned above, the most important parameter will be the ratio of the $R^0$ mass to the $\tilde{\gamma}$ mass:

$$r \equiv \frac{M}{m}.$$  

(4)

This is by far the most crucial parameter, with the relic abundance having an exponential dependence upon $r$. We find that limits to the magnitude of the contribution to the present mass density from relic photinos requires $r \lesssim 2.2$ while $r$ must be larger than about 1.2 if the photino relic density is to be significant. This narrow band of $r$ encompasses the large uncertainties in lifetimes and cross sections. If the mass ratio is between about 1.6 and 2, then light-mass relic photinos could dominate the Universe and provide the dark matter with $\Omega_{\tilde{\gamma}} \sim 1$.

In the concluding section we explore the proposal that light photinos are the dark matter, and discuss possibilities for testing the idea. We lay the groundwork for this suggestion in the next section as we develop a new scenario for decoupling and freeze-out for the photinos and gluinos. In Section III we consider the cross sections and lifetimes used in Section IV to calculate the reaction rates relevant for the determination of the freeze-out abundance of the photinos (and hence $\Omega_{\tilde{\gamma}} h^2$). In Section V we compare the reaction rates to the expansion rate and estimate when photinos decouple.

---

6Or else $R$-parity must be violated so the photinos decay.
II. SCENARIO FOR PHOTINO/GLUINO FREEZE OUT

The standard procedure for the calculation of the present number density of a thermal relic of the early-Universe is to assume that the particle species was once in thermal equilibrium until at some point the rates for self-annihilation and pair-creation processes became much smaller than the expansion rate, and the particle species effectively froze out of equilibrium. After freeze out, its number density decreased only because of the dilution due to the expansion of the Universe. (For a discussion, see Ref. [11].)

Since subsequent to freeze out the number of particles in a co-moving volume is constant, it is convenient to express the number density of the particle species in terms of the entropy density, since the entropy in a co-moving volume is also constant for most of the history of the Universe. The number density-to-entropy ratio is usually denoted by $Y$. If a species of mass $m$ is in equilibrium and non-relativistic, $Y$ is simply given in terms of the mass-to-temperature ratio $x \equiv m/T$ as

$$Y_{EQ}(x) = 0.145(g/g_*)x^{3/2} \exp(-x),$$

where $g$ is the number of spin degrees of freedom, and $g_*$ is the total number of relativistic degrees of freedom in the Universe at temperature $T = m/x$. Well after freeze-out $Y(x)$ is constant, and we will denote this asymptotic value of $Y$ as $Y_\infty$.

If self annihilation determines the final abundance of a species, $Y_\infty$ can be found by integrating the Boltzmann equation (dot denotes $d/dt$)

$$\dot{n} + 3Hn = -\langle |v|\sigma_A \rangle \left(n^2 - n_{EQ}^2\right),$$

where $n$ is the actual number density, $n_{EQ}$ is the equilibrium density, $H$ is the expansion rate of the Universe, and $\langle |v|\sigma_A \rangle$ is the thermal average of the annihilation rate.

There are no general closed-form solutions to the Boltzmann equation, but there are reliable, well tested approximations for the late-time solution, i.e., $Y_\infty$. Then with
knowledge of $Y_\infty$, the contribution to $\Omega h^2$ from the species can easily be found. Let us specialize to the survival of photinos assuming self-annihilation determines freeze out.

Calculation of the relic abundance involves first calculating the value of $x$, known as $x_f$, where the abundance starts to depart from the equilibrium abundance. Using standard approximate solutions to the Boltzmann equation [11] gives

$$x_f = \ln(0.0481m_p m \sigma_0) - 1.5 \ln[\ln(0.0481m_p m \sigma_0)],$$

where we have used $g = 2$ and $g_* = 10$, and parameterized the non-relativistic annihilation cross section as $\langle |v| \sigma_A \rangle = \sigma_0 x^{-1}$. In anticipation of the results of the next section, we use $\sigma_0 = 2 \times 10^{-11} \mu_8^2 \mu_4^{-4} \text{mb}$, and we find $x_f \simeq 12.3 + \ln(\mu_8^3/\mu_4^4)$. The value of $x_f$ determines $Y_\infty$:

$$Y_\infty = \frac{2.4 x_f^2}{m_p m \sigma_0} \simeq 7.4 \times 10^{-7} \mu_8^{-3} \mu_4^4.$$ (8)

Once $Y_\infty$ is known, the present photino energy density can be easily calculated:

$$\rho_\gamma = m n_\gamma = 0.8 \mu_8 \text{GeV} \cdot Y_\infty 2970 \text{cm}^{-3}.$$ When this result is divided by the critical density, $\rho_C = 1.054 h^2 \times 10^{-5} \text{GeV cm}^{-3}$, the fraction of the critical density contributed by the photino is $\Omega_\gamma h^2 = 2.25 \times 10^8 \mu_8 Y_\infty$. For $Y_\infty$ in Eq. (8), $\Omega_\gamma h^2 = 167 \mu_8^{-2} \mu_4^4$.

The age of the Universe restricts $\Omega_\gamma h^2$ to be less than one, so for $\mu_S = 1$, the photino must be more massive than about 10 GeV if its relic abundance is determined by self-annihilation.

But in this paper we point out that for models in which both the photino and the gluino are light, freeze-out is not determined by photino self annihilation, but by $\tilde{\gamma} - R^0$ interconversion. The basic point is that since the $R^0$ has strong interactions, it will stay in equilibrium longer than the photino, even though it is more massive. As long

\footnote{Freeze-out aficionados will notice that we use the formulae appropriate for $p$-wave annihilation because Fermi statistics requires the initial identical Majorana fermions to be in an $L = 1$ state.}
as $\tilde{\gamma} \leftrightarrow R^0$ interconversion occurs at a rate larger than $H$, then through its interactions with the $R^0$ the photino will be able to maintain its equilibrium abundance even after self-annihilation has frozen out.\footnote{Actually, interconversion can also play an important role in determining the relic abundance of heavier photinos. When the photino is more massive and freeze-out occurs above the confinement phase transition, the analysis is similar to the one here; in fact simpler because perturbation theory can be used to compute the relevant rates involving gluinos and photinos. Since the qualitative relation between interconversion and self-annihilation rates is independent of whether the gluino is free or confined in an $R^0$, one can get a crude idea of the required gluino-photino mass ratio, $r$, just by using the analysis in this paper and scaling the results to the value of $\mu_8$ of interest. We concentrate on the light gaugino scenario because it is attractive in its own right, and also because it \emph{naturally} produces $r$ in the right ballpark.}

Before we demonstrate that this scenario naturally occurs for the types of photino and $R^0$ masses expected, we must determine the cross sections and decay width of the reactions involving the photino and the gluino.

