Supporting Information

ABSTRACT: DNA-stabilized silver clusters are remarkable for the selection of fluorescence color by the sequence of the stabilizing DNA oligomer. Yet despite a growing number of applications that exploit this property, no large-scale studies have probed origins of cluster color or whether certain colors occur more frequently than others. Here we employ a set of 684 randomly chosen 10-base oligomers to address these questions. Rather than a flat distribution, we find that specific color bands dominate. Cluster size data indicate that these “magic colors” originate from the existence of magic numbers for DNA-stabilized silver clusters, which differ from those of spheroidal gold clusters stabilized by small-molecule ligands. Elongated cluster structures, enforced by multiple base ligands along the DNA, can account for both magic number sizes and color variation around peak wavelength populations.

SECTION: Physical Processes in Nanomaterials and Nanostructures

Ligand-stabilized metal nanoclusters are an exciting class of materials due to their remarkable chemical, electrical, and optical properties, and promise for applications in catalysis, nanoelectronics, and biosensing. Ligands enable cluster sizes that are not otherwise stable in solution. The physical, chemical, and optical properties of a ligand-stabilized metal cluster are intimately connected to the properties of the ligand itself. Ligand–metal bonds at the cluster surface can even dictate the so-called “magic numbers” of gold clusters that occur due to enhanced stability of certain clusters with select numbers of metal atoms, reflecting electronic shell closings.

Most ligand-stabilized noble metal nanoclusters have quasispherical geometries. However, a new class of DNA-stabilized silver clusters ($\text{Ag}_{N_{\text{f}}}\text{-DNA}$) displays evidence for rod-like shapes, an exciting feature due to the possibility of new functionalities based on shape-tuned color and anisotropic polarization response. The challenge of isolating these small fluorescent clusters, which are surrounded by bulky DNA ligands, was recently overcome, enabling identification of total silver content as $N = 10–24$ Ag atoms, with $1–2$ DNA oligomers associated with each cluster. Reported optical properties of $\text{Ag}_{N_{\text{f}}}\text{-DNA}$ vary widely, depending on DNA strand specifics. Some are brightly fluorescent, with narrowband emission wavelengths spanning the visible and near-IR and quantum yields exceeding 90%. High photostabilities have also been reported. Due to these unique fluorescence properties, $\text{Ag}_{N_{\text{f}}}\text{-DNA}$ are now employed in a number of fascinating sensing applications, including detection of metal ions, microRNAs, target DNA strands in the presence of serum, and single base mutations relevant to human diseases.

Despite this growing list of applications, little is known about the origins of cluster color in $\text{Ag}_{N_{\text{f}}}\text{-DNA}$. Strategies for selecting cluster-stabilizing DNA oligomers generally focus on experimentally testing small sets of cytosine (C)-rich or guanine (G)-rich oligomers, which are important for forming fluorescent products, to find sequences that produce attributes appropriate to a specific application. Here we instead use a large set of 684 distinct 10-base oligomers with widely varying composition to probe the origins of clusters with varying colors. We randomly selected sequences containing at least three total C plus G bases from a larger set produced using a random number generator with equal probability of placing A, C, G, or T bases at each site. Sequences containing less than a total of three C plus G bases were excluded to increase the probability of obtaining fluorescent $\text{Ag}_{N_{\text{f}}}\text{-DNA}$ solutions, which only slightly changes the base content of the random sequence set (see Supporting Information Figure S1).

Robotic parallel synthesis of $\text{Ag}_{N_{\text{f}}}\text{-DNA}$ under identical conditions was performed in well plate format (Figure 1b). In each well, the hydrated DNA oligomer was mixed with $\text{AgNO}_3$ followed by $\text{NaBH}_4$ reduction. All clusters were excited via the DNA bases using 280 nm excitation. Spectra of resulting products were fitted to single Gaussian
Figure 1. (a) Peak fluorescence wavelength histograms for Ag$_{\text{G}}$-DNA stabilized by randomly generated 10-base oligomers, synthesized at 10 $\mu$M DNA and 20 $\mu$M DNA with Ag$^+$/DNA = 5:1 and measured 1 week after synthesis to ensure stability of measured products. The number of data, $N$, indicated on each graph, represents the number of brightly fluorescent Ag$_{\text{G}}$-DNA with single-Gaussian spectra that are histogrammed in each plot (see main text). Maximum likelihood estimation fits to a sum of two normal distributions are in red. b) Cartoon schematic of parallel robotic synthesis and fluorescence characterization. c) A histogram of published Ag$_{\text{G}}$-DNA fluorescence wavelengths is strikingly similar to those resulting from the randomly chosen 10-base strands (Figure 1a).

