We study bulk and edge correlations in the compressible half-filled state $\frac{1}{2}$, using a modified version of the plasma analogy. The corresponding plasma has anomalously weak screening properties, and as a consequence we find that the correlations along the edge do not decay algebraically as in the Laughlin (incompressible) case, while the bulk correlations decay in the same way. The results suggest that due to the strong coupling between charged modes on the edge and the neutral Fermions in the bulk, reflected by the weak screening in the plasma analogue, the (attractive) correlation hole is not well defined on the edge. Hence, the system there can be modeled as a free Fermi gas of electrons (with an appropriate boundary condition). We finally comment on a possible scenario, in which the Laughlin–like dynamical edge correlations may nevertheless be realized.

I. INTRODUCTION AND PRINCIPAL RESULTS

Laughlin’s theory of the fractional quantum Hall effect (QHE) $\frac{1}{2}$ was given in terms of wave functions of the ground state and quasihole excitation. Using a plasma analogy to calculate the static many-body correlators, which characterize these wave functions, he was able to advance a very successful physical picture of the electron system. The wave functions, describing the incompressible states, contain the Laughlin-Jastrow factor, which leads to a special, later introduced, Girvin-MacDonald (GM) correlations in the bulk $\frac{1}{2}$, and Wen’s correlations on the edge $\frac{1}{2}$. The Laughlin-Jastrow factor is ever-present in QHE states - it exists even in the compressible half-filled state $\frac{1}{2}$, for which an explicit wave–function has been proposed by Read and Rezayi (RR) $\frac{1}{2}$. The question arises whether its manifestations, in terms of the above mentioned correlations, survive in more general quantum Hall states, and in particular in the compressible states. Why is this question important? The correlations that are embodied in theLaughlin–Jastrow factor lie at the heart of various quasiparticle pictures $\frac{1}{2}$ (composite fermions, composite bosons) of the QHE in the bulk. From the theoretical viewpoint, it is interesting to understand the status of Bose condensation, implicit in the Laughlin-Jastrow factor $\frac{1}{2}$, in the compressible state. Related to this is the question to what extent Laughlin’s quasihole construction in the compressible state (a zero of the wave function) can be considered as an elementary excitation of the system.

Experimentally, these correlations are in principle accessible by tunneling measurements. Indeed, recent edge–tunneling experiments by M. Grayson et al $\frac{1}{2}$ prompted the question whether the Luttinger liquid picture $\frac{1}{2}$, which is characterized by Wen’s correlations, is valid for general quantum Hall systems, including the compressible states. A number of theoretical works $\frac{1}{2}$ have attempted to explain the puzzling results of Ref. $\frac{1}{2}$, in terms of charged excitations on the edge that are effectively decoupled from the bulk $\frac{1}{2}$.

In this paper we concentrate on the compressible QHE system at filling factor one-half. We assume that the RR wave function well describes the ground state of the system, even when we consider a system with an edge. Namely, we assume the composite fermion (or more precisely dipole) picture $\frac{1}{2}$ to apply everywhere. We rederive the GM and Wen’s correlations in the Laughlin state considering the leading order contributions of a weak-coupling plasma approximation (see also Ref. $\frac{1}{2}$). Then we consider the same correlations (appropriately redefined) in the RR state. In calculating these we use the same approach – a systematic expansion of a plasma free energy – with necessary modifications to include the Fermi sea correlations $\frac{1}{2}$. This introduces a statistical mechanics viewpoint of the problem, in terms of an anomalous, weakly-screening plasma.

Applying the aforementioned procedure (and viewpoint) on the RR state, we find that Wen’s correlations of the edge do not decay algebraically (at large distances) as in the Laughlin state. This excludes the possibility of existence of a subspace of charge density waves on the edge (of the type found in the Laughlin state), that is decoupled from the rest of the excitations – i.e., the neutral bulk excitations. The form of the obtained equal-time electron Green’s function on the edge suggests that, in the first approximation, the physical picture of the RR edge is that of a Fermi gas of electrons. The bulk GM correlations, on the other hand, decay algebraically, in an almost identical way as in the Laughlin state.

Below we detail the derivation of the correlators, in the bulk (Sec. $\frac{1}{2}$) and on the edge (Sec. $\frac{1}{2}$). A discussion of theoretical and experimental implications of the results is given in Sec. $\frac{1}{2}$.

II. CORRELATIONS OF THE BULK

In this section, we employ the plasma analogy to derive the appropriately generalized GM correlator in the compressible RR state. To introduce the method, we first use it to derive the known result for the Laughlin state (Eq. (2) below).

A. Correlations of the bulk in the Laughlin state

In the Laughlin state, corresponding to filling factors \( \frac{1}{m} \) with \( m \) odd, the GM correlator \([3]\) is defined as the density matrix,

\[
\rho(z, z') = \frac{N \int d^2 z_2 \cdots \int d^2 z_N \Psi_b(z, z_2, \ldots, z_N) \times \Psi_b(z', z_2, \ldots, z_N)}{\int d^2 z_1 \cdots \int d^2 z_N |\Psi|^2},
\]  

(1)

for the bosonic many-body function,

\[
\Psi_b = \prod_{i<j} [z_i - z_j]^m \exp\left(-\frac{1}{4} \sum |z_i|^2\right),
\]  

(2)

obtained from the Laughlin wave function by omitting the phases of the relative distances between any two electrons, \((z_i - z_j)\). As shown in \([4]\), the asymptotic form of \(\rho(z, z')\) is

\[
\rho(z, z') \sim |z - z'|^{-2}. \tag{3}
\]

This correlator expresses a Bose condensation, with algebraic off-diagonal long range order, of composite bosons - defined as electrons with \(m\) flux quanta attached. We now derive the above form using the weak-coupling plasma analogy.

