Abstract. We examine the change in behaviour of the solutions of a simple one degree
of freedom, periodically forced, impact oscillator following a grazing bifurcation in
which an impact of zero velocity occurs following a change in one of the parameters of
the system. It is shown that such a bifurcation leads to intermittent chaotic behaviour
with low velocity impacts followed by an irregular sequence of high velocity impacts. We
also show that there is a natural, discontinuous one-dimensional map associated with this
relating one low velocity impact to the next and the properties of this map are analysed.
We also construct the bifurcation diagram of the change in behaviour and show that this
contains a series of periodic windows, with the period of the solutions increasing
monotonically by one in each successive window as the bifurcation point is approached.
By restricting our attention to the resonant case where the forcing frequency is twice the
natural frequency of the oscillator it is possible to make asymptotic estimates of the form
of the intermittent chaotic behaviour and these estimates are compared with some
numerical calculations.

1. Introduction

In many forced vibrating mechanical systems, oscillating components collide with
each other or with rigid obstacles. The motion of the components is then a
combination of a smooth motion governed by a differential equation interrupted by
a series of non-smooth collisions. Such systems are usually termed impact oscillators
and have recently been the subject of growing interest both in the engineering and
mathematical literature. The reasons for this are twofold: firstly, they can be used to
model a wide variety of different systems arising in engineering, for examples see
Thompson and Stewart (1986), Shaw and Holmes (1983), Shaw (1985), and Moon
(1987). Secondly, they are examples of nonlinear dynamical systems with discontin-
uities and as well as exhibiting the usual complexity of behaviour associated with
smooth nonlinear systems we also observe new forms of behaviour related to the
discontinuities. Some of this is reported in the papers by Whiston (1987), Hindmarsh
and Jeffries (1984), Nordmark (1991), Foale and Bishop (1992), Nusse et al (1993),
Budd et al (1993) and Dux (1993).

In this paper we investigate a particularly interesting phenomenon which can
occur in an impact oscillator, namely a bifurcation from a steady periodic solution
to an intermittent chaotic one as a parameter—in this case the mean separation
between the oscillating components—is varied. This bifurcation has many similarities to the intermittency phenomena described by Pomeau and Manneville (1980), which arise in smooth systems when a stable fixed point disappears at a saddle-node bifurcation. The presence of the discontinuity in impact oscillators gives rise, however, to new and fascinating behaviour and a new form of bifurcation called a 'grazing' bifurcation. Grazing bifurcations have been identified and studied by Whiston (1987) and Nordmark (1991) for the respective cases of unstable periodic motions corresponding to a saddle point of an associated Poincaré map and stable periodic motions corresponding to a node of the same map. In this paper we extend the discussion of Nordmark (1991) by looking at a special case of a grazing bifurcation in which we can reduce the study of an impact oscillator to that of a one-dimensional map.

A simple model for a forced impact oscillator is a linear one-degree-of-freedom system in which an oscillating component at a position $x(t)$ collides with an obstacle at position $U$. Between impacts the $x(t)$ satisfies the simple differential equation

$$\ddot{x} + x = \cos(\omega t) \quad x < \sigma.$$  \hfill (1.1)

An impact occurs when $x = \sigma$ and we model this by an instantaneous restitution law:

$$v \equiv \dot{x} \leftrightarrow -rv \quad r < 1.$$  \hfill (1.2)

In Nordmark (1991) and Foale and Bishop (1992) somewhat more general systems are studied, but the simplification we make in looking at an undamped piecewise linear system does not significantly detract from the generality of our results. The system above is dissipative as $r < 1$ and it is this case that we study in this paper. (The problem with $r = 1$ is closely related to work on billiard balls, see for example the review by Katok and Strelcyn (1986).) Indeed, for all computations and numerical examples we consider the special case $r = 0.8$. We presume that the system starts in some (bounded) initial state and that we are observing its subsequent motion. It has been shown by Whiston (1987) that when $r < 1$, there is a bounded set which attracts trajectories for all initial data and we study the motion in this set. A detailed analysis of all subsequent forms of motion and of some of their bifurcations is presented in Budd et al (1993). There, the system is defined to be 'resonant' if $\omega = 2n$, (this leads to the largest amplitude motions when $\sigma = 0$) and we study the case $\omega \approx 2$ in this paper.

The system (1.1), (1.2) leads to a discontinuous dynamical system for two reasons. Firstly, and most obviously, there is a discontinuity in the velocity of $x$ at each collision. Secondly, the system has a discontinuous dependence upon the initial data which occurs when it just misses an impact or has an impact with a very low velocity. We can see this by considering figure 1.1 in which three adjacent initial states lead to a motion (A) with a low velocity impact, (B) with a zero velocity impact and (C) with no impact. Although these three trajectories look very similar,
Intermittency in impact oscillators

Figure 1.2. A globally attracting periodic orbit occurring when \( r = 0.8, \omega = 2, \sigma = -0.33 \), together with a transient.

The addition of an impact in (B), (C) profoundly changes the nature of the dynamics and makes the whole system much more sensitive to changes in the initial data. Full details of the mechanism behind this are given in Whiston (1987). This leads to sudden destabilisation of periodic states and the occurrence of chaotic motion. The zero velocity orbit in (B) is termed a graze in Whiston (1987), Nordmark (1991), Foale and Bishop (1992) and the occurrence of a graze as a parameter is varied is termed a grazing bifurcation (in Nusse et al 1993) a grazing bifurcation is presented as an example of a border-collision.

Because of the dissipation in (1.1), (1.2) the impact oscillator settles down onto an attractor after a transient period of several impacts. The simplest form of such an attractor is a periodic motion in which the system exactly repeats itself between impacts. (These forms of motion are analysed in detail in Budd et al (1993).) In figure 1.2 we present an example of a globally attracting, stable periodic orbit which arises when \( \psi = 2, \sigma = -0.33 \) and \( r = 0.8 \). We also show the transient motion of about 30 impacts which arises from taking as initial data, \( x = \sigma, \dot{x} = 0 \) at \( t = 0 \), and observe that the periodic motion has a local maximum value between impacts. If \( \sigma \) is decreased from \(-0.33\) and \( \omega \) is kept fixed at \( 2 \), then we may continuously deform the periodic orbit until this maximum value grazes the obstacle. When \( r = 0.8 \), this occurs when \( \sigma = \sigma^* = -0.3312 \ldots \). For \( \sigma < \sigma^* \) the local maximum is replaced by a low velocity impact and the periodic orbit disappears. For \( \sigma < \sigma^* \) we observe instead, an intermittent chaotic motion, which for \( \sigma \) close to \( \sigma^* \) remains in a neighbourhood of the original periodic motion. This transition to chaotic behaviour through the grazing of a stable periodic orbit was first observed by Nordmark (1991). The form that this motion takes when \( \sigma = -0.333 \) is presented in figure 1.3.

