ARTICLE

Plant roots increase both decomposition and stable organic matter formation in boreal forest soil

Bartosz Adamczyk, Outi-Maaria Sietiö, Petra Straková, Judith Prommer, Birgit Wild, Marleena Hagner, Mari Pihlatie, Hannu Fritze, Andreas Richter & Jussi Heinonsalo

Boreal forests are ecosystems with low nitrogen (N) availability that store globally significant amounts of carbon (C), mainly in plant biomass and soil organic matter (SOM). Although crucial for future climate change predictions, the mechanisms controlling boreal C and N pools are not well understood. Here, using a three-year field experiment, we compare SOM decomposition and stabilization in the presence of roots, with exclusion of roots but presence of fungal hyphae and with exclusion of both roots and fungal hyphae. Roots accelerate SOM decomposition compared to the root exclusion treatments, but also promote a different soil N economy with higher concentrations of organic soil N compared to inorganic soil N accompanied with the build-up of stable SOM-N. In contrast, root exclusion leads to an inorganic soil N economy (i.e., high level of inorganic N) with reduced stable SOM-N build-up. Based on our findings, we provide a framework on how plant roots affect SOM decomposition and stabilization.

Boreal forests are key components of the global carbon (C) cycle due to their high C storage and enormous potential for C sequestration into soil organic matter (SOM). Nevertheless, with climate change SOM decomposition might increase shifting boreal forests from C sinks to C sources, thereby accelerating global warming. The mechanisms behind accumulation and stabilization of SOM in boreal forest soils are poorly understood but essential for predicting C stocks in a future climate. The boreal forest C storage is tightly linked to the nitrogen (N) cycle, which is characterized by the binding or complexation of a large fraction of soil N to other soil compounds such as minerals and polyphenols, resulting in low N availability. Thus forest soil N is to a large extent present in chemically stable form, with the remainder in labile form (easily available N forms, dissolved inorganic and organic N) or retained in living organisms, e.g. mycorrhizal fungi.

Transformations of boreal forest SOM are driven by a complex network of interactions among soil microorganisms, including ectomycorrhizal and ericoid mycorrhizal (EEM) fungi, saprotrophic fungi, bacteria, and plant roots. Plant roots support microorganisms in the rhizosphere, i.e. in the narrow soil zone surrounding roots, with easily available C, which may stimulate microbial activity and thereby increase SOM decomposition (referred to as the rhizosphere priming effect). Interactions between different microbial guilds can further influence SOM decomposition rates; for instance, EEM fungi may suppress fungal saprotrophs, thereby decreasing SOM decomposition and carbon dioxide (CO$_2$) production (a phenomenon known as the Gadgil effect). In addition to soil microorganisms, soil fauna may enhance the SOM decomposition by fragmentation and processing dead organic matter into a more available form for microbes. An emerging view underlines the role of microorganisms not only in SOM decomposition but also in SOM stabilization, i.e. the transformation of SOM into more stable forms. According to the microbial carbon pump concept, microorganisms metabolically process plant residues and generate biomass, and microbial residues are stabilized in soil (in vivo turnover) via multiple mechanisms including reactions with minerals and soil aggregates. Alternatively, microbial enzymes may stabilize plant residues by transforming them into less-available forms (ex vivo modification). Overall, EEM plants may thus accelerate SOM decomposition through the rhizosphere priming effect or decelerate decomposition (e.g. via the Gadgil effect) and increase the formation of stable SOM (e.g. via the microbial C pump). The balance between microbial priming and soil C increase has been proposed to regulate the stable soil C pool. Although crucial for modelling responses of SOM stocks to land use and climate change, an in-depth mechanistic understanding of SOM transformations is still lacking.

This study aims to elucidate the mechanisms underlying SOM transformations and improve our understanding of its controls, especially those related to N pools. The classic hypothesis is formed that roots and associated microorganisms would stimulate microbial biomass growth and activity (priming) and consequently SOM decomposition rates including stable SOM to obtain N for plants and vice versa the lack of roots would result in lower decomposition rates (hypothesis 1). Alternatively, this root-induced priming effect is at some point exceeded by the build-up of stable SOM-N from decomposition-released organic C and N inputs (hypothesis 2). This would lead to stable soil C formation especially in treatment with roots providing significant amounts of C and N inputs.