Figure 2. (a,b) Neutral Ag atom numbers, $N_0$, extracted from previous Ag$_{\text{G}}$-DNA size data$^7$ and (c,d) measured for select 10-base well plate strands that produced bright fluorescence and HPLC-stable products. (a,c) $N_0$ vs $N$ for HPLC-purified Ag$_{\text{G}}$-DNA, determined by MS. Brightly fluorescent clusters are indicated by colored dots; RGB colors match fluorescence wavelength (IR-emitting clusters are gray). Black data points represent Ag$_{\text{G}}$-DNA that were not measurably fluorescent but still sizable by MS. Vertical error bars are standard errors in the cluster charge, $N_e$, and horizontal error bars represent uncertainty in $N$. (b,d) Histograms of $N_0$ values show abundances of clusters with even $N_0$. Magic numbers predicted by the spherical superatom model (dashed lines) differ from those observed for Ag$_{\text{G}}$-DNA.

The remaining 75% of the strands either did not stabilize silver clusters, stabilized “dark” clusters that were not measurably fluorescent, or stabilized clusters that produced very low fluorescent signals due to low chemical yields or quantum yields of fluorescent products. These strands are presumably not favorable hosts for silver clusters, perhaps due to insufficient association to Ag$^+$ or because silver clusters stabilized by these strands are not in environments that favor radiative decay.

Histograms of fluorescence wavelengths from single-peak solutions demonstrate bimodal color distributions with enhanced abundances of “green” Ag$_{\text{G}}$-DNA near 540 nm and “red” Ag$_{\text{G}}$-DNA near 630 nm (Figure 1a and S2). Although relative heights change somewhat, histogram peaks are invariant over time (one day, one week, and four weeks after synthesis) and synthesis conditions (data for additional synthesis conditions and time points are in Supporting Information), suggesting enhanced stabilities of Ag$_{\text{G}}$-DNA that possess colors near 540 and 630 nm. The 850 nm sensitivity limit of the well plate reader precludes detection at longer wavelengths.

To investigate whether these color bands are specific to 10-base oligomers, we surveyed results on 79 strands previously reported to form fluorescent Ag$_{\text{G}}$-DNA with widely varying sequence lengths (6–34 bases) and synthesis conditions. Care was taken to avoid duplicating reported results on identical strands (many oligomers are utilized across multiple studies). A histogram of reported peak fluorescence wavelengths shows a similar color distribution (Figure 1c), with abundances of green and red species as compared to other colors (an additional peak in the near-IR has also been seen) may also indicate a third abundance that is not detectable with our plate reader, which has poor sensitivity beyond $\sim$750 nm.) Apparently “magic colors” are generic, rather than special to strands of specific length.
We next consider whether Ag_N-DNA within a “magic color” grouping also share similar cluster properties, regardless of sequence specifics. Previous work used high-performance liquid chromatography with in-line mass spectrometry (HPLC-MS) to identify total numbers of silver atoms, N_0, and silver cations, N_+, for 51 different Ag_N-DNA products that formed on 10 different mixed base sequences with 16–34 bases. From this data we extract the number of neutral silver atoms, N_0, in each cluster: N_0 = N – N_+. Distinct groupings are apparent for even N_0 despite wide-ranging numbers of silver cations (Figure 2a; for N_0 = 6, N_+ ranges from 6 to 10). A histogram of N_0 (Figure 2b) displays marked enhancement at even values. Thus, it appears that even magic numbers of N_0 correspond to enhanced abundances of Ag_N-DNA species, regardless of N_. Additionally, brightly fluorescent Ag_N-DNA (colored circles in Figure 2a; RGB colors match peak fluorescence) demonstrate color groupings, with green and red clusters grouped separately, mirroring the histogram color peaks in Figure 1b.

We selected three 10-base strands that produced bright fluorescence to investigate whether Ag_N-DNA forming on 10-base template strands also contain the magic numbers of N_0 observed in Figure 2a,b and lie in the same magic color bands. Aliquots of the main synthesis products were collected by HPLC separation and examined by negative ion MS (electrospray ionization) (see Supporting Information). Figure 2c,d shows that Ag_N-DNA formed by these strands, both fluorescent and dark, indeed shows an overwhelming propensity for even N_0, and that colors lie in the same bands exhibited in Figure 2a. (If the neutral silver atoms were not included in a single cluster, there would be no reason for color to red-shift with larger N_0, a trend that is clear in Figure 2 and is discussed in more detail in ref 7.)