**III. CROSS SECTIONS AND DECAY WIDTH**

In this section we characterize the cross sections and decay width required for the determination of the relic photino abundance, and also discuss the uncertainties. We should emphasize that all cross sections are calculated in the non-relativistic (N.R.) limit, and by $\langle \cdots \rangle$ we imply that the quantity is to be evaluated as a thermal average \cite{12,13}. In the N.R. limit a temperature dependence to the cross sections enters if the annihilation proceeds through a $p$-wave, as required if the initial state consists of identical fermions \cite{8}. For $p$-wave annihilation, at low energy the cross section is proportional to $v^2$, where $|v|$ is the relative velocity of the initial particles. The thermal average reduces

---

8 Actually, interconversion can also play an important role in determining the relic abundance of heavier photinos. When the photino is more massive and freeze-out occurs above the confinement phase transition, the analysis is similar to the one here; in fact simpler because perturbation theory can be used to compute the relevant rates involving gluinos and photinos. Since the qualitative relation between interconversion and self-annihilation rates is independent of whether the gluino is free or confined in an $R^0$, one can get a crude idea of the required gluino-photino mass ratio, $r$, just by using the analysis in this paper and scaling the results to the value of $\mu_8$ of interest. We concentrate on the light gaugino scenario because it is attractive in its own right, and also because it \emph{naturally} produces $r$ in the right ballpark. In a conventional SUSY-breaking scheme fine-tuning is generally necessary to give $r$ the right value for the interconversion mechanism to play an important role.
to replacing $v^2$ by $6T/m$, where $m$ is the mass of the particle in the initial state.

We now consider in turn the cross sections and width for the individual reactions discussed in the previous section.

A. Self-annihilations and co-annihilation

The first type of reactions we will consider are those which change the number of $R$-odd particles.

$R^0 R^0 \rightarrow X$: We will refer to this process as $R^0$ self-annihilation. At the constituent level the relevant reactions are $\tilde{g} + \tilde{g} \rightarrow g + g$ and $\tilde{g} + \tilde{g} \rightarrow q + \bar{q}$, which are unsuppressed by any powers of $M_\tilde{S}$, and should be typical of strong interaction cross sections. In the N.R. limit, we expect the $R^0 R^0$ annihilation cross section to be comparable to the $\bar{p}p$ cross section, but with an extra factor of $v^2$, accounting for the fact that there are identical fermions in the initial state, so annihilation must proceed through a $p$-wave. There is some energy dependence to the $\bar{p}p$ cross section, but it is sufficient to consider $\langle |v|\sigma_{R^0 R^0} \rangle$ to be a constant, approximately given by

$$\langle |v|\sigma_{R^0 R^0} \rangle \simeq 100 v^2 \text{mb} = 600 x^{-1} r^{-1} \text{mb}, \quad (9)$$

where we have used for the relative velocity $v^2 = 6T/M = 6/(rx)$, with $x \equiv m/T$.

We should note that the thermal average of the cross section might be even larger if there are resonances near threshold. In any case, this cross section should be much larger than any cross section involving the photino, and will ensure that the $R^0$ remains in equilibrium longer than the $\tilde{\gamma}$, greatly simplifying our considerations.

$\tilde{\gamma}\tilde{\gamma} \rightarrow X$: In photino self-annihilation at low energies the final state $X$ is a lepton-

9In general the result is not so simple. For instance, in addition to the term proportional to $v^2$, the cross section also involves a term proportional to the square of the masses of the initial and final particles.
antilepton pair, or a quark-antiquark pair which appears as light mesons. The process involves the $t$-channel exchange of a virtual squark or slepton between the photinos, producing the final-state fermion-antifermion pair. In the low-energy limit the mass $M_\tilde{S}$ of the squark/slepton is much greater than $\sqrt{s}$, and the photino-photino-fermion-antifermion operator appears in the low-energy theory with a coefficient proportional to $e_i^2/M_\tilde{S}^2$, with $e_i$ the charge of the final-state fermion. Also, as there are two identical fermions in the initial state, the annihilation proceeds as a $p$-wave, which introduces a factor of $v^2$ in the low-energy cross section. The resultant low-energy photino self-annihilation cross section is:

$$\langle |v| \sigma \tilde{\gamma}_R \rangle = 8\pi \alpha_{EM}^2 \sum_i q_i^4 \frac{m_i^2}{M_\tilde{S}^4} \frac{v^2}{3} \simeq 2.0 \times 10^{-11} \frac{1}{x^2} \left[ \mu_\tilde{S}^2 \mu_\tilde{S}^{-4} \right] \frac{mb}{v^2},$$

(10)

where we have used for the relative velocity $v^2 = 6/x$ with $x = m/T$, and $q_i$ is the magnitude of the charge of a final-state fermion in units of the electron charge. For the light photinos we consider, summing over $e$, $\mu$, and three colors of $u$, $d$, and $s$ quarks leads to $\sum_i q_i^4 = 8/3$.

$\tilde{\gamma}R^0 \to X$: This is an example of a phenomenon known as co-annihilation, whereby the particle of interest (in our case the photino) disappears by annihilating with another particle (here, the $R^0$). Of course co-annihilation also leads to a net decrease in $R$-odd particles.

In all processes involving the photino-$R^0$ interaction, the leading tree-level short-distance operator containing $\tilde{g} \tilde{\gamma}$ is $\lambda^\dagger \lambda \gamma_i q_i q_i + h.c.$, with coefficient $e_i g_s/M_\tilde{S}^2$. For three light quarks, $\sum_i q_i^2 = 2$. Thus we can estimate the cross section for $\tilde{\gamma}R^0 \to X$ in terms of the $\tilde{\gamma}$ self annihilation cross section:

$$\langle |v| \sigma_{\tilde{\gamma}R^0} \rangle \simeq \frac{\alpha_S}{\alpha_{EM}} \frac{4}{3} \frac{2}{8/3} \frac{M}{m} \frac{3}{v^2} \langle |v| \sigma_{\tilde{\gamma} \tilde{\gamma}} \rangle,$$

(11)

$^{10}$The electric charge $e$ and the strong charge $g_s$ are to be evaluated at a scale of order $M_\tilde{S}$, so in numerical estimates we use $\alpha_{EM} = 1/128$ and $\alpha_S = 0.117$. 

10
where the ratio of $\alpha$'s arises because the short-distance operator for co-annihilation is proportional to $e_1^2 g_5^2$ rather than $e_1^4$, the second factor is the color factor coming from the gluino coupling, and the third factor comes from the ratio of $\sum_i q_i^2 / \sum_i q_i^4$ for the participating fermions. We have replaced $m^2$ appearing in Eq. (10) by $mM$, although the actual dependence on $m$ and $M$ may be more complicated. Finally, the annihilation is $s$-wave so there is no $v^2/3$ suppression as in photino self-annihilation.