Here we test these hypotheses in a field experiment where mesh bags filled with unsterilized, homogenized soil organic layer with the natural microbial community were returned into the organic layer of the boreal pine forest soil and collected after one, two and three growing seasons. Three mesh sizes were compared that excluded the ingrowth of plant roots as well as mycorrhizal hyphae (1 µm mesh size treatment), permitted the ingrowth of hyphae but not of roots (50 µm mesh size treatment) or permitted the ingrowth of both hyphae and roots (1000 µm mesh size treatment). We compare SOM loss and stable SOM-N formation, soil chemistry and fauna, microbial community structure and activities (enzymatic activity and microbial N transformations) between the mesh size treatments, focussing specifically on N pools and fluxes that may be tightly linked to C storage in boreal forests. Based on our field experiment, we provide a framework on the role of plant roots in SOM decomposition and stabilization. Plant roots not only accelerate SOM decomposition but also increase the chemically stable N pool. On the other hand, exclusion of plant roots leads to increased levels of inorganic N (IN) and reduced build-up of stable soil N, as well as decreased decomposition rates due to a lack of rhizosphere priming support from plants. Thus our field study sheds light on the mechanisms behind plant root-driven SOM transformations, increasing the systems understanding needed for improving forest soil management to enhance SOM accumulation.

Results and discussion

Decomposition and microbial decomposers. In our 3-year experiment, chemical and biological soil properties (Fig. 1) were significantly affected by both time and mesh size ($P < 0.001$, $R^2 = 0.490$) overall effect for different years and $P < 0.05$, $R^2 = 0.328$) overall effect for different mesh sizes, with permutational multivariate analysis of variance (PERMANOVA). The 1000 µ
treatment that permitted root ingrowth showed the highest SOM and total N loss throughout all years (P < 0.01; Fig. 2a, b). In the last year, the fungal hyphal treatment (50 µm) also tended to accelerate SOM and N losses (P < 0.09 and P < 0.05, respectively, Fig. 2a, b). These results confirm our first hypothesis that microorganisms supported by plant C increase SOM decomposition, compared to microorganisms lacking plant C input (1 µm treatment). The positive effect of plant roots on SOM decomposition rate falls in line with previous studies on rhizosphere priming effect13,14,28, as well as with a meta-analysis where decomposition rate falls in line with previous studies on rhizo-position, compared to microorganisms lacking plant C input.

Consistent differences between the treatments (Supplementary Fig. 1), Fungal PLFA markers became more dominant with time in the 1000 µm treatment compared to the other treatments in the same year (Fig. 2c), whereas bacteria showed higher abundance in 1000 µm treatment only during the second year (P < 0.05) (Fig. 2d). The highest SOM decomposition in the 1000 µm treatment may therefore be ascribed to increased microbial community composition was significantly different between the treatments within 1 year are indicated by different letters, and the differences between different years for the same treatment are indicated by capital letters. The error bars represent ±s.e.m. Source data are provided as a Source Data file.