We first rewrite the integrand as \([4]\)

\[
\Psi_b(z, \ldots, z_N) \times \Psi_b(z', \ldots, z_N) = \exp\{2m \sum_{i<j} \ln |z_i - z_j|\}
\times \exp\{m \sum_{i} \ln |z - z_i| + m \sum_{i} \ln |z' - z_i|\}
\times \exp\left(-\frac{1}{2} \sum_{i} |z_i|^2 - \frac{1}{4} |z|^2 - \frac{1}{4} |z'|^2\right)
\]  

(4)

and similarly the numerator. (The prime means that \(i = 1\) is excluded from the summations.) Using the Laughlin plasma analogy we can write \(\rho(z, z')\) as

\[
\rho(z, z') = |z - z'|^{-2} \frac{Z(z, z')}{Z(z, z)}, \tag{5}
\]

where \(Z(z, z')\) is a partition function of a classical 2D plasma with inverse temperature \(\beta = \frac{2}{m}\), each particle with charge \(m\), and two impurities with charge \(\frac{m}{2}\) each, at the locations \(z\) and \(z'\). \((Z(z, z')\) is a partition function with one impurity of charge \(m\) at an arbitrary location, because the value of the partition function does not depend on \(z\).) \(n\) is the average density of particles (equal to \(\frac{1}{2\pi \pi m}\) in the usual units). To calculate the ratio of the two partition functions we may expand the exponentials in the parameter \(m\), which we will assume to be small. The expansion will generate terms that can be described by diagrams and corresponding rules.

As usual in this kind of expansion in the statistical mechanics analogue, the expansion of the denominator involves only connected diagrams. Each diagram consists of parts, hereon called disconnected parts, which connect two impurities at \(z\) and \(z'\) but are otherwise disconnected among themselves. Then, the rules that correspond to each diagram in the expansion are as follows:

1. Associate with each interaction line a two-momentum satisfying momentum conservation at each internal vertex,

2. Associate with each interaction line between particles \(-\frac{2\pi \beta m}{|\vec{k}|^2}\), with each interaction line between a particle and an impurity \(-\frac{2\pi \beta m \times \vec{k}}{|\vec{k}|^2}\), with each interaction line between impurities \(-\frac{2\pi \beta m (\vec{m} \times \vec{n})}{|\vec{k}|^2}\), and with each internal vertex \(n\),

3. For each incoming (from \(z\)) which is also outgoing to \(z'\) momentum for each disconnected part, integrate as \(\int \frac{d^2 k}{(2\pi)^2} \exp\{i\vec{k}(\vec{r} - \vec{r}')\}\), but for each internal momentum as \(\int \frac{d^2 k}{(2\pi)^2}\).

4. Multiply with a symmetry factor (if any). The symmetry factor is an inverse of the number of ways that we can interchange a given number of identical parts of a given diagram, and recover the same graph.

The diagrams that represent the interaction with the background are mutually canceled (as we checked for the first diagrams in the expansion) and we will not consider them. In our problem the density \(n\) is fixed and depends on the small parameter \(m\). In order to get the correct order of the diagram (i.e. the power of \(m\)) in the expansion, we must take this into account. The lowest order diagram has value one. The next in order are diagrams of the form shown in Fig. 1 and are of order \(m\). We can easily sum them and the result is

\[
V_{\text{eff}}(|\vec{r} - \vec{r}'|) = \left(\frac{m}{2}\right)^2 \frac{\int \frac{d^2 k}{(2\pi)^2} \exp\{i\vec{k}(\vec{r} - \vec{r}')\}}{1 + \frac{2\pi \beta m^2}{|\vec{k}|^2} n}\tag{6}
\]

The sum represents an effective screened interaction between two impurities. The infinite summation of certain type of diagrams that diverge even more singulary as we increase the number of interaction lines, is a well
known ansatz in the many-body theory of the Coulomb-interacting electron gas in three dimensions. This captures well the phenomenon of screening that is characteristic of long-range forces. In our case the infinite summation is even further enforced, given the fact that the diverging diagrams are of the same order in $m$.

![Diagram](image)

**FIG. 1.** The diagrams leading to screening of the interaction in the bulk.

We now rewrite the ratio of partition functions in Eq. (6) as

$$
\frac{Z(z,z')}{Z(z,z)} = \exp\{-\beta \Delta f(z,z')\},
$$

where $\Delta f(z,z')$ represents the difference in the free energy between the two configurations of the impurities. The above exponential form can be obtained by summing the set of diagrams, whose disconnected parts are of the form shown in Fig. 1. Thus we find

$$
\frac{Z(z,z')}{Z(z,z)} = \exp\{V_{eff}(\vec{r} - \vec{r}')\}. \tag{8}
$$

As $|\vec{r} - \vec{r}'| \to \infty$ the ratio approaches unity, because $V_{eff}$ is an effective screened interaction $\left[14\right]$. Hence, Eq. (8) reduces to the well-known expression for the GM correlator, Eq. (3).

This result is derived, and found to have the same form for larger, physical $m$’s $\left[4\right]$. Therefore, it is possible to analytically continue the correlator obtained in the weak-coupling approach to larger $m$’s. Applying the same weak-coupling infinite summation, it can be shown that the continuation is valid also in the calculation of the static structure factor in the small-momentum limit (when corrections to the infinite summation are added, this includes also the term proportional to the fourth power of the momentum $\left[4\right]$).

It is interesting to check what does the weak-coupling approach yield for the distribution of the charge in the tail of the Laughlin quasihole excitation $\left[3\right]$. The quantity that describes this is $\left[3\right]$

$$
g_{12}(|z_1 - w|) = \frac{N}{Z} \int d^2z_2 \cdots \int d^2z_N \prod_{i=1}^{N} (z_i - w) \Psi|^2,
$$

where $\Psi$ and $Z$ is the Laughlin wave function and its norm, respectively. In order to capture the physics of screening we sum the same, most important diagrams as before, and approximate Eq. (9) by $\left[14\right]$

$$
g_{12}(|z_1 - w|) = n + \int \frac{d^2k}{(2\pi)^2} \exp\{i\vec{k}(\vec{r}_1 - \vec{w})\}\frac{2\pi\beta(m\times 1)}{|\vec{k}|^2} \frac{1}{1 + n \frac{2\pi\beta m^2}{|\vec{k}|^2}}. \tag{10}
$$

As $|z_1 - w| \to \infty$ the function $g_{12}(|z_1 - w|)$ should tend to the unperturbed density $n$, and it behaves as

$$
g_{12}(|z_1 - w|) = n - m \text{Const} \frac{1}{\sqrt{|z_1 - w|}} \exp\{- \frac{|z_1 - w|}{r_D}\}, \tag{11}
$$

where $1/r_D^2 = 2\pi\beta m^2 n = 2$, $r_D$ being the Debye length.