In this motion we see transient behaviour of several high velocity impacts (very similar to that observed for \( \sigma = -0.33 \) before the system settled down to a stable periodic state), followed by a low velocity impact, followed by another transient periodic of high velocity impacts and so on. Indeed, we observe \( N \), high velocity impacts.
impacts between the $i$th and $(i+1)$th low velocity impacts, where the value of $N_i$ depends chaotically upon $i$, but has a maximum, $N(\sigma)$, of $N(\sigma) = 25$ impacts. We show in section 4 that

$$N(\sigma) = \frac{1}{2} \log(\sigma^* - \sigma) - \log \left( \frac{1}{2} \log(\sigma^* - \sigma) \right) \to \infty \quad \text{as} \quad \sigma \to \sigma^* \quad (1.3)$$

and further, that if $v(\sigma^*)$ is the impact velocity of the periodic orbit and $v_{\text{max}}(\sigma)$ the maximum impact velocity of the chaotic motion, then

$$v_{\text{max}}(\sigma) - v(\sigma^*) = K(\sigma^* - \sigma)^{1/2} \quad (1.4)$$

where $K$ depends slowly upon $\sigma$. Result (1.4) was first observed by Nordmark (1991).

In figure 1.4 we plot one successive low-velocity impact velocity $v_j$ against the next low velocity impact for the case of $\sigma = -0.333$. (Here an impact velocity $v_i$ is defined to be 'low' if $v_i < 0.5$.) This figure is striking as it appears that when $\sigma$ is close to $\sigma^*$, there is a natural, discontinuous, piecewise smooth approximately one-dimensional map effectively relating one low velocity impact to the next. A major purpose of this paper is to construct and analyse this map and show why it is asymptotic to a one-dimensional map in the limit of $\sigma \to \sigma^*$. (In the papers by Froale and Bishop (1992) and Nusse et al (1993) an alternative approach to studying grazing is taken in which various one-dimensional maps with discontinuous first derivative are studied and their bifurcations analysed.)

In figure 1.5 we present a bifurcation diagram showing the different forms of motion as $\sigma$ is varied, plotting the values of $v$ at each impact. This diagram was computed for each value of $\sigma$ by calculating the first 4000 impacts of the impact oscillator and then recording the velocity of the following 5000 impacts. The most significant feature of this figure is the very rapid increase in the mean velocity of impact as $\sigma$ decreases through $\sigma^*$ and the simultaneous appearance low velocity

### Figure 1.4. The return map for successive low velocity impacts.
Intermittency in impact oscillators

Figure 1.5. The bifurcation diagram showing the final impact velocities of the periodic and intermittent motions as a function of $\sigma$.

impacts. Indeed, the velocity increases proportionally to the square-root of $(\sigma^* - \sigma)$ as predicted by (1.4). This is a significant observation from an engineering point of view, as the rapid increase in the mean velocity will lead to dramatic increase in the mean wear rate of the system. As $\sigma$ becomes more negative we also observe windows of periodic behaviour and period doubling bifurcations. These were also observed and studied for the more general system by Nordmark (1991). This behaviour is reminiscent of that of the one-dimensional logistic map and is partly due to properties of the natural discontinuous one-dimensional map, $f$, described above.

The layout of this paper is as follows. In section 2, we define a two dimensional (impact) map, $P: S^1 \times \mathbb{R} \to S^1 \times \mathbb{R}$, associated with (1.1), (1.2) and will determine some of its properties. In particular we study the dynamical effects of grazing and a consequent local reduction of $P$ to a one-dimensional map. (This section is rather technical and some of it could be omitted at a first reading. Further details are given in either Whiston (1987) or Nordmark (1991).) In section 3 we use numerical methods to investigate the bifurcation to intermittent chaos in more detail and demonstrate the existence of an underlying discontinuous one-dimensional map. In this section the main properties of the one-dimensional map are described. In section 4 we examine the local structure of the bifurcation close to $\sigma^*$ and prove the results of section 3, in particular justifying the existence and the properties of the one-dimensional map. Finally in section 5 we extend our analysis to more negative values of $\sigma$ which are not so close to $\sigma^*$. At these values certain global properties of $P$ become important, causing the form of the map to change. This enables us to explain features of figure 1.5 not predicted by the local analysis of section 4.

2. The impact map $P$

The basic dynamics of the system (1.1), (1.2) may be studied by reducing it to a map $P$, which we call the impact map, on the surface $\{x = \sigma, v \geq 0\}$ taking the phase and velocity $(\phi_0, v_0)$ at an impact at time $t = t_0$ to the phase and velocity $(\phi_1, v_1)$ at the
next. Here the phase, \( \phi \) is defined by \( \phi = t \mod(2\pi) \). The geometry of this map has been studied in detail by Whiston (1987) and Chillingworth (1989).

Given an impact with phase \( \phi_0 \) and velocity \( v_0 \), we firstly apply the instantaneous linear impact rule, which can be expressed as a map

\[
G : S^1 \times [0, \infty) \to S^1 \times (-\infty, 0],
\]

such that

\[
G(\phi, v) \mapsto (\phi, -rv).
\]

and then allow the system to evolve according to equation (1.1) until the next impact. If \( F \) is the map for this evolution then

\[
P := F \circ G.
\]

There are certain technical difficulties associated with the definition of \( P \) when \( v = 0 \). In particular, if \( v = 0 \) and the acceleration toward the obstacle is positive then the particle remains stuck to the obstacle for a non-zero period of time. Moreover, if \( v = 0 \) then there are certain values of the phase for which a subsequent impact does not occur and \( P \) is not defined. Extensions to the definition of \( P \) which overcome these difficulties are given in Whiston (1987) and their dynamical consequences discussed in Budd and Dux (1994).

The most significant feature of \( P \) of interest to us here is the fact, discussed in the introduction, that it is discontinuous. If we define

\[
\Sigma_0 := (\phi^*, \phi') \times [0]
\]

to be the set of zero-velocity or grazing impacts which lie in the range of \( P \) and correspond to maxima of \( x(t) \), then it is the existence impacts which leads to discontinuities in \( P \).

**Lemma 2.1.** Let \( \eta \) be a point such that \( \eta \not\in \Sigma_0 \), \( P(\eta) \in \Sigma_0 \) and the flow has a non-degenerate local maximum at this point, then \( P \) is discontinuous at \( \eta \).

**Proof.** Let \( \eta = (\phi_0, v_0) \) where \( v_0 \neq 0 \) and \( P(\eta) = (\phi_1, 0) \). Furthermore let the flow starting at \( \eta \) be \( x(t) \) such that \( x(\phi_0) = \sigma \). Then, \( x(t) \) has a local maximum at \( t_1 \) (with corresponding phase \( \phi_1 \)) such that \( x(t_1) = \sigma \) and \( x'(t_1) = -2m < 0 \). We now consider a sequence of trajectories \( x(t; \alpha) \) such that \( dx(t; \alpha)/dt = 0 \) and \( x(t_1; \alpha) = \sigma + \alpha \). If \( \alpha \) is close to 0 then, by the continuity of the flow (reversing the direction of time), and the assumption that \( v_0 \neq 0 \), it follows that \( x(t_1; \alpha) = \sigma \) at a time \( t(\alpha) \) which is a continuous function of \( \alpha \) with \( t(0) = \phi_0 \). Moreover, the velocity \( u(\alpha) \) at the time \( t(\alpha) \) will also be a continuous function of \( \alpha \). Such a trajectory will thus correspond to an initial point \( \xi(\alpha) = (t(\alpha), u(\alpha)) \) such that \( \xi(\alpha) \to \eta \) as \( \alpha \to 0 \). Now by the continuity of the flow it follows that there is a neighbourhood \([t_2, t_3] \) of \( t_1 \) (which does not depend on \( \alpha \) if \( \alpha \) is small) such that if we take \( \alpha \) sufficiently small then

\[
-3m < x(t; \alpha) < -m \text{ if } t \in (t_2, t_3).
\]

