Abstract—This paper experimentally evaluates continuum deformation cooperative control for the first time. Theoretical results are expanded to place a bounding triangle on the leader-follower system such that the team is contained despite nontrivial tracking error. Flight tests were conducted with custom quadrotors running a modified version of ArduPilot on a BeagleBone Blue in M-Air, an outdoor netted flight facility. Motion capture and an onboard inertial measurement unit were used for state estimation. Position error was characterized in single vehicle tests using quintic spline trajectories and different reference velocities. Five-quadrotor leader trajectories were generated, and followers executed the continuum deformation control law in-flight. Flight tests successfully demonstrated continuum deformation; future work in characterizing error propagation from leaders to followers is discussed.

I. INTRODUCTION

Cooperative control is a popular area of theoretical research. Virtual structure (VS) [1], consensus [2]–[4], containment control [5], [6], and continuum deformation [7], [8] are examples of multi-agent system (MAS) control. VS is a centralized approach, while others are decentralized. Consensus is the most commonly-applied decentralized cooperative control technique [3], [4], [9]–[11]. Distributed consensus was applied for agent coordination in [12], [13] and flight tested in [14], [15]. Consensus guided by a single leader is studied in [16], [17] and flight tested in [18], [19]. Cooperative control has been applied to unmanned aircraft system (UAS) teams for tasks such as surveillance [20], area surveys [21], and payload delivery [22].

Continuum deformation, the approach experimentally evaluated in this paper, treats agents as particles of a body that deforms under a homogeneous transformation [7], [23]. A desired n-D homogeneous transformation \( n = 1, 2, 3 \) is defined by \( n + 1 \) leaders in \( \mathbb{R}^n \) and acquired by followers through local communication. Shared state data is weighted based on a reference configuration. Continuum deformation stability is analyzed in [7], while coordination under switching communication topologies is studied in [8]. Characterization of the homogeneous transformation and safety guarantees are key features of continuum deformation.

This paper presents results from the first experimental evaluation of continuum deformation. Single-agent error is characterized and used in designing leader agent trajectories that satisfy four constraints: (1) Follower containment, (2) Collision avoidance, (3) Bounding of agent deviation from local desired position, and (4) Bounding of agent deviation from global desired position. A five-quadrotor team receiving motion capture data is deployed in tests. Leaders execute prescribed trajectories; followers receive neighbor positions via the communication topology in Fig. 1C. Tracking errors of leaders and followers are analyzed with respect to the bounding envelope designed to contain the team given expected single-vehicle deviations.

Sec. II summarizes continuum deformation theory, while Sec. III describes leader flight planning and presents test trajectories. Sec. IV summarizes the experimental apparatus including quadrotors, electronics, sensors, and software. Sec. V presents flight test results, followed by a discussion (Sec. VI) and conclusion (Sec. VII).

II. CONTINUUM DEFORMATION COORDINATION REVIEW

A 2D continuum deformation is defined by a homogeneous transformation [24]:

\[
t \geq t_0, \mathbf{r}_{i, HT}(t) = Q(t, t_0)\mathbf{r}_{i, 0} + \mathbf{d}(t, t_0),
\]

where \( t_0 \) denotes the initial time, \( Q = \begin{bmatrix} Q_{1,1} & Q_{1,1} \\ Q_{2,1} & Q_{2,2} \end{bmatrix} \) is the Jacobian matrix, \( \mathbf{d} = \begin{bmatrix} d_1 \\ d_2 \end{bmatrix} \) is the rigid body displacement vector, and \( \mathbf{r}_{i, HT} = \begin{bmatrix} x_{i, HT} \\ y_{i, HT} \end{bmatrix} \) is the global...
desired position of agent i. Note that \(d(t_0, t_0) = 0 \in \mathbb{R}^{2 \times 1}\), and \(Q(t_0, t_0) = L_2 \in \mathbb{R}^{2 \times 2}\), so \(r_{i,0} = r_{i,HT}(t_0) = [x_{i,0} y_{i,0}]^T\) is the initial position of quadrotor \(i \in \mathcal{V}\) and \(t_0\) is initial time.