**B. Correlations of the bulk in the compressible half-filled state**

The theory and physical picture of the filling fractions $\frac{1}{m}$ where $m$ is even, evolved from some Fermi condensation of charged (Chern-Simons) composite fermions (electrons with even number of flux quanta attached) to a well-defined Fermi condensation of dipole quasiparticles $\left[4\right]$. This emphasized the advantage of Read’s picture $\left[17\right]$, which, from the beginning, takes into account the binding of electrons to (so-called) correlation hole. (Equivalently, the statement is that the zeros of the many body functions are found at or near the electrons). At even denominators the overall neutral composite object is a dipole (with Fermi statistics).

The ground state wave function that corresponds to this picture is the RR wave function $\left[2\right]$

$$
\Psi_{RR} = \mathcal{P}_{LLL} \{ \det[i\vec{k}_I \vec{R}_j] \} \Psi_L, \tag{12}
$$

with a Slater determinant of free waves that fill a Fermi sea, which when projected to the lowest Landau level (LLL) ($\mathcal{P}_{LLL}$ stands for the projector), acts on $\Psi_L$ - the Laughlin wave function. In Eq. (12) we wrote the determinant in terms of plane waves, which constitute a convenient basis for a system of free particles (in a rectangular geometry). The Laughlin wave function, on the other hand, is very often expressed in the rotationally-symmetric gauge (corresponding to a rotationally-symmetric geometry) amenable to the Laughlin plasma analogy. In order to facilitate our computations we will keep these two distinct geometry choices in the RR wave function. We justify this by the fact that, first, we will be interested in the (long-wavelength) properties of the system in the thermodynamic limit (when the boundary conditions should not matter), and second, each component of $\Psi_{RR}$ will enter our calculations in the form of translationally invariant, geometry independent elements.
To illustrate the dipole physics contained in Eq. (13), we note that the LLL projection translates factors of the form \( \exp \{ i(k_{\tau} z) / 2 \} \), where \( k = k_x + ik_y \) and \( z = x + iy \), into the shift operator \( \exp \{ ik \partial / \partial z \} \), which acts on the original (before projection) holomorphic (\( z \)-dependent) part of the wave function. This effectively means that each electron becomes displaced from the position of its correlation hole by \( -ik \) (where \( k \) takes values from the Fermi sea), and therefore dipole moments are induced.

In the calculation of correlation functions the effects of the LLL projection can be taken into account by using the following identity

\[
\Psi(z, z_2, \ldots, z_N) = \prod_{i=2}^{N} \left| z - z_i \right|^2 \exp \{ \text{sgn} \sigma \prod_{i=2}^{N} \exp \{ i(k_{\sigma(i)} z_i) / 2 \} \}
\]

\[
\times \sum_{\sigma \in \mathcal{S}_{N-1}} \text{sgn} \sigma \prod_{i=2}^{N} \exp \{ i(k_{\sigma(i)} z_i) / 2 \}
\]

\[
\times \prod_{i<j} \left| z_i - z_j + ik_{\sigma(i)} - ik_{\sigma(j)} \right|^2
\]

\[
\times \prod_{i=2}^{N} \left| z - z_i - ik_{\sigma(i)} \right|^2 \exp \{ - \frac{1}{4} \sum_{i} \left| z_i \right|^2 \}.
\]

We next assume that the dominant correlations lie in the (Jastrow-Laughlin) differences, and for the moment neglect the Slater determinant. The complete plasma analogy is again possible and, as explained above, the infinite summation of the diagrams of type Fig. 1 (for small \( m \)) is relevant. In the presence of the determinant the first necessary correction to this picture is the introduction of a new vertex, that captures also possible Fermi (exchange) correlations between two points in the coordinate space. In the momentum space, the vertex then corresponds to the static structure factor of the free Fermi gas,

\[
s_0(q) = n + n^2 \int d^2 r \exp \{ iq \cdot r \} (g(|r|) - 1)\]

(16)

where \( q \neq 0 \), and the radial distribution function is

\[
g(r) = \frac{1}{n^2} \int_{k_1 \in \text{F.S.}} \frac{d^2 k_1}{(2\pi)^2} \int_{k_2 \in \text{F.S.}} \frac{d^2 k_2}{(2\pi)^2} (1 - \exp \{ i(k_1 - k_2) \cdot r \})
\]

(17)

(F.S. stands for the Fermi sphere). Symbolically, the new vertex is depicted in Fig. 2, as a sum of a direct and an exchange part, in which full lines represent Fermi particle lines.

![FIG. 2. The vertex \( s_0(q) \) in the bulk of a RR state.](image)

From Eq. (13), and the definition Eq. (16),

\[
s_0(q) - n = - \int_R \frac{d^2 k}{(2\pi)^2}.
\]

Here \( R \) represents the area of overlap between two Fermi spheres as shown in Fig. 3, where the center of one of the two spheres is displaced by \( q \) from the center of the
other one. The value of $s_0(q)$ is then given exactly by the shaded area in Fig. 3. The area is easily calculated for $|q|$ small and the result is

\[
s_0(q) = \frac{3k_f|q|}{4\pi^2}.
\]  

(19)

With the necessary introduction of the new vertex $s_0(q)$, the interaction becomes less effectively screened than in the usual (Laughlin) case. It becomes

\[
V_{eff}(|q|) = \frac{2\pi\beta_m^2}{|q|^2} \frac{|q|^2}{1 + \frac{2\pi\beta_m^2}{|q|^2} s_0(q)};
\]  

(20)

where the denominator can be interpreted as an anomalous dielectric constant of the corresponding modified plasma. In the coordinate space, at large distances, $V_{eff} \sim 1/r$, i.e. it is still long ranged and only partially screened.

\[\begin{align*}
\text{FIG. 3.} & \quad \text{The overlap of two shifted Fermi spheres.}
\end{align*}\]

Nevertheless, if (keeping this change in mind) we apply the same summations and arguments as in the Laughlin case, we come up with the same algebraic decay of the GM correlations as in that case $^{[4]}$. This decay is slightly modified by the exponential (Eq. 8) of the partially-screened interaction (effectively a constant as in the Laughlin case at large distances).