To better understand the magic nature of certain N_0 rather than certain N, we consider the well-studied spherical, ligand-stabilized gold clusters.\(^5\) In these “superatoms,” total Au atom number, N, is not magic because ligands effectively remove some gold atoms from the cluster.\(^5\) For thiolate- and phosphine-stabilized Au clusters, ligands bind to surface Au atoms and withdraw a fraction of the cluster’s electrons, forming protective units around the cluster and leaving behind a magic number of electrons, and thus neutral gold atoms, in the cluster core.\(^4,5\) Magic numbers of these core electrons are predicted by electronic shell closings in the spherical model.\(^4,5\) While ligand-protected Au clusters, base-Ag+ units to influence color by determining cluster shape. The existence of dark Ag_N-DNA with N_0 = 0 and up to six Ag+ (Figure 2a) shows that fluorescent clusters may also contain Ag+ that are not incorporated into the base-Ag+ ligand units surrounding the neutral cluster core. Ag+ content varies from N_0 = 6–9 in red-emitting clusters with N_0 = 6, suggesting that up to three Ag+ are associated with bases detached from the cluster, where they may still affect wavelength by altering the potential seen by the cluster’s delocalized electrons.

Figure 3 shows variants on such a silver cluster nanorod, adapted from previously suggested structures,\(^7,37\) (AMBER structure generation details in the Supporting Information). Like ligand-protected Au clusters, base-Ag+ units protect a neutral cluster core containing a magic number of neutral silver atoms, even N_0 due to spin degeneracy (Figure 3a,b). Ag–Ag bond angle variation within the core can produce a range of aspect ratios and/or curvatures that can optimally be tuned by modifying Ag bond angles and base stacking energies. Molecular dynamics simulations\(^38\) show that clusters may assume curved shapes due to Coulomb interactions, and addition or subtraction of silver ions near the cluster can modify cluster shape (Figure 3c,d). We expect that a combination of such shape factors account for the breadth of histogram peaks in Figure 1b.

Finally, we consider the specificity of Ag_N-DNA color to the particular DNA template sequence, an important issue for Ag_N-DNA colorimetric sensing schemes. Our array data studies show that many distinct sequences produce nearly the same fluorescence color. In particular, for red emitters we find 26
distinct ten-base strands that produce the same peak fluorescence color to within 10 nm (see Supporting Information). This will challenge the development of sensing schemes aimed at distinguishing the presence of specific sequences amid a background of other DNA.

In conclusion, we observe significantly enhanced abundances of Ag$_{N_0}$-DNA stabilized by random DNA oligomers with fluorescence peaks near 540 and 630 nm. HPLC-MS data shows that these color groupings correspond to cluster populations with even numbers of neutral silver atoms, different from magic numbers for spherical clusters. Due to the dependence of fluorescence wavelength on neutral silver atom number, magic numbers of silver atoms result in "magic color" bands. Variants on rod-like cluster models qualitatively explain the breadth of the color histogram peaks relative to magic numbers by permitting variations in cluster length and immediate environment. The existence of such "magic colors" has implications for the palette available to colorimetric assays and could be exploited in sensing applications where transitions between green and red emissive clusters act as signals for a desired process.

**EXPERIMENTAL METHODS**

**Parallel Cluster Synthesis.** Random 10-base DNA sequences were generated by a MATLAB random number generator, excluding sequences with fewer than 3 C plus G bases. Well-plate format DNA was ordered presuspended in water with standard desalting from Integrated DNA Technologies. Several wells contained a control oligomer known to produce bright fluorescence to confirm proper synthesis. A Beckman Coulter Biomek 2000 pipetting robot was used to synthesize Ag$_{N_0}$-DNA at four synthesis conditions: 10 μM and 20 μM DNA, with [AgNO$_3$]/[DNA] = 5 and 10. Synthesis was performed at pH 7 in 10 mM NH$_4$OAc, with [NaBH$_4$]/[AgNO$_3$] = 0.5. See Supporting Information for details.

**Spectral Characterization and Histogram Fitting.** Fluorescence spectra were measured using a Tecan Infinite 200 PRO reader and fitted to single Gaussians as a function of energy to extract spectral parameters using Igor Pro 6, WaveMetrics. Ag$_{N_0}$-DNA solutions with dim fluorescence or multiple peaks were excluded from histograms (see Supporting Information for details). Maximum likelihood estimation fits to bimodal distributions were performed using MATLAB R2012a.

**Mass Spectrometry of Silver Clusters.** Synthesis of select bright Ag$_{N_0}$-DNA was scaled to 1 mL, and products were purified by HPLC and sized by MS to obtain total silver content, $N_0$, and the number of silver cations, $N_+$. For details and spectra, see Supporting Information.