**Continuum Deformation Definition:** A 2D homogeneous transformation can be acquired by an \(N\)-agent quadrotor team with index numbers \(\mathcal{V} = \{1, \cdots, N\}\). Let \(\mathcal{V} = \mathcal{V}_L \cup \mathcal{V}_F\), with leaders \(\mathcal{V}_L = \{1, 2, 3\}\) and followers \(\mathcal{V}_F = \{4, \cdots, N\}\). Leaders form a leading triangle for all \(t \geq t_0\). Followers acquire the continuum deformation by local communication. Leader positions can be uniquely related to \(Q\) and \(d\) [7]:

\[
t \geq t_0, \quad \left[\begin{array}{c}
vec(Q^T) \\
d
\end{array}\right] = \left[\begin{array}{c}
I_2 \otimes P_0 \\
I_2 \otimes I_3
\end{array}\right]^{-1} \vec(P_{HT}),
\]

where "\(\otimes\)" is the Kronecker product symbol, \(I_2 \in \mathbb{R}^{2 \times 2}\) is the identity matrix, and \(I_3 \in \mathbb{R}^{3 \times 1}\) is the one-entry matrix,

\[
P_0 = \left[\begin{array}{c}
I_{1,0}^T \\
I_{2,0}^T \\
I_{3,0}^T
\end{array}\right] \in \mathbb{R}^{3 \times 2}, \quad P_{HT} = \vec\left[\begin{array}{c}
I_{1,HT}^T \\
I_{2,HT}^T \\
I_{3,HT}^T
\end{array}\right].
\]

**Continuum Deformation Acquisition:** A weighted directed graph \(G = (\mathcal{V}, E)\) defines inter-agent communication as shown in Fig. 1. Given edge set \(E \subset \mathcal{V} \times \mathcal{V}\), the in-neighbor agents of follower \(i \in \mathcal{V}_F\) is defined by

\[
\forall i \in \mathcal{V}_F, \quad \mathcal{N}_i = \{j|i \in \mathcal{V}_F, j \in \mathcal{N}_i\}.
\]

For an \(n\)-D continuum deformation, \(|\mathcal{N}_i| = n + 1, \forall i \in \mathcal{V}_L\) and in-neighbor agents of every follower form an \(n\)-D polytope. Therefore, each follower communicates with three in-neighbor agents, forming a triangle in a 2D continuum deformation. Let \(i_1, i_2, \text{ and } i_3\) denote index numbers of follower \(i\)'s in-neighbor agents, initially positioned at \(r_{i,0}\), \(r_{i,0}\), and \(r_{i,0}\). Then, communication weights of follower \(i \in \mathcal{V}_F\) denoted \(w_{i_1,i}, w_{i_2,i}, \text{ and } w_{i_3,i}\) are given by [7]:

\[
\left[\begin{array}{c}
w_{i_1,i} \\
w_{i_2,i} \\
w_{i_3,i}
\end{array}\right] = \left[\begin{array}{ccc}
x_{i_1,0} & x_{i_2,0} & x_{i_3,0} \\
y_{i_1,0} & y_{i_2,0} & y_{i_3,0} \\
1 & 1 & 1
\end{array}\right]^{-1} \left[\begin{array}{c}
x_{i,0} \\
y_{i,0} \\
1
\end{array}\right].
\]

(3)

Let \(r_i\) denote actual position of agent \(i \in \mathcal{V}\). The desired trajectory of follower \(i \in \mathcal{V}_F\), i.e., local desired position, is:

\[
r_{d,i} = \begin{cases} 
  r_{i,HT} & i \in \mathcal{V}_L \\
  r_{d,i} = \sum_{j \in \mathcal{N}_i} w_{i,j} r_j & i \in \mathcal{V}_F
\end{cases}
\]

(4)

where \(r_{d,i}\) is the reference trajectory of each quadrotor \(i \in \mathcal{V}\).

**Continuum Deformation Coordination Safety:** Given leader desired trajectories, we define a bounding triangle as a dilation of the original leading triangle with the following properties: (1) Both leading and bounding triangles have a common centroid at any time \(t\), (2) Parallel sides of both triangles are separated by \(D_1\) at any time \(t\) (see Fig. 2).

**Theorem 1:** Assume each quadrotor is enclosed by a ball of radius \(\epsilon\). \(D_1\) denotes the minimum separation distance between any pair of agents at \(t = t_0\). \(D_0\) is the minimum distance from any follower to the leading triangle boundary, and \(D_1 = \delta + \epsilon\) is the distance of two parallel sides of the leading and bounding triangles. If the deviation of every quadrotor \(i \in \mathcal{V}\) does not exceed \(\delta\), \(\|r_i - r_{i,HT}\| \leq \delta, \forall i \in \mathcal{V}\).

