². Miguel Torres, S.A., Barcelona, Spain

The wine industry in Catalonia (Spain) plays an important role in the economy of the region. In this framework, Miguel Torres S.A. is a well known company specializing in production of high-quality wines and brandy, which possesses its own vineyard. Two of the main solid wastes produced in this kind of industry are: stalk (waste from grape harvesting which is only produced during September and October) and wine sludge from the biological wastewater treatment plant which is steadily generated. A composting process was proposed to treat these two organic wastes for recycling its organic matter content to the vineyard crops. Experiments at laboratory-scale in static composting systems did not show positive results for different stalk:sludge mixtures due to the high moisture content of both wastes. Field composting experiments with windrow methods showed that the thermophilic range of composting could be achieved for a 2:1 stalk:sludge volumetric ratio resulting in a complete sanitation of the material with thermophilic temperature of over 55°C for 28 days. The stability and maturity of the final compost were very high (Dewar self-heating test maturity grade V and static respirometric index 0.10 mg O₂·g Total Organic Matter⁻¹·h⁻¹). Due to its seasonal production, stalk storage was necessary. A study of the changes of stalk properties during one year is also presented. Bulk density and water holding capacity decreased with storage time while FAS (Free Air Space) and porosity increased. No remarkable changes in organic matter content were observed. Cocombusting of stalk and wine sludge generated in the wine industry is presented as a sustainable waste management strategy, which produces a sanitized fertilizer suitable for application in the vineyard, closing the organic matter cycle.

Introduction

Spain is a European leader in innovations in the wine industry. Large investments have been characteristic in the last years, which have led to improvement of the quality of wines and spirits and the image of the cellars. Miguel Torres S.A. (Vilafranca del Penedès, Barcelona, Spain) is a well known company that specializes in production of high-quality wines and brandy. During the production process, significant amounts of liquid and solid wastes are generated. Miguel Torres has a wastewater treatment plant in its facilities for the treatment of wastewater and vinasse generated in the industry. Approximately, 80% of the total wastes generated are organic wastes or by-products. The characteristic of the wastes produced at Miguel Torres are grape pomace (50%), lees (20%), stalk (7.6%) and dewatered wine sludge from the wastewater treatment plant (7%). Recycling of grape pomace (grape peels and seeds) which is produced during the grape pressing, and lees, consisting of the sediments from the fermentation and the clarification operations, is already well-established. The management of the other two important organic solid wastes, stalk and wine sludge, is at the moment directed to an external company.

At present, there is a tendency towards agricultural use of sludge. The unique legal restriction to direct land application of the sludge is given by its content of heavy metals and potentially toxic compounds. Therefore “clean” sludges coming from agricultural industries may be suitable for direct land application. Miguel Torres owns vineyards in Spain, California and Chile. Given that Spanish soils are poor in organic matter, vineyard crops require organic fertilization. However, the European Commission is preparing a Directive on the biological treatment of organic wastes (European Commission 2001). According to this Directive, the sanitation of sludge before application to land will be mandatory. The absence of pathogen microorganisms is also crucial in the vineyard cultivation. Composting is one of the alternatives proposed by the Directive in order to achieve sludge sanitation.

Main factors influencing the composting process are temperature, water content, oxygen concentration in the composting matrix, porosity and free air space (FAS). Temperature is both a consequence of the com-
posting process (microbial metabolism) and a control parameter. Temperatures providing the maximum degradation velocity are in the range of 40-70°C (Haug 1993). The water content of sewage sludge is usually too high for direct composting and a bulking agent is necessary to reach an optimum water content, porosity and FAS (Haug 1993). The optimization of the sludge-bulking agent mixtures for urban or industrial sludge composting has been extensively studied (Miner et al. 2001; Milne et al. 1998; Morisaki et al. 1989; Sesay et al. 1997). Also, the type of bulking agent used and its particle size has been empathized as an important factor in sludge composting (Jokela et al. 1997; Morisaki et al. 1989). Studies on sludge composting are presented at different scales, laboratory, pilot plant or field scale (Jokela et al. 1997; Sesay et al. 1997), being the temperature profile the main difference observed at the studied scales. Obviously, the amount of heat generated and the heat retention capacity of the material increase as the mass of the material increases.