Thus, if \( \alpha < 0 \) then \( x(t; \alpha) \neq \sigma \) at any point in this interval whereas if \( \alpha > 0 \) then \( x(t; \alpha) = \sigma \) at a time \( T(\alpha) \) in the interval \( t_1 - (2\alpha/m)^{1/2} < T < t_1 - (2\alpha/3m)^{1/2} \). We conclude that if \( \alpha \to 0^+ \) then a trajectory starting at the point \( \xi(\alpha) \) impacts at the time \( T \) close to \( t_1 \) and hence \( P(\xi) \to P(\eta) \) as \( \xi(\alpha) \to \eta \). In contrast, if \( \alpha \to 0^- \), then the trajectory impacts at a time \( T > t_3 \) which
is bounded away from $t_1$ as $\xi(\alpha) \to \eta$. The map $P$ is therefore discontinuous at the point $\eta.$

**Note.** We can easily extend this result by defining two disjoint non-empty open subsets $V_1, V_2$ of a neighbourhood $U$ of $\eta$, such that if $\xi \in V_1$ has a corresponding flow $x(t, \xi)$ with a maximum at a time close to $t_1$ with height $h_{\max}(\xi)$ then $h_{\max}(\xi) > \sigma$ if $\xi \in V_1$ and $h_{\max}(\xi) < \sigma$ if $\xi \in V_2$. The map $P$ then has a discontinuity as $\xi$ passes from $V_1$ to $V_2$.

**Corollary 2.2.** Let $\xi \in V_2$ tend to $\eta$. If $P^2(\eta) \notin \Sigma_0$, then

$$P(\xi) \to P^2(\eta) \quad \text{as} \quad \xi \to \eta.$$

**Proof.** If the height of the maximum close to $t_2$ is smaller than but close to $\sigma$ then the proof of lemma 2.1 indicates that the next impact will be at a time $T > t_2$. As the flow is continuous, this impact must be in turn close to a point of impact of the trajectory $x(t)$ starting at $\eta$, which as $P^2(\eta) \notin \Sigma_0$ must also be the next impact. The result then follows.

At first sight it might appear that these discontinuities are unimportant and are merely the bi-product of a 'poor' definition of $P$. However, a grazing impact profoundly alters the stability of the flow $x(t)$ leading directly to the curious dynamics discussed in this paper.

Following Whiston (1987). We define the *discontinuity* set of $P$ to be the set $S$ where

$$S := P^{-1}(\Sigma_0).$$

We also define $W$ the dual of $S$ by

$$W := P(\Sigma_0) = P^2(S).$$

Furthermore we define

$$S^n := P^{-n}(\Sigma_0)$$

$$W^n := P^n(\Sigma_0)$$

for $n = 1, 2, 3 \ldots$.

The set $S$ is a subset of the projection onto $S_1 \times \mathbb{R}$ of the set $(\phi_0, v_0, \Lambda_0)$ of solutions to the equations $x(\phi_0 + \Lambda_0) = \sigma$, $v(\phi_0 + \Lambda_0) = 0$. It is locally a smooth curve but may contain branch points, which are singularities of the projection. In the present context is the effect of the discontinuity on the dynamics of $P$, governed by the behaviour of the derivative $DP$ near $S$ which is of interest. More details on the form of $S$ are given in Whiston (1987) and Chillingworth (1989).

Initially we prove a few simple geometric results on $S$ and $W$.

**Lemma 2.3.** Where it exists, the map $P^{-1}$ is given by,

$$P^{-1} = \begin{pmatrix} -1 & 0 \\ 0 & 1/r \end{pmatrix} \circ P \circ \begin{pmatrix} -1 & 0 \\ 0 & 1/r \end{pmatrix}.$$
Proof. Reversing the time direction in equation (1.1) or (1.2) has the effect of reflecting the \((x, \phi, v)\) phase space about the plane \(\phi = 0\). Thus the map
\[
\begin{pmatrix}
-1 & 0 \\
0 & -1
\end{pmatrix}
\circ F
\circ
\begin{pmatrix}
-1 & 0 \\
0 & -1
\end{pmatrix}
\circ P
\circ G^{-1}
\circ
\begin{pmatrix}
-1 & 0 \\
0 & -1
\end{pmatrix},
\]
takes the phase and velocity immediately before one impact to the phase and velocity immediately after the previous impact. Pre-multiplying by \(G^{-1}\) therefore gives \(P^{-1}\).

We deduce that
\[
P^{-1}(\Sigma_0) = \begin{pmatrix}
-1 & 0 \\
0 & 1/r
\end{pmatrix} P(\Sigma_0)
\]
and hence
\[
W = \left\{ \left( \frac{2\pi}{\omega} - \phi, rv \right) : (\phi, v) \in S \right\}.
\]

Since \(S\) and \(W\) are parameterized by \(\phi \in (\phi^*, \phi')\), we may introduce orientations on them by identifying as the positive direction, the direction in which \(\phi\) increases. With respect to this orientation we consistently define (at least locally) a right-hand side and a left-hand side. As \((\phi_0, v_0)\) approaches \(S\) from one side then \(v_1\) tends smoothly to 0 and the image point \(P(\phi_1, v_1)\) lies on one side of \(W\). Following Nordmark (1991) we call this side of \(S\) (and \(W\)) the impact side. Conversely, \((\phi_0, v_0)\) approaches \(S\) from the other side, then \(\phi_1\) and \(v_1\) jump to the other side of \(W\) as a new intervening impact occurs. This side of \(S\) (and \(W\)) is defined to be the non-impact side. The map \(P\) introduces stretching to the phase space on the impact side of \(S\).

For the remainder of this section we consider the behaviour of the map \(P\) in a neighbourhood of the set \(S\) and in particular consider the stretching introduced by the discontinuity. The discussion in this section will be limited and further details are given in Whiston (1987).

We presume that an impact at phase \(\phi_0\) and velocity \(v_0\) leads to a second impact at phase \(\phi_1\) and velocity \(v_1\). On the impact side of \(S\), \(v_1\) is close to zero and it is bounded away from zero on the nonimpact side. By solving the differential equations in (1.1) between impacts we may construct an explicit expression for the Jacobian
\[
DP(\phi_0, v_0) := \frac{\partial (\phi_1, v_1)}{\partial (\phi_0, v_0)}.
\]
of \(P\). This is derived in Budd et al (1993) and has the following form
\[
D_0 = DP(\phi_0, v_0)
\]
\[
= \begin{pmatrix}
\frac{1}{v_1} (-rv_0 \cos(A_0) + A_0 \sin(A_0)) & \frac{r}{v_1} \sin(A_0) \\
(-A_0 + rA_1 \frac{v_0}{v_1}) \cos(A_0) - \left( r v_0 - \frac{A_1 A_0}{v_1} \right) \sin(A_0) & -r \left( \cos(A_0) - \frac{A_1}{v_1} \sin(A_0) \right)
\end{pmatrix}
\]
\[
(2.1)
\]
Here $A_i = \cos(\omega \phi_i) - \sigma$ is the acceleration at each impact and $\Lambda_0 = t_1 - t_0$.