Formation of stable SOM. Although SOM loss was the highest in the 1000 µm treatment, also here the stable SOM-N pool showed the strongest increase among the three treatments, by 23% after 3 years (P < 0.01, Fig. 3a). This result contradicts hypothesis 1 and suggests that the presence of plant roots did not only enhance net SOM decomposition but also simultaneously the formation of stable SOM-N. Characterization of soil from mesh bags with Fourier-transform infrared spectroscopy (FTIR) revealed differences between treatments mainly in polyphenols and polypeptides (Supplementary Figs. 6 and 7). The concentrations of condensed tannins (CTs) and FTIR absorbance values representing polypeptides were greatest in the 1000 µm treatment (Fig. 3b, c), and CTs were significantly correlated with the stable SOM-N (r = 0.680, P < 0.01, Pearson correlation, Fig. 3d). In addition, FTIR absorbance values representing polypeptides as
as concentrations of chitin were also greatest in the 1000 µm treatment (Fig. 3 e, f) and correlated with CTs (for FTIR polyphenolics $r = 0.698$, $P < 0.036$, chitin for third year only $r = 0.750$, $P < 0.001$, Pearson correlation). We here propose that this significant increase in the stable SOM-N resulted from the formation of complexes with root-derived CTs, i.e. polyphenols able to form complexes with proteins\(^{30,32}\), and other organic N compounds, e.g. chitin\(^{4,5}\). These results are in line with our earlier paper, in which we showed that CTs stabilize fungal necromass in boreal forest soil\(^{20,27,35,36}\). Thus we suggest the formation of organic N–CT complexes as one of the mechanisms behind the stabilization of SOM-N in the presence of plant roots, which is in agreement with build-up of SOM from root- and fungal-derived biomass\(^{20,27,35,36}\), and supports our hypothesis 2. In our experiment, formation of stable SOM-N reached 5 mg N g\(^{-1}\) SOM after 3 years. Assuming that complexation of proteins and chitin with CTs is responsible for stable SOM-N formation and knowing that C:N ratio of complexes is about 6:1\(^{17}\), we can extrapolate it into 30 mg of C stabilized after 3 years. Taking into account that fine root turnover may be higher than previously assumed\(^{38}\) and that fine roots provide significant amount of CTs to the soil\(^{35}\), this mechanism might play a significant role in SOM stabilization in boreal forest soils. In addition, increased fungal biomass could directly decrease N availability through N immobilization\(^{23}\) and increase stabilization of SOM via recalcitrant melanin production\(^{29,40}\). Therefore, those potential mechanisms of SOM build-up could explain how ectomycorrhizal trees decrease N availability in boreal forest ecosystems and drive soil C accumulation.

Going further, it is important to consider the role of stable SOM-N formation through reactions with CTs in the N cycle. The complexation of proteins by tannins has been proposed to

- **a** stable SOM-N pool,
- **b** condensed tannins,
- **c** Fourier-transform infrared (FTIR) polyphenolics (sums of 1512, 1421 and 1388 infrared (IR) bands),
- **d** correlation between stable SOM-N vs CT plotted for the whole set of data,
- **e** FTIR polypeptides (sums of 1668 and 1543 IR bands) (see Supplementary Figs. 5 and 6),
- **f** chitin concentration,
- **g** dissolved organic N/inorganic N (DON/IN) ratio (logarithmic values).

The different mesh sizes are represented with different colours (from left to right): 1000 µm (green), 50 µm (magenta) and 1 µm (black). The given values are the means of the 24 replicates (except 9 for FTIR and chitin). More results characterizing the soil are given in Supplementary Figs. 3–6. Significant differences ($P < 0.05$) between treatments within 1 year are indicated by different letters, and the differences between different years for the same treatment are indicated by capital letters. The error bars represent ±s.e.m. Source data are provided as a Source Data file.
induce a shift from mineral- to organic-dominated N cycling, i.e. that an increasing fraction of dissolved N released from litter is in organic rather than mineral forms. In line with this concept, we observed the highest dissolved organic N (DON)/inorganic N (IN) ratio in the 1000 µm treatment (P < 0.05; Fig. 3g), which reflects natural forest conditions. Lower concentrations of IN in this treatment may emerge not only from lower N mineralization but also from higher IN uptake by plants roots. Previous work at our study site in Hyytiälä also demonstrated a tight N cycle that was dominated by organic N and proposed that most of the N assimilated into tree biomass originated from SOM decomposition, with negligible amounts of IN in the soil.