Let

\[
\delta_{\text{max}} = \min \left\{ \frac{D_L - 2\epsilon}{2}, D_H - \epsilon \right\}.
\]

(5)

Inter-agent collision avoidance is guaranteed, no follower leaves the leading triangle, and no agent leaves the bounding triangle if

\[
\lambda_{\text{min}} \leq \inf_{\mathcal{V}} \left\{ \lambda_1(t), \lambda_2(t) \right\},
\]

(6)

where

\[
\lambda_{\text{min}} = \frac{\delta + \epsilon}{\delta_{\text{max}} + \epsilon}.
\]

(7)

\(\lambda_1\) and \(\lambda_2\) denote eigenvalues of matrix \(U_D = (Q^T Q)^{1/2}\).

**Proof:** See the proof in [25]. \(\blacksquare\)

**III. Generating the Leading Triangle Path**

Flight tests investigate if real-world continuum deformation will satisfy four constraints: follower containment within the leading triangle, collision avoidance between agents, bounding of deviation from local desired position, and bounding of deviation from global desired position. To evaluate, leaders are set as close together as they theoretically can be. Leader separation is given by scaling factor \(\lambda_{\text{min}}\).
desired velocity serves as a feed-forward term in the velocity-tracking portion of the cascaded PID controller (Sec. [IV]). Time of flight \((t_f - t_0)\) between each pair of poses is 3.75s resulting in a translation of 1m when \(v_{max} = 50 \text{cm/s}\).

IV. EXPERIMENTAL SETUP

Five identical quadrotors were constructed from off-the-shelf hobbyist components and 3D-printed parts (Fig. [I]). The frame measures 33cm diagonally between each pair of 920kV brushless DC motors controlled by 600Hz Electronic Speed Controllers (ESCs) spinning 8"x4.5" nylon propellers. A 3S 3000mAh Lithium Polymer battery provides power, and a BeagleBone Blue runs a modified version of the ArduPilot (APM) open-source software. A propeller guard frame consists of four custom 3D-printed corner pieces connected by eight carbon fiber rods. The propeller guard assembly measures 56cm diagonally \((\epsilon = 28\text{cm})\), has a mass of 200g, and provides resilience against minor in-flight collisions. Each vehicle has mass 1075±10g.

Fig. 4 describes the experimental setup. Vehicle state is provided by an Optitrack motion capture system with eight Prime13 cameras. A BeagleBone Black Ground Control Station receives pose estimates of all vehicles from the motion capture system and uses individual 2.4GHz XBee radios to send pose estimate, desired position (followers only), and a synchronization state variable at 60Hz to each quadrotor. A 40ms time delay was measured experimentally between Optitrack pose receipt on the vehicle and APM’s onboard state estimate. A pilot uses a 2.4GHz DSMX Transmitter for manual override in case of system anomalies; a separate computer receives telemetry data from each vehicle over WiFi. All multi-vehicle tests were conducted in M-Air, an 80′x120′x50’ outdoor netted facility at the University of Michigan. A wind vane and cup anemometer were used to obtain wind data. Outdoor tests were conducted at night to improve motion capture performance.

Fig. 5 outlines vehicle software. We modified APM’s cascaded proportional-integral-derivative (PID) position control to use Optitrack position data. In cascaded PID, position tracking error is scaled by a proportional gain and added to the feed-forward velocity set by desired velocity \(\dot{r}_d\). Velocity estimates are obtained from a derivative filter on position estimate (Eq. [9]) where \(T\) is the sampling period [26]. Velocity tracking error becomes a desired acceleration and error from the acceleration tracking loop is fed into an attitude controller that relies on three-axis onboard inertial measurement unit (IMU) data. APM runs the control loop at 400Hz. Leaders
TABLE I: Statistical parameters of controller error increase as $v_{\text{max}}$ increases. Tests performed indoors at 150cm altitude.

| $v_{\text{max}}$ (cm/s) | Mean (cm) | Std. Dev (cm) | Max (cm) |

use a synchronization state variable and a pre-loaded flight path file to generate desired positions and velocities for the position controller. Followers receive a position setpoint via XBee that is the weighted sum of its neighbors’ real-time positions set per continuum deformation.

$$\dot{r}(t) = \frac{1}{8T} \left[2 \left(r(t-T) - r(t-3T)\right) + \left(r(t) - r(t-4T)\right)\right]$$