Stalk appears to be an ideal bulking agent for sludge composting, due to physical properties such as porosity (provided by its branch-type structure) and resistance to biodegradation of the hard-wood fraction (Tuomela et al. 2000). Its chemical properties are also optimal. Stalk C/N ratio is high (around 39) and equilibrates the low C/N ratio of sludge (around 5). Co-composting wine sludge from the wastewater treatment plant with stalk as bulking agent would generate a stabilized fertilizer suitable for its application to the vineyard crops. Moreover the composting process allows treating different wood wastes that are generated sporadically in the wine industry, such as ground old oak barrels (Bertrán 2004).

Wine sludge from the wastewater treatment plant is generated steadily during the year and stalk is yearly produced during the grape harvest, a short period of 4-6 weeks around September. Stalk storage is necessary to use it in wine sludge composting during the rest of the year.

The objectives of this work are: i) to study the co-compostability of stalk with wine sludge to ensure a complete sanitation of the material, ii) to determine the stability and maturity of the final compost and iii) to monitor the properties of ground stalk during the storage time to study their influence on the optimum ground stalk:sludge volumetric ratio for composting.

Materials and Methods

Materials

The waste materials studied were dewatered (by centrifugation) wine sludge from Miguel Torres wastewater treatment plant; and stalk from the wine production process after grape harvest. Wine sludge is steadily generated during the year and was sampled just after dewatering. Stalk is generated only during the grape harvest in September and October. Stalk was ground to 5 cm after the grape harvest and stored in a pile in the open air. These materials were monthly sampled for analysis. Composting experiments were carried out during the year following the grape harvest in September.

Pine wood chips were used as alternative bulking agent. Sawdust was used as drying agent. Both materials were obtained from a local carpentry.

Composting Experiments

Laboratory-scale experiments were undertaken using 4.5-L Dewar® vessels conditioned for static composting providing a stopper and placing a rigid wire net near the bottom to separate the material from possible leachates. The stopper was perforated in three points for temperature and oxygen content monitoring and air supply. Wine sludge and stalk were used in the laboratory-scale experiments mixed in different volumetric ratios. In some experiments, wood chips were used as an alternative bulking agent, whereas sawdust was used as absorbent material to decrease the moisture content of the wine sludge. A complete description of the composting Dewar vessel can be found in Gea et al. (2003).

Field scale composting experiments were carried out under real conditions in Miguel Torres facilities using a dynamic windrow composting system. Two composting piles of approximately 150 m³ (height: 2 m, width: 3 m) were built. The volumetric ratios (stalk:sludge) of the piles were 1:1 and 2:1 for Pile 1 and 2, respectively. Initial mixing and pile turnings were performed using a front end loader. Pile turning was performed weekly during the composting experiment. The piles were not covered and situated on a concrete floor to collect the possible leachates generated in the process. Temperature and interstitial oxygen of the piles were routinely monitored.

Oxygen, Aeration Control and Temperature Monitoring

Laboratory-scale: Air was supplied to the vessels in aeration cycles where the total time of the cycle, aeration time and air flow were programmed and changed on the basis of the measured oxygen concentration, to ensure an oxygen concentration over 10%. Pt-100 sensors were used for temperature monitoring connected to a data acquisition system (DAS-8000, Desin, Spain) which was connected to a standard PC. The system al-
lowed, by means of the proper software (Proasis®
Das-Win 2.1, Desin, Spain), the continuous on-line vi-
sualization and registration of temperature. Pt-100
sensors were placed in the material to measure tem-
perature at half of the height of the material in the De-
war vessel.