Soil nitrogen economy. The combined results suggest that plant roots with associated microorganisms (1000 µm) promoted an organic soil N economy, i.e. the domination of organic N forms and stable SOM-N build-up (Fig. 4). In contrast, the artificial treatments where ingrowth of roots (50 µm) and roots as well as fungal hyphae (1 µm) were excluded showed an inorganic soil N economy with the accumulation of IN (Fig. 4), potentially promoting N losses by leaching and denitrification. This N economy observed for boreal forests cannot be simply extrapolated to temperate and tropical forests where soil N stock per area (kg N m⁻²) is about three times lower than in boreal forests. Moreover, formation of stable SOM-N may be significantly affected by quantity and quality of soil components. For instance, the clay content of boreal forest soils is almost three times lower than that of temperate forests and up to ten times lower than that of tropical forests. Similarly, also mycorrhizal component can play a crucial role, as it was shown that soil in ecosystems with ecto- and ericoïd mycorrhiza (like boreal forests) contains 70% more C per unit N than soil in ecosystems dominated by arbuscular mycorrhizal plants, suggesting different mechanisms of soil C storage.

We have to be aware that the mesh bag-based experimental design may suffer from some caveats. For example, in addition to the loss of SOM from mesh bags due to decomposition and uptake, C loss may partially emerge from leaching of dissolved organic carbon (DOC) into deeper soil horizons. The translocation of organic C to mineral soils may also stabilize organic matter, which is responsible for the formation of decadal and centurial old C pools in boreal forest soils. The DOC pool may also be susceptible to leaching from the soil to surface and ground waters, although as the DOC outflow from undisturbed forest soils is generally low, we assumed that also in our experiment DOC leaching is of minor effect. Similarly to the trenching method, mesh bag manipulations can also potentially be affected by differences in moisture and limitation of soil fauna entrance. However, in our study the moisture content and soil fauna abundance did not show major differences between treatments (Supplementary Tables 1 and 2). All in all, these caveats did not have substantial effect on our results.

Implications for biogeochemical predictions. We provide a framework on the role of plant roots in SOM decomposition and stabilization based on a field experiment in boreal forest soils (Fig. 4). Plant roots promote organic N economy not only with

Fig. 4 Framework of SOM-N transformations: organic N economy under natural conditions (1000 µm), inorganic N economy for exclusion of roots (50 µm), as well as roots and fungal hyphae (1 µm). Organic N economy (i.e. the domination of organic N) includes also build-up of stable SOM due to stabilization of organic N compounds with plant-derived tannins. Exclusion treatments (50 and 1 µm) led to an inorganic N economy (i.e. increased concentration of inorganic N forms) with reduced SOM build-up. The arrow thickness is proportional to the magnitude of the net flux. CT condensed tannins (shown as a monomer), SOM soil organic matter, DON dissolved organic N, IN inorganic N. The sizes of DON and IN are proportional to their concentrations.
accelerated SOM decomposition but also with stabilization of SOM-N. On the other hand, exclusion of plant roots leads to increased levels of IN (IN economy) and reduced build-up of stable soil N, as well as decreased SOM decomposition rates due to a lack of rhizosphere priming support from plants. The framework provided by our study may facilitate an improved understanding of boreal forest soil responses to global change and improve predictions of biogeochemical effects of possible shifts in SOM accumulation and decomposition. The incorporation of this framework into other forest ecosystems appears to be the next step to understand mechanisms controlling the soil C sequestration. However, extrapolation to other ecosystems than boreal forests may require significant modifications according to differences in plant CT contents and soil processes that are affected by, for example, mycorrizal type (ectomycorrhiza vs arbuscular mycorrizal) and its effect on soil carbon content or differences in the C cost of N acquisition. Finally, additional studies are required to test how major global environmental changes (e.g. N deposition, climate warming) alter interactions between ECM fungi and free-living microbial decomposers and, consequently, change soil C storage.

Methods

Experimental design. Soil for this study was collected in the vicinity of the SMEAR II station of Helsinki University at Hyytiälä (61°84′N, 24°6′E) in southern Finland (see ref. for site details). The soil was a haplic Podzol, and Scots pine mycorrhiza and its effect on soil carbon content or differences by, for example, mycorrhizal type (ectomycorrhiza vs arbuscular mycorrizal) and its effect on soil carbon content or differences in the C cost of N acquisition. Finally, additional studies are required to test how major global environmental changes (e.g. N deposition, climate warming) alter interactions between ECM fungi and free-living microbial decomposers and, consequently, change soil C storage.