The question that arises immediately is whether the analytical continuation to larger (physical) $m$’s is possible, and, moreover, whether the screening plasma approach is reliable in giving the leading behavior of the correlator. Because of the absence of a complete analogy with some physical, well-studied plasma, there are no available results for larger $m$ to compare with. It was found $^{[14]}$ that the weakly-screening plasma approach gives the right (valid also for large $m$ $^{[18]}$) leading (small-momentum) behavior for the static structure factor of the compressible state, and generates expected (odd) powers of momentum in the expansion. If we try to go beyond the approach, and look for small- $m$ (expected) corrections, it seems that they can not be generated $^{[4]}$.

This is probably due to the nonanalyticities present in the compressible case (which were absent in the Laughlin case) that do not allow a perturbative treatment. Therefore we believe that the approach (essentially non–perturbative) can generate the correct (large $m$) leading behavior for the correlations that we study. They are between points which are directly connected only to the charge (Jastrow-Laughlin) part of the wave function, and that immediately suggests an approach that captures screening for their calculation.

The weak-screening property of this modified plasma can be very well seen by considering a zero of the electron coordinates at a point $w$ $^{[4]}$, which corresponds to the Laughlin quasihole in the incompressible case,

\[
\prod_{i=1}^{N} (z_i - w) \Psi_{RR}.
\]  

(21)

To simplify the calculation of the distribution of charge in the tail of this excited state, we will assume the unprojected version of the RR state in Eq. (1) (The use of the projected state involves some complications which are not essential and do not influence the final result). Now the appropriate infinite sum of the modified plasma can be expressed, in terms of diagrams depicted in Fig. 4, with the shaded circle representing the new vertex, i.e., in this case,

\[
g_{12}(|z_1 - w|) = n + \int \frac{d^2 k}{(2\pi)^2} \exp\{i\vec{k}(\vec{r}_1 - \vec{w})\} \frac{2\pi\beta(m\times 1)}{|k|^2} s_0(\vec{k}) \frac{2\pi\beta m^2}{|k|^2}.
\]  

(22)

\[\begin{align*}
\text{FIG. 4.} & \quad \text{The diagrams contributing to the calculation of } g_{12}(|z_1 - w|) \text{ in the RR state.}
\end{align*}\]

The most important contributions to $g_{12}$ in the limit $|z_1 - w| \rightarrow \infty$ come from nonanalyticities present in the integrand. They stem from the nonanalytic behavior of $s_0$ at $k = 0$ and $k = 2k_f$. Assuming that the small-momentum result Eq. $^{[14]}$ for $s_0$ is valid for any $k$
(analogously to the Thomas-Fermi approximation for the electron gas in three dimensions) we get the contribution from the \( k = 0 \) region,

\[
\left\{ g_{12}(|z_1 - w|) - n \right\}_{T.F.} \propto -\frac{k_f}{m} \frac{1}{|z_1 - w|^3}. \tag{23}
\]

The contribution from the \( k = 2k_f \) region can be calculated to be

\[
\left\{ g_{12}(|z_1 - w|) - n \right\}_{F.O.} \propto -\frac{1}{k_f} \frac{1}{|z_1 - w|^3} \sin(2k_f r). \tag{24}
\]

We may conclude from the expressions Eq. (23) and Eq. (24), which summed up give the change in the distribution of the charge from the uniform ground state contribution \( n \) (in the \( |z_1 - w| \to \infty \) limit), that the density far from the point \( w \) tends to \( n \) very slowly in comparison with the Laughlin case. The charge of this excited state (which may be argued to be \( \frac{1}{m} \) as for the Laughlin quasihole \( [17] \)) is spread over a much larger region than the one in the Laughlin case, due to the poor-screening properties of the modified plasma.

III. CORRELATIONS OF THE EDGE

A. Edge correlations in the Laughlin case

In \( [6] \), Wen showed how calculation of the equal-time correlator along the edge in the Laughlin case can be reduced to the problem of finding the electrostatic energy of placing an impurity outside the Laughlin plasma. For the sake of completeness and easy reference for our calculation we will, in brief, repeat his arguments. We then demonstrate, that the result is recovered in a weak coupling expansion.

Review of Wen’s procedure. We consider a disc of the Laughlin plasma, with a fixed radius \( R \), at fixed filling factor \( \frac{1}{m} \). As we increase the number of particles \( N \), the density will increase (with appropriate change in the magnetic field \( B \) to keep \( \frac{1}{m} \) constant) and the description that neglects details of the order of a magnetic length would be more and more accurate, and the Laughlin plasma will behave as a metal (with its screening properties).

To calculate the edge correlator we envision placing an impurity of charge \( m \) outside the disc of such a plasma, at a distance \( z \) where \( |z| \gg R \) (so that the details of the edge do not matter), and consider the ratio \( Z_I/Z \), in which

\[
Z_I(z, z) = \int \prod d^2 z_i \exp\left\{ \sum_{i<j} 2m \ln |z_i - z_j| \right\} \times \exp\left\{ \sum_{k=1}^{N} \left\{ -\frac{1}{2} |z_k|^2 + 2m \ln |z - z_k| \right\} \right\} \tag{25}
\]

and

\[
Z = \int \prod d^2 z_i \exp\{\sum_{i<j} 2m \ln |z_i - z_j| + \sum_{k=1}^{N} \left\{ -\frac{1}{2} |z_k|^2 \right\}. \tag{26}
\]

From the first-quantization (quantum-mechanical) point of view the ratio is the one-particle (electron) density at point \( z \). On the other hand, from the point of view of the plasma analogue, \( \ln \frac{Z_I}{Z} \) is the electrostatic energy required to transfer the impurity from infinity to the point \( z \). This energy can be expressed as

\[
\ln \frac{Z_I}{Z} = mN2 \ln |z| - m \ln(1 - \frac{R^2}{|z|^2}) + o(1/N). \tag{27}
\]

The first contribution is the electrostatic energy between the total charge \( N \) and the impurity, where in the first approximation the plasma droplet is assumed undeformed by the presence of the impurity. The second contribution describes the most important part of the deformation that occurs: the image charges of the impurity \( [19] \). The rest of the contributions are expected to be of order \( \frac{1}{N} \) or less (Due to the form of the first contributions, analiticity in \( N \) is expected.)