Although the short-distance physics is perturbative, the initial gluino appears in a light hadron, and there are complications in the momentum fraction of the $R^0$ carried by the gluino and other non-perturbative effects. For our purposes it will be sufficient to account for the uncertainty by including in the cross section an unknown coefficient $A$, leading to a final expression

$$\langle |v| \sigma_{\tilde{\gamma}R^0} \rangle \simeq 1.5 \times 10^{-10} \times \mu_{\tilde{S}}^2 \mu_{\tilde{\gamma}}^4 A \text{ mb.}$$

It is reassuring that if one estimates $\langle |v| \sigma_{\tilde{\gamma}R^0} \rangle$ starting from $\langle |v| \sigma_{R^0 R^0} \rangle$ a similar result is obtained. We find that co-annihilation will not be important unless $A$ is larger than $10^2$ or so, which we believe is unlikely.

### B. $\tilde{\gamma}-R^0$ interconversion

In what we call interconversion processes, there is an $R$-odd particle in the initial as well as the final state. Although the reactions do not of themselves change the number of $R$-odd particles, they keep the photinos in equilibrium with the $R^0$s, which in turn are kept in equilibrium through their self annihilations.

$R^0 \rightarrow \tilde{\gamma}\pi$: $R^0$ decay can occur via, e.g., the gluino inside the initial $R^0$ turning into an antiquark and a virtual squark, followed by squark decay into a photino and a quark. In the low-energy limit the quark–antiquark–gluino–photino vertex can be described by the same type of four-Fermi interaction as in co-annihilation. One expects on dimensional
grounds a decay width $\Gamma_0 \propto \alpha_{EM} \alpha_S M^5/M^4_S$. The lifetime of a free gluino to decay to a photino and massless quark-antiquark pair was computed in Ref. [10]. However this does not provide a very useful estimate when the gluino mass is less than the photino mass.

The lifetime for $R^0$ decay was studied in Ref. [2]. In an attempt to account for the effects of gluino-gluon interactions in the $R^0$, necessary for even a crude estimate of the $R^0$ lifetime, the following picture was developed: The $R^0$ is viewed as a state with a massless gluon carrying momentum fraction $x$, and a gluino carrying momentum fraction $(1 - x)$ having therefore an effective mass $M \sqrt{1 - x}$. The gluon structure function $F(x)$ gives the probability in an interval $x$ to $x + dx$ of finding a gluon, and the corresponding effective mass for the gluino. One then obtains the $R^0$ decay width (neglecting the mass of final state hadrons):

$$\Gamma(M, r) = \Gamma_0(M, 0) \int_0^{1-r^2} dx \ (1 - x)^{5/2} F(x) \ f(1/r \sqrt{1 - x}),$$

(13)

where $\Gamma_0(M, 0)$ is the rate for a gluino of mass $M$ to decay to a massless photino, and $f(y) = [(1 - y^2)(1 + 2y - 7y^2 + 20y^3 - 7y^4 + 2y^5 + y^6) + 24y^3(1 - y + y^2) \log y]$ contains the phase space suppression which is important when the photino becomes massive in comparison to the gluino. Modeling $K^\pm$ decay in a similar manner underestimates the lifetime by a factor of 2 to 4. This is in surprisingly good agreement; however caution should be exercised when extending the model to $R^0$ decay, because kaon decay is much less sensitive to the phase-space suppression from the final state masses than the present case, since the range of interest will turn out to be $r \sim 1.2 - 2.2$. For $r$ in this range, taking $F(x) \sim 6x(1 - x)$ following the discussion in Ref. [3] leads to an approximate

\[11\] Of course there should be no confusion with the fact that in the discussion of the $R^0$ lifetime we use $x$ to denote the gluon momentum fraction whereas throughout the rest of the paper $x$ denotes $m/T$. 

12
behavior

\[ \Gamma_{R^0 \rightarrow \tilde{\gamma}\pi} = 2.0 \times 10^{-14} \mathcal{F}(r) \text{ GeV} \left[ \mu^5 S \mu^{-4} B \right], \]

where \( \mathcal{F}(r) = r^5(1 - r^{-1})^6 \), and the factor \( B \) reflects the overall uncertainty. We believe a reasonable range for \( B \) is \( 1/30 \lesssim B \lesssim 3 \).

\underline{R^0\pi \leftrightarrow \tilde{\gamma}\pi}: We will refer to these processes as photino-\( R^0 \) conversion, since an initial \( R^0 \) (or \( \tilde{\gamma} \)) is converted to a final \( \tilde{\gamma} \) (or \( R^0 \)). The short-distance subprocess in this reaction is \( q + \tilde{g} \rightarrow q + \tilde{\gamma} \), again described by the same low-energy effective operator as in co-annihilation and \( R^0 \) decay. At the hadronic level the matrix element for \( R^0\pi \rightarrow \tilde{\gamma}X \) is the same as for \( R^0\tilde{\gamma} \rightarrow \pi X \) for any \( X \), evaluated in different physical regions. Thus the difference between the various cross sections is just due to the difference in fluxes and final state phase space integrations, and variations of the matrix element with kinematic variables. Given the crude nature of the analysis here, and the great uncertainty in the overall magnitude of the cross sections, incorporating the constraints of crossing symmetry are not justified at present.

We can point to one specific hadronic effect which we do not include but which is potentially important. It is likely that near threshold there is a resonance (the \( R_\pi\)) which would increase the cross section by a factor of \( 4M^2_R/\Gamma^2_R \), where \( M_R \) is the mass and \( \Gamma_R \) the width of the resonance. This complicates matters because neither the resonance’s width nor its distance above threshold is known. If a resonance is important, it would also be necessary to perform the thermal average over the resonance in a more careful manner [13].

We will parameterize our uncertainty by including a factor \( C \) in the cross section to express the uncertainty due to hadronic physics and the possible existence of a resonance. Putting everything together, we obtain

\[ \langle |v|\sigma_{R^0\pi} \rangle \simeq 1.5 \times 10^{-10} \, r \left[ \mu^5 S \mu^{-4} C \right] \text{ mb.} \]
Table I: Cross sections and the decay width used in the calculation of the relic photino abundance.

The dimensionless parameters $\mu_8$ and $\mu_S$ were defined in Eq. (3), and $F(r)$ was discussed below Eq. (14). The coefficients $A$, $B$, and $C$ reflect uncertainties involving the calculation of hadronic matrix elements.

| Process                  | Cross section or width                      |
|--------------------------|---------------------------------------------|
| $R^0$ self annihilation: | $\langle |v|\sigma_{R^0 R^0} \rangle$ 600 $x^{-1} r^{-1}$ mb |
| $\tilde{\gamma}$ self annihilation: | $\langle |v|\sigma_{\tilde{\gamma} \tilde{\gamma}} \rangle$ $2.0 \times 10^{-11}$ $x^{-1}$ $[\mu_8^2 \mu_S^{-4}]$ mb |
| co-annihilation:         | $\langle |v|\sigma_{\tilde{\gamma} R^0} \rangle$ $1.5 \times 10^{-10} r [\mu_8^2 \mu_S^{-4} A]$ mb |
| $R^0$ decay:             | $\Gamma_{R^0 \to \tilde{\gamma}\pi}$ $2.0 \times 10^{-14} F(r) [\mu_8^2 \mu_S^{-4} B]$ GeV |
| $\tilde{\gamma} - R^0$ conversion: | $\langle |v|\sigma_{\tilde{\gamma} R^0 \pi} \rangle$ $1.5 \times 10^{-10} r [\mu_8^2 \mu_S^{-4} C]$ mb |

We would expect $C$ to fall in the range $1 \lesssim C \lesssim 10^3$. We will use detailed balance arguments which allow us to avoid using the inverse reaction, $\tilde{\gamma}\pi \rightarrow R^0\pi$.