**Lemma 2.4.**

$$\text{Det}(D_0) = r^2 \frac{v_0}{v_1}. \quad (2.2)$$

Thus, as $r < 1$, the map $P$ on average is area contracting on phase space. However, if $v_1$ is small, as it will be on the impact side of $S$, the locally $P$ will introduce considerable stretching.

This result may be obtained by a direct calculation but also applies to more general impacting systems where there is no energy loss between impacts. A more general derivation is given in Budd et al (1993) where it is also shown that if $P$ is considered to be a map from $(\phi, v^2)$ to $(\phi, v^2)$ then $\text{Det}(D_0) = r^2$.

More insight may be obtained by considering a geometrically motivated decomposition of $D_0$ motivated by the following result.

**Lemma 2.5.** For fixed $c$ let $S_c$ be the curve of points $(\phi, v)$ such that $P(\phi, v) = (\phi_1, c)$ (so that $S_0 = S$) then (up to a scale factor) the normal to $S_c$ is

$$(\alpha(c), \beta(c))^T = ((v_1 A_0 + r A_1 v_0) \cos(\Lambda_0) + r \cos(\Lambda_0))^T. \quad (2.3)$$

**Proof.** As $v_1(\phi_0, v_0) = c$, $(\alpha, \beta) = (\partial v_1 / \partial \phi_0, \partial v_1 / \partial v_0)$ which is as given above.

It now follows by inspection that

$$D_0 = \frac{1}{v_1 A_1} \left[ \begin{array}{c} -1 \\ A_0 \\ A_1 \end{array} \right] \left[ \begin{array}{c} \alpha \\ \beta \\ 1 \end{array} \right] + \frac{1}{A_1} \left[ \begin{array}{c} 1 \\ 0 \\ 0 \end{array} \right] \left[ \begin{array}{c} A_0 \cos(\Lambda_0) + r v_0 \sin(\Lambda_0) \\ r \cos(\Lambda_0) \end{array} \right]. \quad (2.4)$$

Thus as we approach $S$ from the impact side, $D_0$ comprises two components of which one becomes singular as $v_1 \to 0$. However, if we approach $S$ from the non-impact side then $v_1$ does not tend to zero and $D_0$ does not become singular. It is clear from this decomposition of its Jacobian that as $v_1 \to 0$ the map $P$ introduces considerable stretching. Indeed if we consider a point close to $S$ lying on $S_c$, then any vector through this point in a direction not tangent to $S_c$ is to leading order stretched by a factor proportional to $1/c = 1/v_1$ and mapped onto the vector $[1, A_1]^T$. Similarly a vector tangent to $S_c$ is not stretched and mapped parallel to $[1, 0]^T$.

Using this decomposition we may derive an approximate formula for $v_1$ as $v_1 \to 0$. It is clear from its definition that $(\alpha(c), \beta(c)) = (\alpha(0), \beta(0)) + O(c)$ where $(\alpha(0), \beta(0))$ is a well defined vector normal to $S$. We now consider a point $s$ on $S$ and a curve of points $(\phi_0, v_0)$ on the impact side of $S$ given by

$$(\phi_0, v_0) = s - \theta(\alpha(0), \beta(0)) / |(\alpha(0), \beta(0))|^2.$$  

From the derivation of $D_0$ and the formula for $(\alpha(c), \beta(c))$ it follows that,

$$\frac{dv_1}{d\theta} = \frac{1}{v_1} + O(1) \quad \text{as} \quad v_1 \to 0.$$
Hence, as $\theta \to 0$

$$v_1(\theta) = (2\theta)^{1/2} + O(\theta). \quad (2.5)$$

We now consider the effect of applying the map $P$ twice to points on the impact side of $S$. From the definitions it follows that $S$ is mapped to $W$ under the action of $P^2$, indeed, points in a neighbourhood of $S$ are strongly contracted onto $W$. We see this as follows

**Lemma 2.6.** Let $(\phi_0, v_0)$ be a point on $S$ so that $P^i(\phi_0, v_0) = (\phi_i, v_i)$ and $(\phi_2, v_2) \in W$. Then, the tangent vector $\tau$ to $W$ at the point $(\phi_2, v_2)$ is given by

$$\tau = (\gamma, \delta) = \left( \frac{1}{v_2} \sin(\Lambda_1), -\cos(\Lambda_1) + A_2 \frac{\sin(\Lambda_1)}{v_2} \right)$$

where as before, $A_i = \cos(\omega \phi_i) - \sigma$ and $\Lambda_1 = \phi_1 - \phi_0$. \hfill $\square$

**Proof.** The Jacobian of $P$ evaluated at a general point $(\phi_1, v_1)$ is

$$D_1 = \begin{bmatrix}
\frac{1}{v_2} (-rv_1 \cos(\Lambda_1) + A_1 \sin(\Lambda_1)) & \frac{r}{v_2} \sin(\Lambda_1) \\
\left( -\left( A_1 + rA_2 \frac{v_1}{v_2} \right) \cos(\Lambda_1) - \left( rv_1 - A_1 A_2 \frac{v_1}{v_2} \right) \sin(\Lambda_1) \right) & -r \left( \cos(\Lambda_1) - \frac{A_2}{v_2} \sin(\Lambda_1) \right)
\end{bmatrix}$$

Now, if $(\phi_0, v_0) \in S$ then $v_1 = 0$ and the tangent vector to $S$ is mapped to the vector $[1, 0]^T$ which is in turn mapped to a tangent vector of $W$. Setting $v_1 = 0$ in $D_1$, calculating the image of $[1, 0]^T$ and rescaling gives $\tau$. \hfill $\square$

On the set $\Sigma_0$ it is clear from this construction that $D_1 = \begin{bmatrix} \gamma \\ \delta \end{bmatrix} [A_1, r]$. Moreover, as we move away from $\Sigma_0$ the map $P$ and its derivatives are regular and hence for small $v_1$

$$D_1 = \begin{bmatrix} \gamma \\ \delta \end{bmatrix} [A_1, r] + v_1 M_1,$$

where $M_1$ is a matrix which is continuous as $v_1 \to 0$.

The following result now follows immediately.

**Lemma 2.7.** If $s$ is a point on $\Sigma_0$ then any vector through $s$ is mapped by $P$ onto a tangent vector of $W$. Moreover, the vector $b = [-r, A_1]^T$ is mapped to zero.

We conclude from this result that a neighbourhood of $s$ is a mapped to a set which is tangent to $W$. This result will become very important in our discussions of intermittency because the contractive effect of $P$ in the direction of the vector $b$ effectively reduces it to a one-dimensional map in a neighbourhood of $s$.

We now consider the map $P^2$. Combining our two expressions for the Jacobian of $P$ it follows that on the impact side of $S$

$$D(P^2) = D_1 \circ D_0 = -\left( \frac{1 + r}{v_1} \right) \begin{bmatrix} \gamma \\ \delta \end{bmatrix} [\alpha, \beta] + \begin{bmatrix} a \\ b \end{bmatrix} [\alpha, \beta] + \begin{bmatrix} \gamma \\ \delta \end{bmatrix} [c, d] + O(v_1) \quad (2.6)$$
where the constants $a, b, c, d$ are continuous as $v_1 \to 0$.