Field Scale: Temperature was measured with a
portable Pt-100 sensor (Delta Ohm HD9214) at two
different depths of pile, 40 and 90 cm, in at least 7 dif-
f erent points. Temperature values are presented as av-
 erage values.

Oxygen concentration in interstitial air was mea-
sured with a portable O₂ detector (Oxy-ToxiRAE,
RAE) connected to a portable aspiration pump, both
in laboratory and field experiments. Oxygen and tem-
perature were measured at the same points in the field
scale experiments.

Respirometric Tests

A static respirometer was built according to the
original model described previously by Ianotti et al.
(1993) and following the modifications and recom-
mendations given by the U.S. Department of Agricul-
ture and U.S. Composting Council (2001). Approx-
imately 250 mL of a compost sample were placed in a
500 mL Erlenmeyer flask on a nylon mesh screen that
allowed air movement under and through the solid
sample. The setup included a water bath to maintain
the temperature at 37°C during the respirometric test.
Prior to the assays, samples were incubated for 18
hours at 37°C. During the incubation period samples
were aerated with previously humidified air at the
sample temperature. The drop of oxygen content in the
flask containing the compost sample was monitored
with an oxygen meter (Lutron 5510, Lutron Co. Ltd.,
Taiwan) connected to a personal computer (RS232
communication protocol) with a proper software to
register the oxygen values. The rate of respiration of a
compost sample based on total organic matter content
(TOM) was then calculated from the slope of oxygen
level decrease according to the standard procedures
(U.S. Department of Agriculture and U.S. Composting
Council 2001). Results of the static respirometric index
(SRI) referred to total organic matter content are pre-
sented as an average of three replicates.

Germination Tests

Relative Germination Rate and Relative Root
Elongation of cucumber seeds were determined from
a compost extract following the method 05.05-B ‘In-
Vitro Germination and Root Elongation’ proposed by
TMECC (Test Methods for the Examination of Com-
posting and Compost, U.S. Department of Agriculture
and U.S. Composting Council 2001).

Analytical Methods

Different parameters were determined according
to the standard procedures recommended by TMECC
(Test Methods for the Examination of Composting
and Compost, U.S. Department of Agriculture and
U.S. Composting Council 2001) as follows: water and
dry matter content were determined with the method
03.09-A ‘Total Solids and Moisture at 70±5°C’, total or-
ganic matter (TOM) content with the method 05.07-A
‘Loss On Ignition Method’, bulk density, free air space
(FAS), pore space (PS), water holding capacity (WHC)
with the method 03.01-A ‘Quick-Test for Bulk Densi-
ity, Porosity/Pore Space, Free Airspace and Water-
Holding Capacity of Compost’, and Dewar self-heating
maturation test with the method 05.08-D ‘Dewar Self-Heating Test’.

Results and Discussion

Evolution of Material Properties

Figures 1 and 2 show the evolution of water and
organic matter content of the materials under study.
Wine sludge obtained after centrifugation in the
wastewater treatment plant presented a high water
content (average value 88%), and an average organic
matter content of 70%. Ground stalk, stored outdoors,
presented high water content (60-80%) due to the rain-
fall in winter and spring and the humidity of the area.
Consequently, water content within the recommend-
ed range of 40-60% (Haug 1993; Saña and Soliva 1987)
could not be achieved by mixing the two materials.
Therefore it was decided to cover a part of the ground
stalk storage pile to prevent the contact of the materi-
al with water from rainfall (covered stalk). As Figure 1
shows, this strategy produced an important reduction
of the stalk water content.