To find out the electron correlator between points \( z_1 \) and \( z_2 \) (on the edge), Wen first noticed that the expression on the right-hand side of Eq. (27) is holomorphic in \( z \) and anti-holomorphic in \( \bar{z} \) (outside the system), and therefore can be analytically continued, i.e.

\[
\ln \frac{Z_I(z_1, z_2)}{Z} \approx mN \ln(z_1 \bar{z}_2) - m \ln(1 - \frac{R^2}{z_1 \bar{z}_2}). \tag{28}
\]

\( z_1 \) and \( z_2 \) can be considered to be even on the edge if the final result of the analytical continuation exists, i.e. if it is finite. This excludes the points \( z_1 = z_2 \) on the edge (\( |z_1| = |z_2| = R \)), where the above expression is logarithmically singular. Then, if \( z_1 = R \exp(\frac{i}{\pi}) \) and \( z_2 = R \), the electron correlator is (in the disc geometry)

\[
< L|\Psi^\dagger(z_1)\Psi(z_2)|L > = \frac{Z_I(z_1, \bar{z}_2)}{Z} \exp\{-\frac{1}{4}|z_1|^2\} \exp\{-\frac{1}{4}|z_2|^2\}. \tag{29}
\]

In the limit \( \frac{y}{m} \ll 1 \), where circular and rectangular geometries are indistinguishable, this becomes

\[
< L|\Psi^\dagger(z_1)\Psi(z_2)|L > \approx \frac{1}{y^m}, \tag{30}
\]

which coincides with the correlations on the edge obtained in the (more familiar) bosonization approach. Derivation of the electrostatic energy of the edge impurity in the Laughlin case using the weak-coupling plasma expansion. According to Wen’s idea, in order to find the equal–time electron correlator, it is sufficient to compute the electrostatic energy of
an impurity of charge \( m \) at a point \( z \) outside the Laughlin plasma. We now describe the diagramatic solution of this Statistical Mechanics problem. To simplify the calculation, we consider a plasma which extends over the half–plane \( x \leq 0 \) instead of a disc (in the thermodynamic limit, the choice of geometry is immaterial); the impurity coordinate is \( z = \xi \) (along the positive \( x \)-axis). The derivation of this electrostatic energy, using the weak-coupling plasma expansion, parallels that of the density in the bulk; i.e. calculating the electrostatic energy of a particle interacting with a negative background - the rest of the particles \([20]\). In the present case the system is not infinite in the \( x \)-direction, and that introduces a new type of vertex in the diagramatic expansion. The vertex connecting two interaction lines of momenta \( q_i, q_f \) in the \( x \)-direction, which in the infinite case is

\[
n \delta(q_i - q_f)
\]

(where \( n \) is the density), is replaced in the half-plane case by

\[
n = \frac{n}{2\pi} \left\{ -i(q_i - q_f) + \pi \delta(q_i - q_f) \right\},
\]

i.e. proportional to the Fourier transform of theta function,

\[
\int_0^0 \exp\{i(q_i - q_f)x\} dx =
\int_{-\infty}^{+\infty} \theta(-x) \exp\{i(q_i - q_f)x\} dx =
\frac{1}{-i(q_i - q_f)} + \pi \delta(q_i - q_f).
\]

The diagrams in Fig. 6 are all relevant and deserve special attention. Their value (at least in the long–distance limit) can be calculated by solving an integral equation for an effective vertex, \( V(q_i, q_f) \),

\[
V(q_i, q_f) =
\frac{n}{2\pi} \left\{ -i(q_i - q_f) + \pi \delta(q_i - q_f) \right\} +
\int dk \left\{ -i(q_i - k) + \pi \delta(q_i - k) \right\} \frac{-4\pi m}{(q^2 + k^2)} V(k, q_f).
\]
This equation can be schematically introduced as in Fig. 7, where we denoted only momenta along the $x$ direction. The momentum $q$ along the $y$ direction is the same on every line as in the infinite-plane case. Then the contribution of all diagrams in Fig. 6, summarized by the diagram on the left hand side of Fig. 7, can be expressed as

$$\frac{1}{2} \int \frac{dq}{(2\pi)} \int \frac{dq_i}{(2\pi)} \int dq_f \exp\{-i(q_i - q_f)\xi\} \times \frac{-4\pi m}{(q^2 + q^2_i)} V(q_i, q_f) \frac{-4\pi m}{(q^2 + q^2_f)}$$

(35)

The solution to the equation, given in the long-distance approximation, can be found in Appendix A. It reproduces the electrostatic energy of the impurity and its image charge in the half-plane case, corresponding to the leading contribution to the second term in Eq. (27) when the disc is considered to be large ($R \gg (|x| - R)$).

\[ \text{FIG. 7. The infinite sum of diagrams included in Fig. 6, represented as an integral equation for the effective vertex } V(q, q_f) \text{ (dotted double-circle).} \]

**B. Edge correlations in the compressible half-filled state**

Now we switch to the calculation of the edge correlations in the RR case using the diagrammatic method. We first consider the unprojected RR state, and as a basis of free waves that enter the Slater determinant, we choose

$$\frac{\exp(ik_y y)}{\sqrt{2\pi}} \times \cos(k_x x)$$

or

$$\frac{\exp(ik_y y)}{\sqrt{2\pi}} \times \sin(k_x x)$$

(36)

where $k_x$ and $k_y$ take values from a Fermi box (not sphere) in the $k$ - space. As in the Laughlin case, we assume that the radius of the Laughlin disc is very large in comparison with the distance (along the edge) over which we measure correlations. So, effectively, we again consider the half-plane problem for which, on the other hand, the basis choices (Eq. (36)) are also appropriate; there is no discrepancy between geometries of the Laughlin–Jastrow and free–wave part in the ground state, as in the full-plane case. In Eq. (36) the coordinate $x$ is measured from the edge of the half-plane, i.e. a tangent to the large disc. If, somehow, the charge and neutral (fermionic) part decouple on the edge, the choices (Eq. (36)) are quite natural, because they satisfy the requirement that the (neutral) current normal to the boundary is zero i.e., that the fermionic number is conserved.

First, we consider the correlations of the object introduced in Eq. 24 to which, due to the correspondence of its construction to the one of the Laughlin quasihole, we will refer as a quasihole. This, of course, does not entail that the quasihole is a well-defined object – eigenstate of the Hamiltonian, as in the case of the Laughlin quasihole. It might be such (on the edge) if we find that its correlations are of the same type as in the Laughlin case (Eq. (36)), and, therefore, the charge degrees of freedom (on the edge) in the RR state can be described in the Luttinger liquid framework (or, microscopically, by the possible states of quasiholes). Again, as in section III A, to mimic the charge part of the electron, in this case, we consider the correlations of the object constructed by putting $m$ ($m = 2$) quasiholes at the same place. Then, to find out if there is a departure from the Laughlin case, we consider the density of this object outside the half-plane system described by the RR state.