This completes the discussion of the lifetimes, cross sections, and their uncertainties. The results are summarized in Table I.

IV. EARLY-UNIVERSE REACTION RATES

To obtain an estimate of when the rates will drop below the expansion rate, we will assume all particles are in LTE (local thermodynamic equilibrium). In LTE a particle of mass $m$ in the N.R. limit has a number density

$$n = \frac{g}{(2\pi)^{3/2}} (mT)^{3/2} \exp(-m/T) = \frac{g}{(2\pi)^{3/2}} (T/m)^{3/2} m^3 \exp(-m/T).$$

(16)

Here $g$ counts the number of spin degrees of freedom, and will be 2 for the $R^0$ and the $\tilde{\gamma}$.

$H$ (the expansion rate): Of course all rates are to be compared with the expansion rate. In the radiation-dominated Universe with $g_* \sim 10$ degrees of freedom

$$H = 1.66 g_*^{1/2} T^2 / m_{Pl} = 2.8 \times 10^{-19} x^{-2} [\mu_8^2] \text{ GeV}. $$

(17)
\( \tilde{\gamma} \tilde{\gamma} \to X \) (photino self-annihilation): In the Boltzmann equation for the evolution of the photino number density there are terms accounting for photino self-annihilation and photino pair-production from light particles in the plasma. Assuming the light annihilation products are in LTE, the terms are of the form

\[
\dot{n}_{\tilde{\gamma}} + 3Hn_{\tilde{\gamma}} \supset -\langle |v|\sigma_{\tilde{\gamma}\tilde{\gamma}} \rangle \left[ \left( n_{\tilde{\gamma}} \right)^2 - \left( n_{\tilde{\gamma}}^{EQ} \right)^2 \right].
\]  

(18)

If we assume that the photino is in equilibrium, the self-annihilation and pair production terms are equal, and we may express the individual terms in the form

\[
\dot{n}_{\tilde{\gamma}} \supset -3Hn_{\tilde{\gamma}} \mp \left[ \langle |v|\sigma_{\tilde{\gamma}\tilde{\gamma}} \rangle n_{\tilde{\gamma}}^{EQ} \right] n_{\tilde{\gamma}}^{EQ},
\]  

(19)

where the upper sign is for self-annihilation and the lower sign is for pair production.

It is obvious that \( \left[ n_{\tilde{\gamma}}^{EQ} \langle |v|\sigma_{\tilde{\gamma}\tilde{\gamma}} \rangle \right] \) plays the role of a “rate” to be compared to \( H \). If this rate is much greater than \( H \), the self-annihilation/pair-production processes will ensure the photino is in equilibrium, while if the rate is much smaller than \( H \), self-annihilation/pair-production cannot enforce equilibrium.

Therefore we define an equilibrium photino annihilation rate by \( \Gamma(\tilde{\gamma} \tilde{\gamma} \to X) = n_{\tilde{\gamma}}^{EQ} \langle |v|\sigma_{\tilde{\gamma}\tilde{\gamma}} \rangle \). Using Eq. (16) for the equilibrium abundance and the annihilation cross section discussed in the previous section, we find

\[
\Gamma(\tilde{\gamma} \tilde{\gamma} \to X) = \frac{2}{(2\pi)^{3/2}} \left( \frac{T}{m} \right)^{3/2} m^3 \exp(-m/T) \frac{2.0 \times 10^{-11} \text{mb}}{0.39 \text{mb GeV}^2} x^{-1} \left[ \mu_S^2 \mu_S^{-4} \right]
\]  

\[
= 3.3 \times 10^{-12} x^{-5/2} \exp(-x) \left[ \mu_S^5 \mu_S^{-4} \right] \text{ GeV.}
\]  

(20)

\( R^0 R^0 \to X \) (\( R^0 \) self-annihilation): Determination of the equilibrium rate for \( R^0 \)-self-annihilation proceeds in a similar manner, yielding \( \Gamma(R^0 R^0 \to X) = n_{R^0}^{EQ} \langle |v|\sigma_{R^0 R^0} \rangle \):

\[
\Gamma(R^0 R^0 \to X) = \frac{2}{(2\pi)^{3/2}} \left( \frac{T}{M} \right)^{3/2} M^3 \exp(-M/T) \frac{240 \ x^{-1} r^{-1} \text{mb}}{0.4 \text{mb GeV}^2}
\]  

\[
= 99 \ r^{1/2} x^{-5/2} \exp(-r x) \left[ \mu_S^3 \right] \text{ GeV.}
\]  

(21)
\[ \bar{\gamma} R^0 \rightarrow X \ (\bar{\gamma} \ co-annihilation): \] In the Boltzmann equation for the evolution of the \( \bar{\gamma} \) density will appear a term \(-n_{R^0} n_{\bar{\gamma}} \langle |v| \sigma_{\bar{\gamma} R^0} \rangle \). Therefore the equilibrium co-annihilation rate for the decrease of the \( \bar{\gamma} \) density is

\[
\Gamma(\bar{\gamma} R^0 \rightarrow X) = n_{R^0}^{EQ} \langle |v| \sigma_{\bar{\gamma} R^0} \rangle = 2.5 \times 10^{-11} \ r^{5/2} \ x^{-3/2} \ \exp(-r x) \ [\mu_{\bar{\gamma}}^5 \mu_S^{-4}] ,
\]

(22)

where we have again assumed the particles in the process are in equilibrium.

\[ \bar{\gamma} \pi \rightarrow R^0 \ (Inverse \ decay): \] If the \( R^0 \) decay products (in this case \( \bar{\gamma} \) and \( \pi \)) are in equilibrium, then the Boltzmann equation for the evolution of \( R^0 \) contains a term

\[
\dot{n}_{R^0} + 3H n_{R^0} \supset -\Gamma_{R^0 \rightarrow \bar{\gamma} \pi} \left( n_{R^0} - n_{R^0}^{EQ} \right) .
\]

(23)

The first term on the rhs represents decay, while the second term represents “inverse decay.” Since inverse decay turns a \( \bar{\gamma} \) into a \( R^0 \), there will be an “inverse decay” term in the equation for the evolution of the \( \bar{\gamma} \) number density:

\[
\dot{n}_{\bar{\gamma}} + 3H n_{\bar{\gamma}} \supset -\Gamma_{R^0 \rightarrow \bar{\gamma} \pi} n_{R^0}^{EQ} .
\]