Additionally, it has to be pointed that although
certain biodegradation took place during storage
time, leading to physical and structural changes that
could be visually recognized, no significant reduction
of the total organic matter content was observed in
stalk when increasing the storage time (Figure 2). This
was due to the fact that stalk is composed mainly by
branches (hard-wood fraction) and the biodegrada-
tion only takes place in the soft-wood fraction which is
a minor fraction of stalk (Tuomela et al. 2000). Wine
sludge composition, on the other hand, presented
steady values of water and organic matter content
during the period of study.
Composting of Residuals Produced in the Catalan Wine Industry

Figure 3 shows the reduction of bulk density and water holding capacity and the increase of FAS and porosity during stalk storage time. This was the result of the biodegradation of the soft-wood fraction of stalk, which consisted of small size particles that filled the void spaces in the structure of the branches. The reduction in stalk bulk density (or FAS increase) can make more difficult the integration with wine sludge when acting as bulking agent. The water holding capacity of stalk also decreases with time and thus the capacity of absorbing excess water from the wine sludge. Consequently an increment of the stalk:sludge volumetric ratio required for composting was expected for long storage times. This fact will probably result in an excessive FAS in the final mixture (Haug 1993).

Composting Experiences at Laboratory-Scale

To evaluate the composting potential of the wastes under study, different ground stalk:sludge mixtures with volumetric ratios of 1:1, 2:1 and 3:1 were tested in 4.5-L composting vessels. Experiments were undertaken at different dates during the monitored period of stalk storage. Table 1 shows the initial water content and the maximum temperature reached in these experiments. Due to the high water content of the original materials, the mixtures resulted in water contents within 75-80% which were higher than those considered as optimal (Haug 1993). The mixtures pre-

| Date    | Volumetric Ratio | Initial Water Content (%) | Maximum Temperature (°C) |
|---------|-----------------|--------------------------|--------------------------|

TABLE 1. Initial water content and maximum temperature achieved in laboratory-scale composting experiments with different mixtures stalk/sludge.
Presented poor activity and only in a few cases temperatures over 40°C were reached. None of the experiments reached the thermophilic range of temperatures (over 45°C) necessary to obtain a sanitized material suitable for land application (European Commission 2001). Figure 4 shows the temperature profile obtained for three of the mixtures tested.

When the stored stalk was covered, its water content was reduced to about 20% (Figure 1). Different experiments were carried out with covered stalk and other alternative bulking agents such as wood chips, but the resulting mixtures again presented an excessive water content and the material did not reach temperatures above 40°C (Table 2).

Since the studied wine sludge was dewatered by centrifugation, one possible strategy to reduce water content in the centrifugation operation might be the addition of polyelectrolyte to the wine sludge. To simulate this, sawdust was added to wine sludge as an absorbent of moisture before mixing with stalk. This strategy improved the results of the composting process. The temperature reached values near 50°C and the thermophilic range was retained for 3.5 days, as can be seen in Figure 5. Adding sawdust in moderate amounts had a positive effect in the composting process because sawdust absorbed excess water from the wine sludge, although the reduction in the total water content of the mixture was low (75.5%, Table 2). Moreover, sawdust produced a very homogeneous mixture with wine sludge breaking the typical aggregated structure of a dewatered sludge and improving its integration with stalk by reducing the size of aggregates. This effect was mainly due to the small particle size of sawdust.
Field Experiments

Piles 1 and 2 (stalk:sludge volumetric ratios of 1:1 and 2:1, respectively) were built during the grape harvest period (September) and monitored during the composting process. Due to the high water content of the fresh stalk, the water content of the initial mixtures of both piles was high, 81% for Pile 1 and 75% for Pile 2. In Pile 1, the material practically had no porosity and consequently temperature did not reach the thermophilic range, remaining under 40ºC (data not shown) and it was decided to stop the composting experiment after two weeks. On the other hand, in Pile 2 the composting process reached average temperatures over 50ºC in one week and over 60ºC in two weeks (Figure 6). Values of temperatures over 55ºC were measured for 4 weeks (days 14-42). As pile turnings were carried out once a week, it can be concluded that the totality of the material was exposed to temperatures in the thermophilic range. Besides, according to U.S. Environmental Protection Agency Rule 503, total sanitation of biosolids is obtained at 55ºC for 15 days and turned 5 times, which was the case of wine sludge composting (U.S. Environmental Protection Agency 1995). On the other hand, aerobic conditions were maintained in the first layer of the pile (40 cm depth), but oxygen content dropped under 8% when approaching the center of the pile (90 cm). Because of water evaporation due to the high temperatures reached, the water content of Pile 2 was reduced from 75 to 68% in 11 days in spite of the rainfall. However, values of moisture in Pile 2 were always in the high range of the composting process (average value of 70%).