In the language of the modified plasma, we are placing a charged impurity (not directly connected to the plane-waves part) outside the system, and checking whether the image charge physics still holds. Due to the poor screening in this modified plasma, the charge induced by the external impurity does not accumulate near the edge (within a microscopic screening length) as in the ideal plasma. Rather, the induced charge is expected to slowly decay towards the interior of the system. To get a handle on the form of the electrostatic energy associated with this effect, we can employ the Thomas-Fermi approximation to compute the induced charge, given the dielectric properties of the modified plasma derived in the previous section (Eq. (24) and the proceeding discussion). The calculation is summarized in Appendix B. We find that unlike the Laughlin (ideal) plasma case, the leading behavior of the “image charge” electrostatic energy is a constant, rather than a logarithmically singular term. We now derive this result systematically in the diagrammatic expansion framework.

We first must find an effective vertex which corresponds to Eq. (23) in the Laughlin case, and represented by the diagrams in Fig. 6. That will be done at the same level of approximations as in the case of the bulk correlations. Explicitly, to find the value of the effective vertex, we consider the two contributions, direct and exchange, depicted symbolically in Fig. 8, in the simplest diagram with only two interaction lines. (The use of the dotted lines is to emphasize that we are now in the half-plane...
The direct contribution (unapproximated) for the first choice of basis for the Fermi sea in Eq. (36) is

\[
\frac{1}{2} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{\pi}{2} (4\pi m)^2 \int \frac{d^2p}{(2\pi)^2} \int \frac{d^2q}{(2\pi)^2} \times \left\{ \exp(-i(q_x - p_x)z) \frac{d^2 \delta(q_y - p_y) \times \int \exp(i(q_x - p_x) x_1) \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) \right\} (37)
\]

where the summation in \( \hat{k} \) runs over the Fermi box. This summation can be rewritten as

\[
\frac{1}{N} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{1}{2} \sqrt\frac{\pi}{4\pi m} \int \frac{d^2p}{(2\pi)^2} \int \frac{d^2q}{(2\pi)^2} \times \left\{ \exp(-i(q_x - p_x)z) \frac{d^2 \delta(q_y - p_y) \times \int \exp(i(q_x - p_x) x_1) \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) \right\} (38)
\]

The second part can be neglected, because it leads to an effective smearing of both the \( \delta \) – function \( \delta(p_x + q_x) \), and the pole \( \sim 1/(p_x + q_x) \) that we would get if it were a constant. The first part is the most important and singular in the infrared limit, which dominates the infinite summation above. Therefore, the direct contribution to the effective vertex is

\[
\frac{1}{2} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{1}{2} + \frac{1}{N} \sum_{k \in \text{F.S.}} \cos(2k_x x_1) (38)
\]

The second part can be neglected, because it leads to an effective smearing of both the \( \delta \) – function \( \delta(p_x + q_x) \), and the pole \( \sim 1/(p_x + q_x) \) that we would get if it were a constant. The first part is the most important and singular in the infrared limit, which dominates the infinite summation above. Therefore, the direct contribution to the effective vertex is

\[
\frac{1}{2} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{1}{2} + \frac{1}{N} \sum_{k \in \text{F.S.}} \cos(2k_x x_1) (38)
\]

The second part can be neglected, because it leads to an effective smearing of both the \( \delta \) – function \( \delta(p_x + q_x) \), and the pole \( \sim 1/(p_x + q_x) \) that we would get if it were a constant. The first part is the most important and singular in the infrared limit, which dominates the infinite summation above. Therefore, the direct contribution to the effective vertex is

\[
\frac{1}{2} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{1}{2} + \frac{1}{N} \sum_{k \in \text{F.S.}} \cos(2k_x x_1) (38)
\]

The second part can be neglected, because it leads to an effective smearing of both the \( \delta \) – function \( \delta(p_x + q_x) \), and the pole \( \sim 1/(p_x + q_x) \) that we would get if it were a constant. The first part is the most important and singular in the infrared limit, which dominates the infinite summation above. Therefore, the direct contribution to the effective vertex is

\[
\frac{1}{2} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{1}{2} + \frac{1}{N} \sum_{k \in \text{F.S.}} \cos(2k_x x_1) (38)
\]

The second part can be neglected, because it leads to an effective smearing of both the \( \delta \) – function \( \delta(p_x + q_x) \), and the pole \( \sim 1/(p_x + q_x) \) that we would get if it were a constant. The first part is the most important and singular in the infrared limit, which dominates the infinite summation above. Therefore, the direct contribution to the effective vertex is

\[
\frac{1}{2} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{1}{2} + \frac{1}{N} \sum_{k \in \text{F.S.}} \cos(2k_x x_1) (38)
\]

The second part can be neglected, because it leads to an effective smearing of both the \( \delta \) – function \( \delta(p_x + q_x) \), and the pole \( \sim 1/(p_x + q_x) \) that we would get if it were a constant. The first part is the most important and singular in the infrared limit, which dominates the infinite summation above. Therefore, the direct contribution to the effective vertex is

\[
\frac{1}{2} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{1}{2} + \frac{1}{N} \sum_{k \in \text{F.S.}} \cos(2k_x x_1) (38)
\]

The second part can be neglected, because it leads to an effective smearing of both the \( \delta \) – function \( \delta(p_x + q_x) \), and the pole \( \sim 1/(p_x + q_x) \) that we would get if it were a constant. The first part is the most important and singular in the infrared limit, which dominates the infinite summation above. Therefore, the direct contribution to the effective vertex is

\[
\frac{1}{2} \sum_{k \in \text{F.S.}} \cos^2(k_x x_1) = \frac{1}{2} + \frac{1}{N} \sum_{k \in \text{F.S.}} \cos(2k_x x_1) (38)
\]
taking into account that the quasiholes in the RR state are not well-defined, well-localized objects in the bulk (see the end of section II B), and certainly not on the edge where the screening seems to be even weaker than in the bulk.