V. EXPERIMENTAL RESULTS

We conducted a series of flights with a single vehicle to empirically bound controller error, $\delta_c$. Results were used to set bounding parameter $\delta$ as $\delta_c$ in the computation for $\lambda_{\text{min}}$ in Eq. [7]. Given the set of prescribed leader trajectories, we command the follower agents in two ways. In the first test series, (Sec. V-A) we set the desired position of each follower $(r_{d,f},)$ to its global desired position $(r_{l,HT})$ $\forall i \in V_F$ as depicted in Fig. 2. In effect, the desired position of the followers is a weighted sum of leaders’ desired positions. With this approach, $\delta_c$ and $\delta$ are equivalent meaning collision avoidance and containment are guaranteed from Thm. [4]. In the second approach (Sec. V-B) we compute desired follower positions as a weighted sum of the actual position of three neighbor agents as prescribed in Eq. [4] (using the weights in Eq. [10]). This approach, although more practical for a large and spatially distributed system (due to shorter communication links), no longer guarantees that the controller error bound for each agent $\delta_c$ is a bound on the global deviation of the followers $\left\| r_i - r_{l,HT} \right\| \forall i \in V_F$.

$$\begin{bmatrix} w_{4,1} \\ w_{4,3} \\ w_{4,5} \end{bmatrix} = \begin{bmatrix} 0.5 \\ 0.134 \\ 0.366 \end{bmatrix}, \begin{bmatrix} w_{5,2} \\ w_{5,3} \\ w_{5,4} \end{bmatrix} = \begin{bmatrix} 0.5 \\ 0.134 \\ 0.366 \end{bmatrix}$$

A. Determining Controller Error

To determine controller error bound $\delta_c$, we flew a single vehicle in a 1m edge-length square while varying parameters to characterize error sources. Parameters varied include battery voltage and environment (indoor vs. outdoor with negligible wind). Largest desired velocity from quintic spline guidance ($v_{\text{max}}$), and altitude above ground level. We also considered the effect of disturbances induced by nearby vehicles by flying all five agents, with followers using global desired positions, to see if controller performance varied from the single-vehicle tests.

Results show that battery voltage, indoor vs. outdoor environment, and altitude above ground (minimum 1m) have negligible impact on controller error $\delta_c$. Battery voltage was varied from 11.4V to 12.5V, a typical operating range, with less than 10% change in $\delta_c$. We varied flight altitude from 0.75m to 1.75m in increments of 0.25m, with a 15% larger standard deviation in error at 0.75m than at other altitudes. Since all altitudes above 0.75m had similar performance, we flew multi-agent tests at 1.5m above ground level.

To check dependence on $v_{\text{max}}$, a single vehicle was flown using the quintic spline guidance law from Eq. [8]. We relax the constraint on final desired position $(r_{d,f}(t_f)) = r_{f,i}$ and instead command a particular velocity halfway through each flight segment $(r_{d,i}(\frac{V_{\text{max}}}{2}) = v_{\text{max}}$. For this test series, time of flight between each waypoint pair is fixed at $(t_f - t_0) = 3.75$s which results in a translation of 1m when $v_{\text{max}} = 50$ cm/s.

Table I shows that tracking error mean, max, and standard deviation increase as $v_{\text{max}}$ increases. We believe a large source of error is introduced in state estimate delay. Each agent receives a position estimate from Optitrack with about a 40ms delay. Then, a derivative filter (Eq. [9]) is used on position data to estimate the actual velocity. The filter adds an additional delay to the velocity estimate, but characterization of the derivatives filter’s delay and its effects on position error was not explored for this paper.

For data shown in Table I, the $v_{\text{max}} = 0$ cm/s hover case is computed over 40 flights. The other datapoints, $v_{\text{max}} = \{25, 50, 75, 100\}$ cm/s in Table I have ten flights for each $v_{\text{max}}$. All flights in this dataset were conducted indoors at an altitude of 150 cm above the floor.

To investigate downwash impact on neighboring agents, we flew all five quadrotors with followers using global desired positions and compared results to those in Table I. Leaders flew the trajectory from Sec. III with $\delta = 40$ cm, $(t_f - t_0) = 3.75$s and $v_{\text{max}} = 50$ cm/s as before. Two full flights with five vehicles were flown resulting in ten datasets overall.

Table II shows the results of the five-agent flights alongside the single-agent flight data copied from the 50 cm/s case in Table I. For the five-agent flights, agent 4 had an anomaly where it did not run any controller-related computations for 0.3s resulting a maximum error of 41.68cm. which is treated as an outlier and excluded from error characterization.