Phospholipid fatty acids. Phospholipid extraction and PLFA analysis were carried out as described earlier. Briefly, between 1 and 1.5 g of fresh soil was freeze-dried and extracted with a chloroform:methanol:citrate buffer mixture (1:2:0.8) and the lipids were separated into neutral lipids, glycolipids and phospholipids on a silicic acid column. The phospholipids were subjected to mild alkaline methanolysis, and the fatty acid methyl esters were detected by gas chromatography (flame ionization detector) using a 50-m HP-5 (phenylmethyl silicone) capillary column. Helium was used as a carrier gas. Oven temperature was programmed as below. Enzyme and DNA analyses, N pool-dilution and KCl extractions were conducted using fresh soil, the rest of the samples was frozen at −20 °C, and later freeze-dried and ground to a fine powder using a ball grinder (2000-2300 Geno/Grinder, Spex Sample Prep, USA).

Total C, N, SOM and pH. Total soil C and N contents were determined with an elemental CN analyser (LECO, Michigan, USA). SOM content was measured as loss on ignition at +550 °C and soil pH in a soil–water suspension of 1:2.5.

Total C, N, SOM and pH. Total soil C and N contents were determined with an elemental CN analyser (LECO, Michigan, USA). SOM content was measured as loss on ignition at +550 °C and soil pH in a soil–water suspension of 1:2.5.

Fungal DNA analysis. Total DNA was extracted from 50 mg of soil using the NucleoSpin® Soil DNA Extraction Kit (Macherey-Nagel GmbH&Co). All the extracted DNA samples were further purified with the PowerClean® Pro DNA Clean Up Kit (MO BIO Laboratories, USA) following the manufacturer’s instructions. From the extracted total DNA, fungal ITS2 regions were sequenced using Illumina® MiSeq at the Institute of Biotechnology (University of Helsinki). The general read quality of raw ITS2 reads was checked with the FastQC software (http://www.bioinformatics.babraham.ac.uk/projects/fastqc/), and adapter and barcode sequences were trimmed away with the sequence cleaning software. The sequence data were further filtered and clustered to operational taxonomic units using mothur and following the workflow described in ref. For identification, fungal sequences were aligned against UNITE database and the obtained fungal taxa were assigned to functional guilds according to the FUN-Guild database.

Fungal biomass. Fungal biomass was measured through its biomarker, ergosterol, with the classic high-performance liquid chromatography (HPLC) method. Briefly, ergosterol was extracted from 0.25 g soil samples by adding 1 ml cyclohexane and 4 ml 10% KOH in methanol. After 15 min ultrasonic treatment, the samples were incubated at 70 °C for 60 min. After the heat treatment, 1 ml distilled water and 2 ml cyclohexane were added. The tubes were shaken and the top phase was moved to another test tube. The procedure with water and cyclohexane was repeated and the combined extracts were evaporated under N2 gas at 40 °C. The samples were re-dissolved in methanol by heating at 40 °C. After centrifugation and filtered through a 0.2 µm PTFE filter. The amount of ergosterol was measured with HPLC (HP Agilent 1100, Hewlett Packard, USA) using a C18 100A reverse-phase column. Ergosterol was analysed using a 10-µl sample injection and isocratic separation with methanol (1 ml min−1) and detected at 282 nm.

Soil fauna. Soil mesofauna and microfauna were measured using modified sugar flotation method, where soil (2 g) was first sieved through 1-mm mesh, diluted to 100 ml sugarwater suspension (1:1) and then left to settle 2 h before extraction (25-µm sieve) of soil organisms from the suspension.

Ammonium-N, nitrate-N and total free amino acid content. Fresh soils (5 g) from mesh bags were extracted with 20 ml of 1 M KOH for 80 min on a reciprocal shaker (120 rpm). Extracts were centrifuged, filtered (0.45-µm filters), PALL Corning® and frozen at −20 °C. Analysis. IN (N-NO3) and NH4-N was measured according to ref. The assay for ammonium-N was based on a modified indophenol method and for NO3-N on the reduction of nitrate by vanadium (III). Soil total free amino acids were measured from KCl extracts using a fluorometric method with o-phthalaldehyde and β-mercaptoethanol, modified as in ref. Absorbance and fluorescence were measured with a microplate reader (Infinite M200, Tecan, Switzerland).