(24)

The right hand side can be written as \( n_{\bar{\gamma}}^{EQ} (n_{R^0}^{EQ} / n_{\bar{\gamma}}^{EQ}) \) \( \Gamma_{R^0 \rightarrow \bar{\gamma} \pi} \). Therefore the inverse decay rate in the evolution of the photino number density contributes a term

\[
\Gamma(\bar{\gamma} \pi \rightarrow R^0) = \Gamma_{R^0 \rightarrow \bar{\gamma} \pi} (n_{R^0}^{EQ} / n_{\bar{\gamma}}^{EQ}) = \Gamma_{R^0 \rightarrow \bar{\gamma} \pi} \left( \frac{M}{m} \right) ^{3/2} \ \exp[-(M - m)/T] \]

\[
= 2.0 \times 10^{-14} \ r^{3/2} \ \mathcal{F}(r) \ \exp[-(r - 1)x] \ [\mu_{\bar{\gamma}}^5 \mu_S^{-4} B] \ \text{GeV} .
\]

(25)

\[ \bar{\gamma} \pi \rightarrow R^0 \pi \ (photino-\ R^0 \ conversion): \] It is easiest to obtain this term by first considering the term in the equation for \( \dot{n}_{R^0} \) due to the reverse process and then using detailed balance:

\[
\dot{n}_{R^0} \supset -n_{\pi} n_{R^0} \langle |v| \sigma_{R^0 \pi} \rangle .
\]

(26)
Table II: The ratio of the equilibrium reaction rates to the expansion rate for the indicated reactions. Shown in [···] is the scaling of the rates with unknown parameters characterizing the cross sections and decay width.

| Process                | $\Gamma/H$                                                                 |
|------------------------|---------------------------------------------------------------------------|
| $\tilde{\gamma}$ self annihilation | $2.7 \times 10^{7} x^{-1/2} \exp(-x)$ [µs$^{-1}$]                        |
| $R^0$ self annihilation | $3.5 \times 10^{30} x^{-1/2} r^{1/2} \exp(-rx)$ [µs$^{-1}$]              |
| co-annihilation        | $8.9 \times 10^{7} x^{1/2} r^{5/2} \exp(-rx)$ [µs$^{-1}$]               |
| inverse decay          | $7.1 \times 10^{4} x^{2} r^{3/2} \mathcal{F}(r) \exp[-(r-1)x]$ [µs$^{-1}$] |
| $\tilde{\gamma} - R^0$ conversion | $9.6 \times 10^{6} x^{1/2} r^{5/2} \exp[-(r-1)x] \exp(-0.175\mu_s^{-1})$ [µs$^{-1}$] |

Since the photino-$R^0$ conversion process creates a $\tilde{\gamma}$ there is a similar term in $\dot{n}_{\tilde{\gamma}}$ with the opposite sign. Now we can write this in a form to calculate the rate for $\tilde{\gamma}$ annihilation by

$$
\dot{n}_{\tilde{\gamma}} \supset -\dot{n}_{R^0} = n_{\pi} n_{R^0} \langle |v| \sigma_{R^0\pi} \rangle = \left[ \frac{n_{\pi} n_{R^0}}{n_{\tilde{\gamma}}} \langle |v| \sigma_{R^0\pi} \rangle \right] n_{\tilde{\gamma}} .
$$

(27)

Assuming equilibrium as before, the rate keeping the $\tilde{\gamma}$ in equilibrium can be expressed as

$$
\Gamma(\tilde{\gamma} \pi \rightarrow R^0 \pi) = \frac{n_{R^0}}{n_{\tilde{\gamma}}} n_{\pi} \langle |v| \sigma_{R^0\pi} \rangle
$$

$$
= 2.7 \times 10^{-12} r^{5/2} x^{-3/2} \exp(-0.175\mu_s^{-1}x) \times \exp[-(r-1)x] \mu_s^{7/2} \mu_S^{-4} C .
$$

(28)

Of course it is the ratio of the reaction rates to the expansion rate that will be used to estimate photino freeze out. These ratios are given in Table II.

There are two striking features apparent when comparing the magnitudes of the equilibrium reaction rates in Table II. The first feature is that the numerical factor in $R^0$ self annihilation is enormous in comparison to the other numerical factors. This simply
reflects the fact that $R^0$ annihilation proceeds through a strong process, while the other processes are all suppressed by a factor of $M_\tilde{S}^{-4}$.

The other important feature is the exponential factors of the rates. They will largely determine when the photino will decouple, so it is worthwhile to examine them in detail.

The exponential factor in $\tilde{\gamma}$ self-annihilation is simply $e^{-m/T}$, which arises from the equilibrium abundance of the $\tilde{\gamma}$. It is simple to understand: the probability of one $\tilde{\gamma}$ to find another $\tilde{\gamma}$ with which to annihilate is proportional to the photino density, which contains a factor of $e^{-m/T}$ in the N.R. limit.

The similar exponential factor in $R^0$ self-annihilation is also easy to understand. An $R^0$ must find another $R^0$ to annihilate, and that probability is proportional to $e^{-M/T} = e^{-rx}$.

Co-annihilation is also an exothermic process, so the only exponential suppression is the probability of a $\tilde{\gamma}$ locating the $R^0$ for co-annihilation, proportional to the equilibrium number density of $R^0$, in turn proportional to $e^{-M/T} = e^{-rx}$.

In inverse-decay the exponential factor is $e^{-(r-1)x} = e^{-(M-m)/T}$. The number density of target pions is $e^{-m\pi/T}$, so this factor is present. It is necessary for the $\pi-\tilde{\gamma}$ collision to have sufficient center-of-mass energy to create the $R^0$. This introduces an additional suppression of $e^{-(M-m-m\pi)/T}$. Combining the two exponential factors gives the result in Table II.

Finally, photino-gluino conversion involves two exponential suppression factors. The first, $e^{-m_{\pi}/T} = e^{-0.175\mu_8^{-1}x}$ represents the suppression in the pion number density\[12\] and since the mass of the $R^0$ is greater than the mass of the $\tilde{\gamma}$, there is an additional $e^{-(M-m)/T}$ suppression.

The factors of $x$ and $r$ originate from three places: a factor of $x^2$ comes from dividing

\[12\] At the temperatures of interest for decoupling, pions might be cheap, but they are not free.
Fig. 1: Equilibrium reaction rates divided by $H$ for $r = 1.25$ and $1.5$, assuming $\mu_S = \mu_S = 1$, and that the factors $A = B = C = 1$. The rates can be easily scaled for other choices of the parameters.
Fig. 2: The same as Fig. 1, but for $r = 1.75$ and 2.
the rates by $H$, factors of $r$ and $x$ arise for pre-exponential factors in the number density, and finally they may appear explicitly in the cross section or decay width.