During the five-agent flights, the XBees occasionally drop packets. Fig. 6 shows the change in time $\Delta t$ between two
 consecutively Optitrack pose estimates received by an agent over XBee. Fig. 6a shows a typical single-agent flight while Fig. 6b is from a five-agent flight where the larger $\Delta t$ corresponds to an integer number of packets lost. Five-agent flights may have larger error in part because of Optitrack data packet drop. Results from Tables I and II show that an error bound of $\delta_e = 40$cm is sufficient. The first five-agent flights sent followers global desired positions to support analysis of continuum deformation constraints in Sec. V-B.

B. Five-Agent Flight: Followers with Pre-set Waypoints

Fig. 7 shows the results for a five-agent test with follower positions based on a weighted sum of the leader desired positions. The wind speed was measured to be 0mph. $\delta = 40$cm was used as a conservative error bound. This test was run to distinguish experimental setup error sources (downwash, communication interference, etc) from coordination-induced error. The four plots in Fig. 7 show team performance with respect to the four constraints from Sec. III: follower containment within the leading triangle, collision avoidance between agents, bounding of deviation from the local desired position, and bounding of deviation from the global desired position. The black vertical lines on each plot use the same symbols from Fig. 6 to show the desired waypoint of the leaders in time. The unlabeled vertical lines between Star (♦) and Diamond (◦) represent an intermediate waypoint added to fit all agents within our motion capture workspace.

Fig. 7A shows the distance from both followers to the leader boundary with a flat horizontal line at $\epsilon = 28$cm and another horizontal line at $-\delta = -40$cm. Crossing the $\epsilon$ line means the follower left the leader boundary while crossing the $-\delta$ line means the follower left the outer bounding triangle. Thus, the followers never leave the leading triangle since their lines never go below the horizontal $\epsilon$ line. Fig. 7B shows each agent’s distance to its nearest neighbor along with a $2\epsilon = 56$cm line. There are no inter-agent collisions because no agent has a distance that goes below the $2\epsilon$ line. Fig. 7C and Fig. 7D show the deviation of each agent from its local and global desired position. No agent has a local or global deviation exceeding $\delta = 40$cm (represented by the horizontal line). Figs. 7A and 7B are identical since followers are being commanded to global desired positions.

C. Five-Agent Flight: Followers with Local Communication

Fig. 8 shows results for the five quadrotor system running continuum deformation under local communication. The average wind speed was 2.1mph at 75° relative to $+X$ (effectively the direction of motion in Fig. 6B; $\Box$ to $\bigcirc$).

Figs. 8B and Figs. 8C show there are no inter-agent collisions and that no agent exceeds the local deviation bound. Fig. 8D shows that followers violate the global deviation constraint in all segments except when the formation moves in the direction of the wind: $\Box$ to $\bigcirc$ and $\bigcirc$ to the intermediate waypoint). In segments where the global deviation constraint is satisfied, neither follower leaves the leader triangle as predicted by Thm. 1. However, there is a segment (intermediate waypoint to $\bigcirc$) where followers violate global deviation while within the leader boundary.

The large follower deviation in Fig. 8D is caused in part by steady-state error in agent $y$-components, most likely due to wind which effectively shifted the entire formation in $+Y$. Follower local desired positions ($\mathbf{r}_{i,LT}$) shift with the leaders while their global desired positions ($\mathbf{r}_{i,HT}$) are unaffected, resulting in a compounding error effect with respect to the follower global desired position reference.

VI. DISCUSSION

In tests where local deviation is equivalent to global deviation (Fig. 7), all four constraints were met. Under strictly local communication of actual positions (Fig. 8), collision and local deviation constraints were met while containment and global deviation were violated. All constraints were satisfied in segments of the flight where the global deviation constraint was met (Thm. 1). However, we found it difficult to predict follower deviation in advance as time delay and error compounding from leaders to follower could not be observed in single-vehicle tests. A large error bound can be
substantially separated which may not be practical.

Errors observed in continuum deformation flights, but such prescribed to satisfy all constraints based on evaluation of errors observed in continuum deformation flights, but such a conservative approach would require the quadrotors to be substantially separated which may not be practical.

VII. CONCLUSION

This paper presented results from the first experimental evaluation of continuum deformation using a five-quadrotor team. Results successfully demonstrated the theory in an outdoor motion capture environment but motivate follow-on work to incorporate knowledge of single-vehicle error bounds into prescribed leader trajectories and in turn continuum reference geometries. Although this paper demonstrated scaling and translation of a 2D leading triangle, continuum deformation allows shear, rotation, and composition of these four fundamental deformations simultaneously. We plan to conduct further experiments that test constraint satisfaction given more complex leader trajectories.