Once we take this point of view that, in fact, the states described by the Laughlin quasihole construction on the edge are extended, a special care must be taken concerning their normalization. In general, the normalization is expected to depend on the size of the system (as in the case of the free waves (in the non–interacting system)). Therefore, the first contribution to the plasma electrostatic energy (Eq. (33)) (that through the infrared cut-off depends on the size of the system) might be a consequence of an incomplete normalization of the quantum–mechanical correlator at the beginning of our calculation. If this term is included (in the normalization) from the beginning, the value of correlator at large distances (in our approximation) approaches unity \[21\].

To find out the electron correlator, we must take into account the correlations that come from the neutral (plane-wave) part of the RR function, alone. These are not included in the preceding (modified plasma) calculations, which gave the correlator of the quasihole, the object that (in our approximation) carries the charge part of the electron. The neutral contribution is expected to be of the form

\[
\rho(x) \sim \frac{\sin(k_F y)}{y}, \tag{45}
\]

where \(g\) is a coefficient that depends on the boundary conditions. When combined with the charge correlator, it produces the usual (physical) decay of the electron correlator with the distance. Except for the dependence on the size of the system, the electron correlations on the edge are as if the system was a free (two-dimensional) Fermi gas of electrons. It can be shown that the same long-distance behavior of the correlations follows from the LLL projected wave function (Eq. (12)).

**IV. DISCUSSION AND CONCLUSIONS**

If we assume that, indeed, the whole description of the edge of the compressible state is equivalent to that of a free Fermi gas, we can try to predict the occupation numbers (probability density) of electron near the edge. Then the second choice for the boundary condition in Eq. (34) is more appropriate because the probability density \(\rho(x)\) should vanish at some point near the edge \((x \sim 0)\). The resulting probability-density distribution

\[
\rho(x) \sim \left[ k_F - \frac{\sin(2k_F x)}{2x} \right] \quad (x < 0), \tag{46}
\]

is very similar to the smooth function that one can get extrapolating the data that describe the occupation numbers for electron near the edge in (finite-system) exact-diagonalization studies \[22\], and the observed oscillations might be identified as the Friedel oscillations. Also, with the above assumption, the density of states for electron tunneling into the compressible edge would be similar to the one for tunneling into a Fermi liquid (metal). This is consistent with our intuitive expectations given the compressible nature of the system, if, loosely speaking, the characteristic energies for the motion of the charge and neutral (Fermi) part are comparable.

We believe that it would be possible to construct an effective \(1 + 1\) dimensional theory along the edge, which has the same correlations that we expect, taking the coordinate normal to the edge to corresponds to time i.e. \(x \equiv vt\), and translating our diagramatic calculations into an effective interaction between a neutral and charged part. This would yield a model for the suppression of the correlation of the chiral boson theory \[43\] (charge part), which assumes that its neutral and charge components move with the same velocity \((v_c = v_n = v)\) along the edge. If the model is generalized to the one for which \(v_c > v_n\), at sufficiently large momenta–high energies where the exchange part of the interaction is suppressed (due to a reduced overlap of the two one-dimensional spheres), we expect that the chiral boson correlations will be released. Therefore, the difference in the dynamics of the charge and neutral part appear to be a necessary condition for the decoupling of the edge and bulk (the charge and neutral part) at high enough energies, as seen in experiments \[10\]. (For a similar explanation of the simultaneous suppression of the neutral part see \[12\].) The “true” (low-energy) correlations should reflect the compressible nature of the system.

In contrast with the edge problem, the bulk correlations in the compressible case that we considered seem to be similar to the ones in the incompressible case. The GM correlations are almost identical, and, due to the finite screening, the quasiholes (correlation holes) have a chance to be considered as well-defined (albeit very extended) objects (like skyrmions when the compressible degree of freedom – spin – is included in the incompressible problem \[23\]). This, intuitively, gives an additional support to the quasiparticle pictures of the bulk that we have by now. On the other hand, the edge correlations differ completely from the ones in the incompressible case. In incompressible states the edge physics is a reflection of the bulk physics, and the same quasiparticle picture of the bulk is possible on the edge. In the compressible case, and, in the plasma analogy, due to the very weak screening on the edge, we probably can not talk about existence of the correlation hole which, in Read’s picture of the bulk, attracts an electron, and creates a weakly–interacting composite object – a Fermi quasiparticle. In the scope of our approach, and in the first approximation, electrons are unbounded and the edge of the compressible state appears to be similar to the edge of free electron gas (with an appropriate boundary condition).

S. would like to thanks the hospitality and support of the Institute of Theoretical Physics in UCSB, Santa Barbara, where part of this work has been carried out.

APPENDIX A:

We consider the integral equation (34) for the case of a general vertex

\[ b \pi \frac{1}{-i(q_i - q_f)} \left[ \alpha(q_i)\pi a \delta(q_i - q_f) + \beta(q_i; q_f)\delta(q_i - q_f) + f(q_i, q_f) \right] \]

Then, the integral equation can be rewritten as

\[ V(q_i, q_f) \left[ 1 - \frac{\pi a c b}{q^2 + q_i^2} \right] = c \sum_{i} \frac{1}{-i(q_i - q_f)} + \pi a \delta(q_i - q_f) + b \int dk \frac{V(k, q_f)}{i(k - q_i)(k^2 + q^2)} \]

where \( b = -4\pi m \). If we try simply to iterate the equation in the limit when \( q_i \to q_f \) we find that each iteration produces a solution of the form

\[ V(q_i, q_f) = \frac{\alpha(q_i, q_f; q)}{-i(q_i - q_f)} + \frac{\beta(q_i; q)\delta(q_i - q_f) + f(q_i, q_f; q)}{\mid = b \pi \frac{1}{-i(q_i - q_f)} \left[ 1 + \beta b q^2 + q_i^2 \right] + \pi a \delta(q_i - q_f) + b \pi \frac{f(q_i, q_f)}{q_i^2 + q^2} + \frac{f(iq, q_f)}{iq (iq - q_i)} \] 

where \( \alpha(k) \equiv \alpha(k, q_i; q) \). In order to equate the \( \delta \)-functions on both sides, (at \( q_i = q_f \)), \( \beta \) must be

\[ \beta = \frac{\pi a c b}{1 - \frac{\pi a c b}{q^2 + q_i^2}} \]