Chemically stable and degradable N pools. We separated soil N pools into a hydrolysable N pool (hereafter called degradable N pool) and non-degradable N pool (hereafter called stable N pool) using acid hydrolysis with methyl sulfonic acid (MSA). Briefly, dried and ground soil was hydrolysed with 4 M HCl in an autoclave (136 °C, 134 kPa, 90 min) in the presence of trypsin to avoid amino acid degradation. This hydrolysis released the degradable N pool but not the recalcitrant N pool. Extracts were neutralized with KOH and stored at −20 °C before analysis for total dissolved N content (TOC-VcpH/cpn TNM-1, Shimadzu, Japan), which consequently reflects the degradable N pool. The chemically stable pool was calculated as the difference between total soil N content and the degradable N pool.

Concentration of CTs. CTs were extracted from 0.2 g ground soil with 70% aqueous acetone, dried, dissolved in water and exposed to a modified acid-butanol assay (proanthocyanidin assay) after extraction from soil with acetone-water (7:3). The method involves the HCl-catalysed depolymerization of CT in butanol to yield a pink-red anthocyanidin which was measured colorimetrically. As a standard, we used CT extracted from Norway spruce needles, which was profoundly characterized before (see ref. for details).

Concentration of chitin. Chitin was measured using HPLC as described by ref. Briefly, 5 g of dried and ground soil was treated with 0.2 N NaOH to remove proteins and amino acids. The soil was hydrolysed with 5 ml 6 N HCl for 7 h at 105 °C. After centrifugation (5000 × g, 10 min), 500 µl of hydrolysate was evaporated to dryness under nitrogen to remove HCl, redissolved in 1 ml of water, evaporated and redissolved again in water and centrifuged (5000 × g, 10 min). The supernatant was then used to measure the glucosamine content (product of chitin hydrolysis in HCl), after derivatization with 9-fluorenylethylchloroformate. Samples were mixed with homocystic acid (5 μM) as internal standard. Separation and detection were carried out on a Waters HPLC with a 250 × 5 mm2 (I.D.) ODS-hypersil (5 μm) column. The column effluent was directed to a fluorescence detector (excitation 330 nm and emission 445 nm). Results are presented as mg glucosamine per g−1 SOM.

15N pool dilution assays. Gross rates of protein depolymerization, microbial amino acid uptake, N mineralization and microbial ammonium uptake were measured using 15N pool dilution assays, as described in principle by Kirkham and Bartholomew. For gross rates of protein depolymerization and microbial amino acid uptake, we followed the assay of Wanek et al., with slight modifications. Samples were then extracted with 20 ml 10 mM CaSO4 that contained 15N (≥96 at%15N) and incubated for 10 and 30 min, respectively. Samples were then extracted with 20 ml 10 mM CaSO4 that contained 3.7% formaldehyde to stop microbial activity, filtered and loaded on pre-cleaned
cations exchange cartridges. Cartridges were eluted with 3 M NH₄OH, and samples were amended with internal standards (nor-valine, nor-leucine, para-chloro-phenylalanine, each 0.05 mg per each sample), dried, derivatized with ethyl chloroformate, and analysed with gas chromatography–mass spectrometry (Thermo TriPlus Autosampler, Trace GC Ultra and IQ Mass spectrometer, Agilent DB-5 column). Concentrations of alanine, glycine, isoleucine, leucine, phenylalanine, proline, valine, aspartate–asparagine and glutamate–glutamine were quantified against external standard curves, and the corresponding ¹⁵N contents were calculated from peak areas of light- and heavy-mass fragments. Aspartate and asparagine, as well as glutamate and glutamine, were not distinguished since formaldehyde causes the deamination of asparagine to aspartate and of glutamine to glutamate. We corrected for background concentrations of amino acids and incomplete recovery from the cation exchange cartridges using blanks and a second set of standards that were processed together with the samples throughout the procedure.