The equilibrium reaction rates divided by $H$ are shown in Figs. 1 and 2 for $r = 1.25, 1.5, 1.75, \text{ and } 2$. In the figures we have assumed $\mu_s = \mu_S = A = B = C = 1$. Using the information in Table II it is possible to scale the curves for other values of the parameters.

V. ANALYSIS

Rather than integrate a complete reaction network for the evolution and freeze out of the photinos, we will assume that the photinos remain in equilibrium so long as there is a reaction depleting the $\tilde{\gamma}$ abundance that is larger than $H$. We will then assume that as soon as the rate of the last such reaction drops below $H$, the photinos immediately freeze out, and the photino-to-entropy ratio is frozen at that value. We will call this approximation the “sudden” approximation.

We can get some idea of the accuracy of the sudden approximation by considering a simple system involving only photino self-annihilation. As discussed in Section II, there is a well developed formalism for calculating the self-annihilation freeze-out of a N.R. species $[11]$. Using that formalism in Section II, Eq. (8), we found $Y_{\infty} \approx 7.4 \times 10^{-7}$.

Now let us compute $Y_\infty$ using the sudden approximation. From Fig. 1 or Fig. 2, we see that $\Gamma(\tilde{\gamma}\tilde{\gamma} \to X) = H$ at $x = 14.7$, independent of $r$. We will denote by $x_*$ the value of $x$ when $\Gamma = H$. Using the sudden approximation that the $\tilde{\gamma}$ is in LTE until $x = x_*$ and immediately freezes out would give a photino to entropy ratio of (again using 2 degrees of freedom and $g_* = 10$)

$$Y_\infty = Y_{EQ}(x_*) = 0.145 \left(\frac{2}{10}\right) x_*^{3/2} \exp(-x_*) = 7 \times 10^{-7} \quad \text{(using } x_* = 14.7). \quad (29)$$

The agreement between $Y_\infty$ obtained using the sudden approximation, Eq. (29), and
the usual freeze-out calculation, Eq. (8), suggests that the sudden approximation is a reasonable point of departure for a first look at this phenomenon. Note, however, that the accuracy of the sudden approximation when self-annihilation is the principal photino equilibration mechanism does not guarantee that it is an equally good approximation when interconversion is the important process. The Boltzmann equation when photino self-annihilation dominates can be written

\[ \frac{dY}{dx} = \frac{-x\langle \sigma_{\gamma\gamma} | v \rangle s}{H(m)} (Y^2 - Y_{EQ}^2), \tag{30} \]

where \( Y_{EQ}(x) \) has the form given in Eq. (29) and \( H(m) = 1.67g_s^{1/2}m^2/m_{pl} \). This is to be contrasted with the analogous expression when interconversion dominates:

\[ \frac{dY}{dx} = \frac{-x\langle \sigma_{\gamma\pi \rightarrow R\pi} | v \rangle s}{H(m)} (Y - Y_{EQ})Y_\pi. \tag{31} \]

Here, \( Y_\pi \) is the equilibrium pion to entropy ratio:

\[ Y_\pi(x) = 0.145(3/2)(2/10)(r_\pi) x^{3/2} \exp(-r_\pi x). \tag{32} \]

We have introduced \( r_\pi \equiv m_\pi/m = 0.175\mu_8^{-1} \), and included the factor \((3/2)\) because the pion has three flavor \( \times \) spin degrees of freedom in comparison to the photino’s two. The difference in these forms, in particular the much weaker exponential dependence on \( x \) for \( Y_\pi \) compared to \( Y_{EQ} \), is largely responsible for the shallower slope of the interconversion and inverse-decay curves as compared to the self-annihilation curves in Figs. 1 and 2. This shallower slope means that the quality of the sudden approximation in this case is inferior to the self-annihilation case, but probably not significantly in comparison to the large uncertainty due to our present poor knowledge of the cross sections. Closer examination of this question is in progress [17].

Now we proceed using the sudden approximation. Given \( x_* \), we wish to determine \( \Omega_\gamma h^2 \). It is, of course, a very sensitive function of \( x_* \): \( \Omega_\gamma h^2 = 2.25 \times 10^8 \left[ \mu_8 \right] Y_\infty = \)
Fig. 3: $\Omega_{\gamma} h^2$ as a function of $x_*$ assuming the photino stays in equilibrium until $x_*$ and immediately decouples (the sudden approximation).

Table III: The value of $\Omega_{\gamma} h^2$ assuming sudden freeze out at $x = x_*$. $\Omega_{\gamma} h^2 = 1$ occurs around $x_* = 20$, and $\Omega_{\gamma} h^2 = 10^{-2}$ around $x_* = 25$. In the Table we have taken $\mu_8 = 1$.

| $x_*$ | 12 | 14 | 16 | 18 | 20 | 21 | 22 | 24 | 25 | 26 | 28 | 30 |
|-------|----|----|----|----|----|----|----|----|----|----|----|----|
| $\Omega_{\gamma} h^2$ | 1660 | 283 | 47 | 7.6 | 1.2 | 0.5 | 0.2 | 0.03 | 0.01 | 0.004 | 0.0007 | $10^{-6}$ |

$6.5 \times 10^6 \ [\mu_8] \ x_*^{3/2} \exp(-x_*)$. The dependence of $\Omega_{\gamma} h^2$ upon $x_*$ is shown in graphical form in Fig. 3, with specific values presented in Table III.

Since the age of the universe restricts $\Omega_{\gamma} h^2$ to be smaller than unity, $x_*$ must be larger than 20. In order for the relic photinos to be dynamically interesting in structure evolution $\Omega_{\gamma} h^2$ must be larger than $10^{-2}$, which obtains for $x_* \lesssim 25$. Photinos would dominate the mass of the Universe if $\Omega_{\gamma} h^2 \gtrsim 0.03$, which would result if $x_* = 24$. For $\Omega_{\gamma} = 1$ and $h \sim 1/2$, $x_*$ must be about 22. Thus we can summarize interesting values of

$\mu_8$.

---

13Nucleosynthesis bounds the contribution from baryons to be about $\Omega_B h^2 \lesssim 0.03$. 

23
Fig. 4: Assuming $\tilde{\gamma}$ freeze out is determined by $\tilde{\gamma}-R^0$ conversion, the figure shows as a function of $r$ the values of $[\mu_8^2\mu_S^{-4}C]$ required to give the indicated values of $\Omega_{\tilde{\gamma}}h^2$. The uncertainty band is generated by allowing $\mu_8$ to vary independently over the range $0.5 \leq \mu_8 \leq 2$. 