We can use this expression to determine the form of $D(P)$ on the nonimpacting side of $S$ by ignoring the collision at $(\phi_1, v_1)$ and setting $r = -1$ in (2.6). In this case $D(P)$ would be regular and equal

$$D(P) = \begin{bmatrix} a \\ b \end{bmatrix} [\alpha, \beta] + \begin{bmatrix} \gamma \\ \delta \end{bmatrix} [c, d].$$

We now use formulae (2.6), (2.7) to determine the image of a rectangular neighbourhood of a point $s$ on $S$. In particular, we consider a small set $K$ of 'size' $\epsilon \ll 1$, parameterized by the scalars $\theta$ and $\psi$ such that

$$K = \{ (\phi, v) = s + \epsilon (\theta (\alpha, \beta) + \psi (-\beta, \alpha))/(\alpha^2 + \beta^2) \} \quad 0 \leq \theta, \psi \leq 1$$

where $(\alpha, \beta)^T$ is, as before, the normal vector to $S$ at $s$, pointing into the impact side. If $\epsilon > 0$ then $K$ lies on the impact side of $S$ and using the previously determined expression for $v_1$ and the above expression for $D(P^2)$ it follows immediately that there is a constant $f$ such that

$$P^2(K) = \left\{ P^2(s) + \left( -\frac{1+r}{2} \epsilon^{1/2} \theta^{1/2} + \epsilon \theta \psi + O(\epsilon) \right) \begin{bmatrix} \gamma \\ \delta \end{bmatrix} + \epsilon \theta \begin{bmatrix} a \\ b \end{bmatrix} + O(\epsilon^{3/2}) \right\}$$

where $(\gamma, \delta)^T$ is, as before, the tangent vector to $W$ at $P^2(s)$. The rectangle $K$ is thus stretched by a factor $\epsilon^{-1/2}$ and mapped to a long thin set tangent to $W$ and lying on the impact side of $W$. Conversely, if $\epsilon < 0$ then $K$ lies on the non-impacting side of $S$ and is mapped by the now regular map to a set of similar dimensions to $K$ on the non-impacting side of $W$.

We illustrate the set $K$ and its images in figure 2.1.

We summarize the results of this section in the following theorem.

**Theorem 2.8.** Let $K$ be the set defined above then

(i) If $\epsilon > 0$, $K$ is stretched by the map $P^2$ into a set tangent to $W$, and if $\epsilon < 0$ then $K$ is mapped to a set transverse to $W$.

(ii) If $\epsilon > 0$ and $\epsilon \theta$ and $\epsilon \psi$ are the coordinates of a point $(\phi, v)$ with respect to vectors normal and tangent to $S$, then the image of $(\phi, v)$ under the action of $P^2$
may be expressed in terms of coordinates $y$ and $x$ with respect to the normal and tangent to $W$ so that

$$y = A\epsilon\theta + O(\epsilon^{3/2}) \quad x = Be^{1/2}\theta^{1/2} + C\epsilon\psi + O(\epsilon\theta, \epsilon^2\psi^2).$$

(iii) If $\epsilon > 0$ then there is a one dimensional projection $Q$ of the set $K$ such that

$$|P^2((\phi, \nu)) - P^2(Q((\phi, \nu)))| = O(\epsilon^{3/2}).$$

Note. The result (ii) is also presented in Nordmark (1991) who obtained it by using a using a different derivation.

**Proof.** The results (i) and (ii) follow immediately from the remarks above. To prove (iii) we consider the preimage on $K$ of the set \{x = constant\} $\cap P^2(K)$. This is illustrated in figure 2.2. This set intersects the boundary of $P^2(K)$ at two points $e_{y_1}$ and $e_{y_2}$, corresponding to points $e(\theta_1, \psi_1)$ and $e(\theta_2, \psi_2)$ in $K$. To leading order

$$y_1 = A\theta_1, y_2 = A\theta_2, x = Be^{1/2}\theta_1^{1/2} + C\epsilon\phi_1 = B\epsilon^{1/2}\theta_2^{1/2} + C\epsilon\psi_2.$$

Thus

$$(y_1 - y_2) = A(\theta_1 - \theta_2) = \frac{AC}{B} \epsilon^{1/2}(\psi_2 - \psi_1)(\theta_1^{1/2} + \theta_2^{1/2}) \leq 2 \frac{AC}{B} \epsilon^{1/2} = O(\epsilon^{1/2}).$$

The pre-image of this set is to leading order the curve $U_x$ given by

$$U_x = \{(\theta, \psi) : Be^{1/2}\theta^{1/2} + C\epsilon\psi = x, 0 \leq \psi, \theta \leq 1\}.$$

It can be shown easily that $B, C > 0$. The collection of the sets $U_x$ as $x$ varies over $P^2(K)$ defines a foliation of $K$ parameterized by $x$. We define $Q$ as follows

$$Q((\theta, \psi)) = (\epsilon\theta^*, 0) : both (\epsilon\theta^*, 0) and e(\theta, \psi) lie in the same set $U_x$.

Alternatively, to leading order

$$Q(\epsilon(\theta, \psi)) = \left(\epsilon^{1/2}\theta^{1/2} + \frac{C}{B} \epsilon\psi\right)^2, 0).$$
It is clear from its construction that
\[ |P^2((\theta, \psi)) - P^2(Q((\theta, \psi)))| = O(\epsilon(y_1-y_2)) = O(\epsilon^3). \]

We see from this last result that if \( \epsilon \) is small then the action of \( P^2 \) on the impact side of \( S \) is essentially equivalent to that of a one-dimensional map. We shall return to this again in section 4 when we study the reduction of \( P \) to a one-dimensional map close to the bifurcation.

3. A qualitative account of intermittency after a grazing bifurcation close to resonance

Having discussed the geometry of the map \( P \) we now consider how this geometry determines the dynamics of the impact oscillator. The simplest form of attracting set of the map \( P \) is a periodic orbit. Such an orbit is a finite sequence of points, \((\phi^{(1)}, v^{(1)}), \ldots, (\phi^{(m)}, v^{(m)})\), such that \( P(\phi^{(m)}, v^{(m)}) = (\phi^{(1)}, v^{(1)}) \). To represent a physical solution of (1.1), (1.2) the corresponding trajectory must also satisfy the following two conditions:

(Ci) \[ v^{(i)} > 0 \quad \forall i, \]
(Cii) \[ x(t; \phi^{(i)}, v^{(i)}) < \sigma, \quad \text{for } t^{(i)} < t < t^{(i+1)}, \left( \text{where } \phi^{(i)} = t^{(i)} \bmod \frac{2\pi}{\omega} \right). \]

As the parameters \( \omega \) and \( \sigma \) are varied, a solution of (3.1) may cease to represent a physical solution of (1.1), (1.2) by violating either one of these conditions in a grazing bifurcation. This occurs in two ways. Either one of the impact velocities becomes negative, violating condition (Ci), or condition (Cii) is violated and an additional impact is included in the sequence. This latter phenomenon occurs when one element of the sequence \((\phi^{(i)}, v^{(i)})\) crosses the set \( S \). We now study an example of this second form of grazing bifurcation.