Then we equate the coefficients with \( \frac{1}{-i(q_i - q_f)} \) at the point \( q_i = q_f \), to get

\[ \alpha(q_i, q_f; q) \bigg|_{q_i = q_f} = \frac{c(q^2 + q_i^2)^2}{(q^2 + q_i^2 - \pi a b c)^2} \]

To be consistent with the iteration result (and also with symmetry arguments),

\[ \alpha(q_i, q_f; q) = c \frac{q_i^2 + q_f^2}{(q^2 + q_i^2 - \pi a b c)(q^2 + q_f^2 - \pi a b c)} \]

although it is not consistent with our assumption that \( \alpha \) is an analytic function at the beginning of the substitution of Eq. (A3). Still, it does satisfy the assumption in its long distance version

\[ \alpha(q_i, q_f; q) \approx \frac{c}{(\pi a b c)^2} \frac{(q^2 + q_i^2)(q^2 + q_f^2)}{(q^2 + q_i^2 - \pi a b c)(q^2 + q_f^2 - \pi a b c)} \]

and the same approximation must be employed in the previous equations.

To complete the solution we must find \( f(q_i, q_f; q) \) from the remaining equation

\[ [1 - \pi(a + 1) b c] \frac{1}{q^2 + q_i^2}] f(q_i, q_f) = \pi c b \frac{f(iq, q_f)}{iq (iq - q_i)} \]

(We used \( \alpha(iq) = 0 \) which is consistent with the fact that the poles at \( k = \pm iq \) in \( \frac{\alpha(k)}{k^2 + q^2} \) at the beginning of the calculation were spurious.) In the long–distance (or small–momentum) approximation, i.e. when

\[ (a + 1) \frac{f(q_i, q_f; q)}{iq + q_i} \approx \frac{f(iq, q_f; q)}{iq} \]

a nontrivial (nonzero) solution exists only when \( a = 1 \) (Laughlin case). It is

\[ f(q_i, q_f; q) = q_i + iq \]

in the limit when \( q_i \to q_f \) (irrespective from the value of \( c \)).

By power counting or by explicit calculation we can find out that the leading contribution in the Laughlin
case comes from the latter part of the solution. An introduction of an infrared cut-off is necessary, but the dependence on it disappears when the $\delta$ - function part of the solution is included. When substituted in Eq. (55), this yields

$$- m \ln(\xi \Lambda) \tag{A12}$$

as the electrostatic energy of the impurity and its image counterpart in the longdistance approximation, where $\Lambda$ is an ultraviolet cut-off (corresponding, e.g., to the inverse screening length of the plasma). There is no dependence on the infrared cut-off, because we are considering a half-plane (semi-infinite) system, and are recovering the well known result for that case.

APPENDIX B: “IMAGE CHARGE” INTERACTION ENERGY IN A MODIFIED PLASMA

We consider a point-like impurity of charge $m$, placed at a distance $\xi$ from the edge of a two-dimensional modified plasma which occupies the half-plane $x \leq 0$. The plasma is characterized by a wave-vector dependent dielectric constant of the form

$$\epsilon(q) = 1 + \frac{q_0}{q}, \quad \text{where} \quad q_0 = \frac{3 k_f}{4 \pi^2} \tag{B1}$$

and $q = |q|$ (see Eqs. (14) and (24)). The electrostatic potential generated by the charge distribution, that the external impurity induces in the plasma, is given by

$$V_{\text{ind}}(\vec{r}) = V_{\text{sc}}(\vec{r}) - V_{\text{ex}}(\vec{r}) \tag{B2}$$

here $V_{\text{sc}}(\vec{r})$ is the screened potential of the impurity

$$V_{\text{sc}}(\vec{r}) = m \int d^2 r' D(\vec{r}, r') \ln |r - \xi \hat{x}|, \quad \text{where} \quad D(\vec{r}, r') = \theta(-x) \theta(-x') \int \frac{d^2 q}{(2\pi)^2} e^{-i\vec{q} \cdot (\vec{r} - \vec{r}')} \epsilon^{-1}(q), \tag{B3}$$

and $\epsilon(q)$ is given by Eq. (B1) (the Theta functions restrict the screening to the half-plane occupied by the plasma). This yields (in $q$-space)

$$V_{\text{ind}}(q) = -\frac{m \pi q_0 e^{-|q_y| \xi}}{(q + q_0)|q_y|(|q_y| - i q_x)}. \tag{B4}$$

The (two-dimensional) Poisson equation then relates this component of the potential to the induced charge

$$\rho_{\text{ind}}(q) = q^2 \frac{1}{2 \pi} V_{\text{ind}}(q) = -\frac{m q_0}{2} \left( \frac{|q_y| + i q_x}{{(q + q_0)|q_y|}} \right) e^{-|q_y| \xi}. \tag{B5}$$

The Fourier transform of Eq. (B7) yields

$$\rho_{\text{ind}}(\vec{r}) = -\theta(-x) \frac{m}{4\pi q_0} \mathcal{R}(r^2 - \xi^2 + 2i\xi y)^{-3/2}, \tag{B6}$$

where $\mathcal{R}$ denotes the real part, and $r^2 = x^2 + y^2$. Note that this charge distribution decays algebraically towards the interior of the plasma, indicating its anomalously poor screening properties. The electrostatic energy associated with the interaction of the impurity and the induced charge is then found to be (to leading order in small $\xi$)

$$E_{\text{el}} \approx -\frac{m^2 \Lambda}{4 q_0} \ln \frac{\Lambda}{q_c}. \tag{B7}$$

The higher order corrections decrease as a function of $\xi$. Multiplying by the inverse temperature $\beta = 2/m$, and with the appropriate definition of the ultraviolet cutoff $\Lambda$, this result coincides with Eq. (13), and hence is consistent with our diagramatic approach.

[15] The bulk correlations were already calculated in [14].

[16] This can be compared with the exact value in the case $m = 1$, for which $\beta \Delta f_\infty = -0.03942$ [4]. (The case $m = 1$ is the upper limit for the expansion that we consider.)

[19] This term has the expected singularity as the edge ($|z| = R$) and reduces to $-m \ln \frac{2(|z| - R)}{R}$, as the radius of the disc is increased.

[20] In that case the contributions of the diagrams multiplied by a minus sign should sum up to account for the positive background potential $\sim \frac{1}{2} |z|^2$.

[21] We thank X.-G. Wen for this suggestion.