$x_*$ by

\begin{align*}
x_* &\lesssim 25; \quad \Omega_{\tilde{\gamma}}h^2 \gtrsim 10^{-2}; \quad \text{dynamically interesting role for photinos} \\
x_* &\lesssim 24; \quad \Omega_{\tilde{\gamma}}h^2 \gtrsim 0.03; \quad \text{photinos dominate baryons} \\
20 &\lesssim x_* \lesssim 23; \quad \Omega_{\tilde{\gamma}}h^2 \sim 0.9, \quad \text{photinos are the dark matter and } \Omega_{TOT} = 1 \\
x_* &\lesssim 20; \quad \Omega_{\tilde{\gamma}}h^2 \gtrsim 1; \quad \text{disallowed by age arguments.}
\end{align*}

Now in turn, $x_*$ is exponentially sensitive to $r = M/m$, so limits to the contribution to the present density from $\tilde{\gamma}$ will be a sensitive probe of $r$.

From Figs. 2 and 3, we see that for the canonical choices $\mu_8 = \mu_S = A = B = C = 1$, either the interconversion process, or decay-inverse decay is the last photino reaction to be of importance. It is impossible to say which one because of the uncertainties in the computation of the cross section and the decay width, so we shall consider both possibilities in turn.

If interconversion determines the relic abundance and we make the sudden approximation then we can determine $\Omega_{\tilde{\gamma}}h^2$ as a function of the unknown parameters. Such a
Assuming \( \tilde{\gamma} \) freeze out is determined by decay/inverse decay, the figure shows as a function of \( r \) the values of \([\mu_s^4 \mu_{\tilde{\gamma}}^{-4} B]\) required to give the indicated values of \( \Omega_{\tilde{\gamma}} h^2 \).

Graph is given in Fig. 4. From the graph we see that \( \Omega_{\tilde{\gamma}} h^2 < 1 \) can result for \( r = 2.2 \) if we allow \( \mu_s^2 \mu_{\tilde{\gamma}}^{-4} C \) to be as large as \( 10^2 \). We also see that a dynamically interesting value of \( \Omega_{\tilde{\gamma}} h^2 \) can result for \( r \) as small as 1.2 if \( \mu_s^2 \mu_{\tilde{\gamma}}^{-4} C = 10^{-2} \), although if the interconversion rate is suppressed this much, it is likely inverse decay would govern freeze out.

A similar calculation can be made assuming that inverse decay is the last operative reaction depleting the photinos. The result of such an analysis is shown in Fig. 5. For \( r > 1.4 \) the behavior of the curves are similar to those in Fig. 5, but for small \( r \) the effect of phase-space suppression becomes important.

In either case, the conclusion is that for \( r \) as large as 2.2, it is possible to have \( \Omega_{\tilde{\gamma}} h^2 \lesssim 1 \); with our “central” choice of parameters, \([\mu_s^3 \mu_{\tilde{\gamma}}^{-4} B] = [\mu_s^{3/2} \mu_{\tilde{\gamma}}^{-4} C] = 1\), \( r \) must be less than 1.8 in order for \( \Omega_{\tilde{\gamma}} h^2 \lesssim 1 \). A value of \( r \) as small as 1.2 may result in \( \Omega_{\tilde{\gamma}} h^2 \gtrsim 10^{-2} \); again with the central choice of parameters the limit is \( r \gtrsim 1.6 \).

Although it apparently is not important for realistic parameters, we mention a pos-
sible special role for the $S^0$, $udsg\bar{g}$, the lightest baryon containing a gluino. Since the $S^0$ has a non-zero baryon number, its abundance is not given by Eq. (3) at low temperature because of the non-zero baryon number of the Universe. So long as the strong interactions are maintaining equilibrium between nucleons and $S^0$'s, its abundance should be 

$$n_{S^0} \sim n_N \exp\left[-(M_{S^0} - m_N)/T\right],$$

where $n_N$ is the nucleon abundance and $m_N$ is the nucleon mass. Thus at very low temperature its abundance will be larger than the $R^0$ abundance, so the co-annihilation and interconversion processes $\tilde{\gamma}S^0 \to KN$ and $\tilde{\gamma}N \to KS^0$ are a potential sink of $\tilde{\gamma}$s which in principle could help keep the $\tilde{\gamma}$ in equilibrium. However for realistic cross sections, this does not seem to be important at the relevant temperatures. Likewise, although at low enough temperatures there are more nucleons than pions so that $\Gamma_{\tilde{\gamma}N \to R^0N}$ is larger than $\Gamma_{\tilde{\gamma}\pi \to R^0\pi}$, freeze out has already occurred before the number density of nucleons begins to dominate that of pions.

**VI. SUMMARY AND CONCLUSIONS**

We have studied the reactions important for the decoupling and freeze-out of photinos having mass $m$ less than about 1.5 GeV. We have found that it is crucial to include the interactions of the photino with the $R^0$, the gluon-gluino bound state whose mass $M$ is expected to lie in the range 1 to 2 GeV. The $R^0$ has strong interactions and thus annihilates extremely efficiently and stays in thermal equilibrium to much lower temperatures. In this circumstance, photino freeze-out occurs when the rate of reactions converting photinos to $R^0$'s falls below the expansion rate of the Universe. The rate of the $\tilde{\gamma} - R^0$ interconversion interactions which keep photinos in thermal equilibrium, $(\tilde{\gamma}\pi \leftrightarrow R^0\pi)$ or $R^0$ decay/inverse decay $(\tilde{\gamma}\pi \leftrightarrow R^0)$, depends on the densities of photinos and pions, rather than on the square of the photino density, as is the case.
for the self-annihilation process. For photinos of the relevant mass range \((m \sim 800\) MeV), the pion abundance is enormous compared to the photino abundance. Therefore the photinos stay in equilibrium to much higher values of \(x \equiv m/T\) than they would if self-annihilation were the only operative process, resulting in a smaller relic density for a given photino mass and cross section. We find using the sudden approximation that light photinos are cosmologically acceptable for a range of \(1.2 \lesssim r \equiv M/m \lesssim 2.2\). Within this range, if \(1.6 \lesssim r \lesssim 2\), the photinos are an excellent dark matter candidate. The precise range of \(r\) for which the photino accounts for the cold dark matter may shift when the sudden approximation is improved and cross sections are better known. However the general conclusion is robust: light photinos can account for the dark matter of the Universe for a suitable value of \(r\), which is consistent with theoretical predictions in an attractive class of SUSY-breaking mechanisms \cite{2}.

Since \(\tilde{\gamma} - R^0\) interconversion governs freeze-out, the usual relation between \(\Omega h^2\) and the relic’s annihilation cross section \cite{13} is not valid. If inverse decay is the operative process, then there is no direct prediction for the \(\tilde{\gamma}\) scattering cross section on matter.\footnote{Since the short-distance dynamics entering the matrix element for \(R^0 \to \tilde{\gamma}\pi\) is the same as for the scattering reaction \(\tilde{\gamma}N \to R^0N\), these could in principle be related. At this time however we do not have sufficient control of the hadron physics involved to make a quantitatively accurate theoretical prediction of the cross sections from the \(R^0\) lifetime.} If \(\tilde{\gamma}\pi \longleftrightarrow R^0\pi\) is the operative process, a quantitative solution of the Boltzmann equations can be used to infer its cross section. It will be significantly smaller, more-or-less by a factor \(n_{\tilde{\gamma}}(x_*)/n_{\pi}(x_*)\), than the conventional cross-section used in planning relic detection experiments.