It is shown by Budd et al. 1993 that any periodic orbit of the harmonically forced impact oscillator must also be a harmonic or subharmonic of the forcing. Since it must also be a periodic point of \( P \), it will be characterized by a pair of numbers \((m, n)\), where \( m \) is as above and \( n \) is the order of the subharmonic of the forcing frequency. In the case of \((1, n)\) orbits, which correspond to fixed points of \( P \), the time between impacts equals \( n \) times the forcing period. From this condition we deduce the following formula giving the phase \( \phi_n \) and the velocity \( v_n \) of such orbits as (implicit) functions of \( \omega \) and \( \sigma \) (see Budd et al. 1993, Whiston 1987, and Hindmarsh and Jeffries 1984.)

\[
\frac{(s_n^2(1+r)^2 + \frac{(1-r)^2}{\omega^2})v_n^2 + 4s_n(1+r)}{(1-c_n)} = 0 \]
\[
\cos(\omega \phi_n) = \gamma + \frac{s_n(1+r)}{2\gamma(1-c_n)} v_n \]

where
\[
s_n = \sin\left(\frac{2\pi n}{\omega}\right) \quad c_n = \cos\left(\frac{2\pi n}{\omega}\right). \]

Thus, for fixed \( \omega > 1 \), the curve of \( v_n \) as a function of \( \sigma \), is part of an ellipse
which crosses the $\sigma$-axis at $\sigma = \pm |\gamma|$, with a saddle-node bifurcation at some value $\sigma_{SN}$ of $\sigma$. This curve is presented in figure 3.1. Inspection of the Jacobian of $P$, reveals that near $\sigma_{SN}$ the upper solution branch is stable. This branch loses stability at a period-doubling bifurcation when $\sigma = \sigma_{PD}$. Explicit expressions for $\sigma_{SN}$ and $\sigma_{PD}$ are given in Budd et al. (1993).

We parameterize the points on the ellipse in terms of $\phi_n$, which ranges from 0 at $(\sigma, v_n) = (-|\gamma|, 0)$ to $\pi/\omega$ at $(+|\gamma|, 0)$. At $(-|\gamma|, 0)$, the acceleration at impact is

$$\cos(\omega\phi_n) - \sigma = 1 + |\gamma|$$

which is always positive. Thus, as $v_n = 0$, the corresponding trajectory of the $(1, n)$ orbit must either intersect the obstacle between impacts or lie completely within the obstacle. Thus, if for some value of $\sigma$ the solution of (3.1) gives a physical orbit, then, by continuity in $\sigma$ it follows that there must be a first point $\sigma^* > -|\gamma|$, with corresponding $\phi_n^*, v_n^* > 0$ for which condition (Cii) is violated and a grazing bifurcation must occur. For many values of $\omega$, this occurs at a value of $\sigma^*$ for which the orbit has already lost stability through a period-doubling or a saddle-node bifurcation. However, this is not the case when $\omega$ is close to the subharmonic value $2n$. It was shown by Budd et al. (1993) that, for $\omega < 2n$, the major axis of the ellipse has positive slope, for $\omega > 2n$, it has negative slope and for $\omega = 2n$, it is vertical. Moreover, when $\omega = 2n$, the value of $v_n$ at both the saddle-node and period doubling bifurcations is zero. We refer to the case of $\omega = 2n$ as the resonant case. Indeed, if $\sigma = 0$ this leads to the largest amplitude behaviour. These values are significant as we may conclude from the above that: if $\omega$ is less than, but close to $2n$, the fixed point $(\phi_n, v_n)$ will remain stable for $\sigma > \sigma^*$, encounters a grazing bifurcation at $\sigma = \sigma^*$ and for $\sigma < \sigma^*$ is replaced by a $(2, 2n)$ orbit which theorem 2.1 indicates will be unstable.

The numerical studies presented in the introduction showed that for $\omega = 2$ and $r = 0.8$, there is a $(1, 1)$ orbit which encounters such a grazing bifurcation at $\sigma^* \approx -0.33126943 \ldots$ leading to a chaotic motion when $\sigma < \sigma^*$ with a characteristic structure akin to the 'intermittency' phenomenon of Pomeau and Manneville (1980).

To study the nature of this motion in more detail we record the velocities $v_i$ at each impact. In figure 3.2 we present a plot of 1000 values of $v_i$ recorded against $i$. 

Figure 3.1. The ellipse describing the impact velocity of the $(1, 1)$ periodic orbit as a function of $\sigma$. 

\begin{center}
\includegraphics[width=\textwidth]{figure3.1.png}
\end{center}
and in figure 3.3 the same velocities but this time ordered by size giving an indication of the measure of the corresponding attractor. It is clear from these figures that the the velocities separate into two very distinct sets $\mathcal{A}$ and $\mathcal{B}$ of 'low' and 'high' velocities where

$$\mathcal{A} = \{v_i : v_i < 0.5\} \quad \text{and} \quad \mathcal{B} = \{v_i : v_i > 0.5\}.$$  

The low velocity impacts may be indexed as $v_i$, where $i_{j-1} < i_j < i_{j+1}$ etc, so that between each impact with a 'low' velocity there are a number of impacts with a 'high' velocity. In figure 1.4 we presented the graph of $v_{i+1}$ plotted as a function of $v_i$ for a data set of 2000 points, where we noted the remarkable result that it appears that the 'low velocity' impacts in $\mathcal{A}$ are related by a well defined, discontinuous, one-dimensional map, $F(v) : \mathcal{A} \rightarrow \mathcal{A}$. Indeed, we may reduce the dynamics on the whole of the phase space to that on $\mathcal{A}$, governed by a closely related map $f$. In
Figure 3.4. The distribution of impact velocities on Ω ordered with respect to size.

Figure 3.4 we present the velocities \( u_i \) ordered with respect to size. It is not unreasonable to conclude that this graph has a square-root form with the probability that \( u_i < V \) proportional to \( V^2 \). This, we show in section 4, follows from the stretching result in theorem 2.8. (Similarly the above figure shows that there is an approximately uniform distribution of velocities in the set \( \mathcal{R} \).) The probability of a low velocity \( u_i \) occurring is thus much lower than a high velocity accounting for the relative sparsity of low velocity points in the plot of \( F(v) \).

The iterates of \( P \) on the whole phase space are given in figure 3.5, showing the strange attractor of the intermittent chaotic motion when \( \sigma = -0.333 \). The set \( \mathcal{M} \) above is a projection of an approximately one-dimensional set \( \mathcal{J} \), indicated on this figure which intersects the line \( v = 0 \) and which approximates a subset of \( W^2 \). A
typical point in the set $\mathcal{J}$ returns to it under iteration after a number of high velocity impacts, during which it moves toward the position that the fixed point of $P$ occupied in phase space before the grazing bifurcation. The strange attractor has $N$ one-dimensional 'fingers' which intersect close to the earlier position of the fixed point. The effect of $P$ is to map one finger into the next with an individual point 'moving down' the fingers toward the point of intersection from which it is mapped into $\mathcal{J}$ and then back onto the first finger. Similar figures to this are presented in Nordmark (1991).

In a sense which we shall make precise in section 4, the points in the set $\mathcal{J}$ are described by a natural coordinate $s$, so that $s = 0$ when $v = 0$ and $s$ increases as $v$ increases. In terms of this coordinate we may describe the above map from $\mathcal{J}$ to itself in terms of the map $f(s)$. The map $F(v)$ is an approximation to this map due to the projection of $\mathcal{J}$ onto the $v$-coordinate.

By studying the form of the map $F(v)$ indicated by figure 1.4 we may infer various properties of the map $f(s)$ which we list as follows.