On the other hand, other monitored parameters correlated well with those found in traditional biosolids composting (Haug 1993). For instance, total organic matter content decreased from an initial value of 77% to a final value of 63%, whereas pH value ranged from 8.2 to 9.3. Finally, an important reduction of total volume was observed in a percentage of 43% in a total composting period of 120 days.

The excellent results obtained for Pile 2 contrast with the laboratory-scale experiments carried out with the same volumetric ratio 2:1 (Figure 4, Table 1) where the thermophilic range was not achieved. As mentioned before, the water content and the FAS of the mixture were critical for the proper composting development. However, in large-scale experiments the thermal inertia of the material compensated the problems presented with FAS and excess of water. Furthermore, frequent turning of the material contributed to the complete higienization of the material and to the disintegration of stalk.

In addition to stalk:sludge volumetric ratio, bulking agent particle size and operation scale are interrelated and can affect the composting process in the same order of magnitude (Gea et al. 2003). The particle size of ground stalk (5 cm) may result too big for composting in 4.5L vessels. On the other hand, as the bulk density of stalk decreased within the storage time, the amount of stalk required for adjusting the properties of the mixture with wine sludge (i.e. water content) increased, leading to high requirements of bulking agent volumetric ratio and to an excessive FAS. This excess of FAS can be reduced when operating at higher scales because of the compaction phenomena of the composting material (McCartney and Chen 2001). Moreover, the bigger the organic matrix is, the higher heat generation and retention occurs, which may improve the temperature profiles obtained (Sherman-Huntoon 2000). On the other hand, open dynamic systems such as turned piles produce higher losses of water by evaporation due to the high surface area available.

Final Compost Properties

One of the most important characteristics to determine in sludge compost intended for vineyard application is the stability and the maturity of the material obtained. Therefore, the Dewar self-heating test and the respirometric index were measured for the compost obtained. These tests are popularly used in predicting compost stability and maturation (Weppen 2002; Adani et al. 2003) and are recommended in standard procedures and regulations (U.S. Department of Agriculture and U.S. Composting Council 2001; European Commission 2001). Static respirometric index (SRI) obtained was 0.10 ± 0.02 mg O₂·g TOM⁻¹·h⁻¹, which can be classified in the range of highly stable
materials (California Compost Quality Council 2001). Also, the Dewar self-heating test resulted in the maximum maturity grade (V) with temperature increments below 2°C.

Finally, the germination indexes obtained for the final compost were 90% and 100% for the Relative Root Elongation and the Relative Germination Rate, respectively. These indexes indicated that there was no evidence of the presence of plant toxic compounds.

**Conclusions**

From this work, it can be concluded that: 1) Bulk density and water holding capacity of stalk decrease during the storage time as biodegradation of soft-wood fraction takes place, while FAS and porosity increase. Thus, the optimum volumetric ratio of stalk:sludge for composting should be increased during the year. 2) High water content of stalk and wine sludge was the main problem in the composting process studied under laboratory-scale conditions. The addition of some adsorbent material or the improvement of the dewatering system are the two strategies proposed to reduce the water content. 3) At field scale, a highly stable and mature final compost was obtained when a 2:1 stalk:sludge volumetric ratio was used. Windrow composting with frequent turning appears to be an optimal technology for the composting of this waste from the wine industry.

In conclusion, cocomposting of stalk and wine sludge generated in the wine industry is presented as a sustainable waste management strategy, which produces a sanitized fertilizer for application in the vineyard, closing the organic matter cycle.