For gross rates of N mineralization and microbial ammonium uptake, duplicates of fresh soil (ca. 1.5 g) were amended with ¹⁵N-enriched (NH₄)₂SO₄ (0.125 mM, 500 µl, 10 at%¹⁵N), and incubated for 4 and 24 h, respectively. Samples were then extracted with 15 ml 2 M KCl and filtered through ash-free filter paper. Ammonium was isolated into acid traps, and the amount and isotopic composition were measured with elemental analysis–isotope ratio mass spectrometry (CE Instrument EA 1110 Elemental Analyzer, Finnigan MAT ConFlo II Interface, Finnigan MAT DeltaPlus IRMS). We corrected for background concentrations of ammonium using blanks that were processed together with the samples throughout the procedure.

For gross rates of protein depolymerization, microbial amino acid uptake, N mineralization and microbial ammonium uptake were calculated using equations modified after Kirkham and Bartholomew. Microbial N use efficiency was calculated as the proportion of N taken up in the form of amino acids that was allocated to growth and enzyme synthesis and not to N mineralization.

**Enzyme measurements.** Extracellular enzymes were recovered from the fresh soil using the filter centrifugation method. Activities of acid phosphatase (EC 3.1.3.2), chitinase (EC 3.2.1.14), β-glucosidase (EC 3.2.1.21), β-glucoronidase (EC 3.2.1.31), β-xylanase (EC 3.2.1.37), cellulohydrolase (EC 3.2.1.91) and leucine aminopeptidase (EC 3.4.11.1) were measured using fluorimetric substrates (Sigma). Fluorescence was measured with a Wallac Victor® (Perkin Elmer, Inc., USA) plate reader using excitation at 355 nm and emission at 460 nm.

**Fourier transform infrared spectroscopy.** Soil infrared spectra were recorded with a FTIR spectrometer (Shimadzu IR Prestige-21; Shimadzu Corporation, Japan) equipped with a high-sensitivity DLATGS detector with Germanium-coated KBr beam splitter and signal/noise ratio 40,000:1. We used the IRRsolution 1.40 software (Shimadzu Corporation). The spectral data within the band range of 4000–400 cm⁻¹ were recorded, and 24 scans were averaged for each spectrum with a spectral resolution of 4 cm⁻¹. Three milligrams of dry and finely ground soil from mesh bags were mixed with 300 mg of KBr and pressed into discs (13 mm in diameter) by applying 12 bars pressure for 2 min (hydraulic press, Perkin Elmer). A blank KBr beam splitter was used to adjust to the baseline level before measurements. All analyses were performed in nine replicates.

**Statistical analysis.** To determine the differences between treatment means, a two-way analysis of variance (ANOVA) test was used with time (year) and mesh size as fixed factors. Where necessary, data were transformed (log10 or arcsin for percentage data) to fulfill the assumptions of the ANOVA. The interactions between time (year) and treatment (mesh size) were all significant. The effect of factors (time or mesh size) were determined separately with post hoc Tukey tests. In the two-way analysis of variance (ANOVA) test was used with time (year) and mesh size. Statistical analysis was performed with the MASS package in the R software and explanatory variables were determined with the anova.cca function. The pCCA analysis was performed with Canoco 5 (Microcomputer Power, USA). Wavenumbers that were most affected by treatment (best fit in PC ordination space) were selected and assigned, as in a previous study. A sum of absorbance values at 1668 and 1543 cm⁻¹ was used as a representative of polypeptides, and a sum of absorbance values at 1611, 1512, 1412 and 1388 cm⁻¹ was used as a representative of phenolic compounds.

**Reporting summary.** Further information on research design is available in the Nature Research Reporting Summary linked to this article.

**Data availability**

The data that support the findings of this study are available on request from the corresponding author (B.A.). The source data underlying Figs. 1–3 and Supplementary Figs. 1–7 are provided as a Source Data file.