1. The map $f(s)$ is a piecewise continuous function. The domain $\mathcal{J}$ of $f$ is divided into $N + 1$ subintervals $J_k$, $0 \leq k \leq N$, on which $f$ is continuous, so that

$$J_k = (a_k, a_{k+1}]$$

Here $0 = a_0 < a_1 < \ldots < a_{N+1}$. The index, $k$, of each interval $J_k$ is such that $k + 1$ equals the number of iterates of $P$ (or high velocity impacts), which separate the corresponding elements of the set $\mathcal{J}$.

2. On each $J_k$, there is a constant $\alpha_k$ such that $f(s)$ has the approximate form

$$f(s) = \frac{(a_{k+1} - s)^{1/2}}{(a_{k+1} - a_k)^{1/2}}$$

except on the last interval $J_N$, where there is a further constant $b_{N+1}$:

$$f(s) = \alpha_N \frac{(b_{N+1} - s)^{1/2}}{(b_{N+1} - a_N)^{1/2}}$$

with

$$b_{N+1} > a_{N+1}.$$ 

Here the values of $\alpha_k$ are bounded above by $a_{N+1}$ and appear to increase with $k$ if $k \geq 1$.

3. The values of $a_k$ are approximately given by

$$a_k = A(r^{-k} - 1)/k$$

for $1 \leq k \leq N$ where $A$ is constant. Substituting $N + 1$ into the above gives the approximate value for $b_{N+1}$.

4. The square-root form of $f(s)$ on each $J_k$ and the increasing lengths of the $J_k$ mean that the invariant measure of $f$ on $\mathcal{J}$ will tend to be concentrated on the intervals $J_N, J_{N-1}$; thus, we would expect to see high velocity excusions between visits to $\mathcal{J}$ of length $N + 1$ or $N$ impacts much more often than shorter excursions. This is illustrated in figure 3.6 which shows a histogram of the numbers of excursions of different lengths for $\sigma = -0.333$ for which $N = 24$.

5. In each subinterval $J_k$, $f(s)$ has a single fixed point corresponding to a $(k + 1, k)$ periodic orbit of $P$. If $\varepsilon$ is small then the slope of $f(s)$ is everywhere less than $-1$ and thus all the corresponding fixed points are unstable.
6. As \( |\sigma - \sigma^*| \) is decreased, the number, \( N + 1 \), of subintervals \( J_k \), increases without bound. New intervals appear at a sequence of discrete values \( \sigma_N \) of \( \sigma \). At each \( \sigma_N \) a new fixed point appears, corresponding to a grazing bifurcation of a \((N+1, N)\) orbit of \( P \) violating condition (Cii). As \( \sigma \to \sigma^* \)

\[
N(\sigma) \approx \frac{1}{2} \frac{\log(\sigma^* - \sigma)}{\log(r)} - \log\left[ \frac{1}{2} \frac{\log(\sigma^* - \sigma)}{\log(r)} \right].
\]

A schematic illustration of the map \( f(s) \) is given in figure 3.7. It should be emphasized that \( f(s) \) is in fact only an approximation to a one-dimensional map.

Figure 3.6. The histogram of the number of high velocity impacts between the low velocity ones showing the peak for 24 impacts.

Figure 3.7. A schematic for the return map \( f(s) \).
Intermittency in impact oscillators

Indeed, if $\epsilon = (\sigma^* - \sigma)$ then, in the limit of small $\epsilon$, each of the curves defining $f(s)$ will be a set of width $O(\epsilon^{3/2})$ and length $O(\epsilon^{1/2})$. As the ratio of the width to the length is $O(\epsilon)$ then this set is asymptotic to a one-dimensional set. The one-dimensional nature of the map is also emphasised by the concentration of the measure of the attractor on those impacts corresponding to points in $J_N$ and $J_{N-1}$.

We note from 5 that on each interval $J_k$, the map $f(s)$ has a fixed point which will (in general) be unstable. (The cases where they are stable are discussed in section 5.) Each point corresponds to an unstable $(k + 1, k)$ periodic solution of the impact oscillator system. It follows from 6 that the grazing bifurcation creates approximately $\log(\epsilon)/(2 \log(r))$ such points.

All of the above results will be proved in section 4 for the case of $\sigma$ close to $\sigma^*$. For more negative values of $\sigma$, the form of $f(s)$ becomes more complicated than that suggested above and, indeed, loses its 'one-dimensional' character. In figure 3.8 we demonstrate this by plotting the related map $F(u)$ for $\sigma = -0.3375$. Although $F(u)$ has broadly similar features to the previous map, the points do not lie on as sharply defined curves but on rather broader sets. Moreover the slope of $F(u)$ on the interval $J_N$ becomes flatter, allowing the fixed point in that interval to become stable for some values of $\sigma$ which then loses stability in a super-critical period doubling bifurcation. This leads to the bifurcation diagram presented in figure 1.5. The reasons for this behaviour are rather subtle and are discussed in section 5.

4. The form of the grazing bifurcation when $\sigma$ is close to $\sigma^*$

We now study the system described in section 3 for $\sigma$ close to $\sigma^*$, $(\sigma^* \approx -0.331 \, 269 \, 43 \ldots$ when $\omega = 2$ and $r = 0.8$) to determine a description of the bifurcation to chaos in terms of $\epsilon = \sigma^* - \sigma$, when $\epsilon$ is small. Our analysis is similar to that of Nordmark (1991) but, by restricting ourselves to the near resonant case, we may extend Nordmark's calculations to a detailed investigation of the map $f(s)$. 
Our calculations are based upon the observation that if $\epsilon$ is small then we may partially analyse the dynamics of the map $P$ in terms of the local linearization of the dynamics of a related map $Q$ in the neighbourhood of a fixed point of this latter map.

We shall assume that a stable $(1,1)$ orbit corresponding to a fixed point $y = (\phi_n, v_n)$ of $P$, undergoes a grazing bifurcation when $\sigma = \sigma^*$. At this value, $y$ crosses a point of intersection:

$$p = (\phi_0, v_0) \in W \cap S$$

at non-zero speed such that $y$ lies above $p$ (i.e. $v_n > v_0$) if $\sigma > \sigma^*$.

Our discussion involves certain technical conjectures about the generic behaviour of $W$ and $S$ as functions of $\epsilon$, which have been verified numerically for the range of parameters considered. Figure 4.1 shows the curves $W$ and $S$ for $\omega = 2$, and for $\sigma$ in a neighbourhood of $\sigma^*$. These curves intersect at a single point, $p$, and the relative orientations are such that the impact side of $S$ lies below $S$ and to the left whereas the impact side of $W$ lies below $W$ and to the right. The sets $W$ and $S$ have a particularly simple form at these parameter values, with no branch points, and this simplicity makes analysis significantly easier. For other parameter ranges where chaos occurs, $W$ and $S$ may have a much more complicated geometry and the chaotic attractors are correspondingly harder to analyse; some examples of these are given in Budd et al (1993) and in Whiston (1987).

A central idea in this section is the construction of a map $Q$ which is related to $P$ and which perturbs smoothly as $\epsilon$ passes through zero.