Direct detection of low-mass relic photinos is more difficult than detection of high-mass (say \(m \sim 50\) GeV) photinos. In addition to the low cross section mentioned above, the average energy deposition is \(\langle E \rangle = m^2 M_T \langle v^2 \rangle / (m + M_T)^2\) where \(M_T\) is the target
mass. Thus existing and planned experiments using relatively heavy targets are not well adapted to this search. On the positive side, our photino is more likely to have spin-independent couplings to nucleons than expected in the conventional picture \[15\]. This is because in the SUSY-breaking mechanism which leads to the light photino and gluino under discussion here, the off-diagonal terms in the squark mass-squared matrix can be comparable to the diagonal terms.\[15\]

Indirect detection via annihilation of gravitationally concentrated photinos \[14,19\], for instance trapped in the Sun, is unlikely. Because they are low-mass WIMPS, evaporation is much more efficient than in the high-mass case, and they do not concentrate sufficiently. (And, of course, the cross section is smaller than conventionally supposed.)

We also note that if the \(S^0\) is stable, there will be a relic abundance of them, with an abundance relative to baryons determined by \(M_{S^0}\) and \(x_S \equiv M_{S^0}/T_S\), where \(T_S\) is the temperature of \(S^0\) freeze-out. The \(S^0\) mass is expected to be 1.5 − 2 GeV, so let us define \(M_{S^0} = 1.5\mu_{1.5}\) GeV. Then

\[
\frac{n_S}{n_B} = \frac{1}{4} \left( \frac{M_{S^0}}{m_N} \right)^{3/2} \exp \left[ -\frac{M_{S^0} - m_N}{T} \right] \\
= \frac{1}{4} \left( \frac{1.5\mu_{1.5}\text{GeV}}{0.94\text{GeV}} \right)^{3/2} \exp\left[-(1 - 0.6/\mu_{1.5})x_S\right],
\]

(34)

where the factor 1/4 accounts for the fact that the \(S^0\) is a spin-0 state and comes in just one flavor, whereas there are 4 spin×flavor degrees of freedom for the baryons. The \(S^0\) self-annihilation cross section should be comparable to that of the \(R^0\), so ignoring the difference between \(R^0\) and \(S^0\) masses, \(x_S \sim x_{RR}\), where \(x_{RR}\) is the value of \(x\) at which \(\Gamma(R^0 R^0 \to X)/H = 1\). From Figs. 1 and 2 we see that \(x_{RR} \sim 45\), giving \(n_S/n_B \sim 7 \times 10^{-9}\) for \(\mu_{1.5} = 1\), and smaller for larger \(\mu_{1.5}\). Since the \(S^0\)'s are strongly interacting, even this small an abundance may be detectable. They will be more gravitationally

\[\text{See Ref. [2] for allowed ranges of the parameters determining the squark mass-squared matrix, } \mu, \tan \beta, \text{and } M_0.\]
concentrated than standard WIMPS of comparable mass because they dissipate energy through their strong interactions, although they do not form atoms or bind to nuclei\textsuperscript{16}.

What, then, is the strategy for testing the proposal that photinos with mass less than or about 1 GeV constitute the cold dark matter of the Universe? Of course if an $R^0$ in the 1 to 2 GeV range could be excluded by laboratory searches, our suggestion for the dark matter would be also excluded. Assuming though that these particles are discovered, knowledge of experimentally accessible properties of the photino and $R^0$ (in particular, their masses, the $R^0$ lifetime, and the cross section for $R^0 N \rightarrow \tilde{\gamma}N$) coupled with detailed numerical analysis of the freeze-out process, will allow a much more accurate prediction of the relic abundance than has been possible here. Since the relic density is exponentially dependent on $r$, which will one day be well measured, an accurate quantitative test of this idea will eventually be possible.

In the meantime, theoretical work can elucidate the viability of this proposal. In the SUSY-breaking mechanism relevant to this scenario the parameters $\mu$, $\tan \beta$, and $M_0$, which determine the photino and gluino masses, are highly constrained \textsuperscript{2}. Relatively soon even more accurate predictions for the photino and gluino masses will be possible, narrowing the possible range of photino masses corresponding to any allowed gluino mass. With use of lattice gauge theory, it should be possible to compute the $R^0$ mass range corresponding to a given gluino mass, and thus to determine a spectrum of possible $r$ values. Lattice gauge calculations can also in principle determine the matrix element for $R^0 \rightarrow \tilde{\gamma}\pi$, given the squark masses (which are fixed by the same unknown parameters determining $m_{\tilde{\gamma}}$ and $m_{\tilde{g}}$, at least with minimal SUSY breaking), and determine the masses of the other $R$-hadrons, which would help in estimating the cross sections. For instance knowledge of the mass of the $R_\pi$ would allow one to better model $\sigma_{R^0\pi}$. With more

\textsuperscript{16}If they were stable and could bind to nuclei, they would have been detected in rare isotope searches\textsuperscript{[1]}, so that possibility is excluded.
accurately fixed inputs, a full numerical solution of the coupled Boltzmann equations would be justified.

Therefore, the most important next steps are:

1. Look hard for $R$-hadrons and other new particles predicted by this scenario. Planned kaon experiments may be able to establish evidence for the $R^0$, and possibly measure the its lifetime and mass, as well as the mass of the photino $[2]$.

2. Do a better job fixing the parameters of the underlying theory, as well as calculating the photino mass produced through radiative corrections.

3. Use lattice gauge theory to calculate the $R^0$ mass and check other predictions of this scenario such as the origin of the $η'$ mass $[3]$. 

4. A more complete treatment modeling the photino freeze-out is necessary $[7]$. An immediate question to address is the quality of the sudden approximation used here. When interconversion is the dominant process, the equation governing the evolution of the photino density has a somewhat different form than in the self-annihilation case, for which the quality of the sudden approximation is well-established.

5. Obtain detailed predictions for the low energy $\tilde{\gamma}$-nucleus cross sections expected in this scenario, and find effective detection techniques for light photinos.

At the very least we have shown that until the value of $r$ is demonstrated to be larger than about 2.2, light photinos are cosmologically acceptable. At best, we have described the scenario for the production and survival of the dark matter of the Universe.

While there is no shortage of candidates for relic dark matter particle species, this proposal extends the idea that photinos may be the dark matter to a previously excluded mass range by incorporating new reactions that determine the photino relic abundance.
If this scenario is correct, direct and indirect detection of dark matter might be even more difficult than anticipated. However the scenario requires the existence of low-mass hadrons, which can be produced and detected at accelerators of moderate energy. Thus particle physics experiments will either disprove this scenario, or make light photinos the leading candidate for dark matter.