**Lemma 4.1.** There exists a neighbourhood $U$ of $p$ on which we may define a map $Q$ as follows.

(i) If $u \in U$ and $u$ is on the non-impact side of $S$, then

$$Q(u) = P(u);$$

---

**Figure 4.1.** The orientations of $W$ and $S$ for $\sigma$ close to $\sigma^*$. 

---
(ii) if \( u \in S \cap U \), then
\[ Q(u) = P^2(u); \]

(iii) if \( u \in U \) and \( u \) is on the impact side of \( S \), then
\[ Q(u) = \left(\phi', v'\right), \]

where \( \phi' \) and \( v' \) are the phase and velocity of the second non-negative velocity crossing of \( x = \sigma \) by the non-impacting solution \( x(t) \) of (1.1) (in other words, we allow one penetrating excursion before the next impact),

(iv) if \( Q(u) \) does not lie in \( \Sigma_0 \) then \( Q \) is continuously differentiable.

**Proof.** The construction of \( Q \) is identical to that of \( P \), except that an impact is ignored. Hence the continuity and differentiability properties are similar provided that \( Q(u) \) does not lie in \( \Sigma_0 \).

The map \( Q \) is illustrated in figure 4.2.

The following results follow immediately from the definition of \( Q \).

**Corollary 4.2.**

(i) If \( W_Q = W \cap U, S_Q = S \cap U \). Then \( Q \) maps \( S_Q \) to \( W_Q \).

(ii) If \( \sigma > \sigma^* \), the fixed point \( y(\varepsilon) \) of \( P \) is a fixed point of \( Q \) (if it lies in \( U \)).

(iii) For \( \sigma < \sigma^* \), the non-physical fixed point \( y(\varepsilon) \), obtained from solving the algebraic conditions (3.1), (3.2), is a fixed point of \( Q \) so long as it lies in \( U \). Moreover, \( y(\varepsilon) \) varies smoothly as \( \varepsilon \) passes through zero and its stability is unchanged.

(iv) If a path \( \Gamma: [0, 1] \rightarrow U \) crosses \( S \) at a point \( g \in U \), with \( g = \Gamma(t_g), \Gamma(0) \) on the non-impacting side and \( \Gamma(1) \) on the impact side. Then we have that

\[ \lim_{t \downarrow t_g} P(\Gamma(t)) = P^2(g) = Q(g). \]

The significance of the map \( Q \) is that points on the non-impact side of \( S \) behave identically under the iteration of both \( P \) and \( Q \). In particular, when \( \sigma < \sigma^* \), the fixed point, \( y \), of \( Q \), has a basin of attraction of which part lies on the non-impacting side of \( S \) and hence points on this side will be attracted toward \( y \) under the iteration of \( P \) until they cross \( S \). During this motion, when they are close to \( y \) their motion can be accurately described by the local linearization of \( Q \) about \( y \). By choosing \( \varepsilon \) small we can always assume that this will be the case.
We now study some of the aspects of the local dynamics of $Q$ in the
neighbourhood of $y$.

For $\omega = 2\pi$, it follows from the expression of the Jacobian given in lemma 2.6
that as $\sin(\Lambda_1) = 0$ and $\cos(\Lambda_1) = -1$ then the Jacobian of $Q$ at $y = (\phi_n, V_n)$ is

$$DQ(\phi_n, V_n) = \begin{pmatrix} r & 0 \\ (1 + r)A & r \end{pmatrix}$$

(where $A_0 = A_1 = A = \cos(\omega \phi_n - \sigma)$). This has a single eigenvector $\begin{pmatrix} 0 \\ 1 \end{pmatrix}$ with a
double eigenvalue. At resonance, the point $y$ is thus a degenerate node with nearby
points being attracted along a one-dimensional local stable manifold. For the case
considered, $\sigma < 0$ and $A > 0$. The dynamics of $Q$ close to $y$ is thus locally
approximated by the pair of linear difference equations

$$x_{k+1} = rx_k,$$
$$y_{k+1} = (1 + r)Ax_k + ry_k$$

where $x_k = \phi_k - \phi_n$ and $y_k = v_k - v_n$. Solving these gives

$$x_k = r^kx_0,$$
$$y_k = k(1 + r)A^{k-1}x_0 + r^ky_0.$$  

Moreover, $Q$ has a one-dimensional invariant manifold, which coincides exactly
with the vertical one dimensional eigenspace spanned by $\begin{pmatrix} 0 \\ 1 \end{pmatrix}$. We see this as follows.

**Lemma 4.3.** Let $C$ be the vertical line through $y$. Then $C$ is invariant under $Q$.

**Proof.** The equations (3.2), (3.3) imply that, for $\omega = 2\pi$, $\phi_n$ is given by,

$$\phi_n = \frac{1}{\omega} \cos^{-1}\left(\frac{\sigma}{\gamma}\right).$$

Explicit expressions for $x$ and $v$ between impacts are easily obtained and are given in
Budd *et al* (1993). Substituting $\omega = 2\pi$, $\phi_0 = \phi_1 = \phi_n$, $\Lambda_0 = \pi$, into these expressions gives,

$$x(t_i) = -\sigma + 2\gamma \cos(\omega \phi_n) = \sigma$$
$$v(t_i) = rv_0 - 2\omega \gamma \sin(\omega \phi_n).$$

Thus, for $\omega = 2\pi$, an impact at $(\phi_n, v_0)$ will be mapped by $Q$ to an impact with the
same phase after a time $2\pi m/\omega = \pi$. \(\Box\)

We now presume that for sufficiently small $\epsilon = \sigma^* - \sigma$, the set $S$ intersects $C$ at a
point $(x, y) = (\phi - \phi_n, v - v_n) = (0, a\epsilon)$ where $a > 0$. Moreover, we shall assume
that $\epsilon$ is small enough so that this point lies in the neighbourhood of $y(\epsilon)$ for which
the local linearization accurately captures the dynamics of $Q$. We presume further (on
the numerical evidence presented in figure 4.1) that the local form of $S$ is given by

$$S = \{(x, y) : x = bs, y = ae - cs, s \in \mathbb{R}\}$$

where $b, c > 0$ are continuous as $\epsilon$ passes through 0. Given this and the above local
form for \(Q\), we may compute the local form of the sets \(S^k\) and \(W^k\) described in section 2 so that

\[
W^k = \{(x, y) : x = r^k bs, y = r^k ae + r^{k-1}(k(1 + r)Ab - rc)s\}
\]

\[
S^k = \{(x, y) : x = r^{1-k} bs, y = r^{1-k} ae - r^{-k}((k - 1)(1 + r)Ab + rc)s\}.
\]

(4.3)

We observe that these sets all intersect at the same point when \(\epsilon = 0\). We also note, from section 2, that this description of the sets is only valid for those points \((x, y)\) which lie above \(W\) (i.e. those points which are images under \(P\) of points on the nonimpacting side of \(S\).)

We illustrate the resulting sets in figure 4.3.

We now take a similar approach to Nordmark, and construct a trapping region \(H\) for the map \(P\) by considering sets invariant under \(P\) and its iterates.

**Lemma 4.4.** Let \(E\) be the approximately triangular closed set bounded by \(C\), \(S\) and \(W\), and let \((\phi, v)\) be a point on the non-impact side of \(S\) lying close to \(y\), with \(\phi > \phi_n\). Then there exists a finite \(N\) such that

\[P^k(\phi, v) \text{ lies on the non-impact side of } S \text{ for } k < N,\]

and

\[Q^N(\phi, v) = P^N(\phi, v) \in E.\]

**Proof.** We presume that \((\phi, v)\) lies sufficiently close to \(y\) so that it is both in its
domain of attraction and in a neighbourhood where the local linearisation of $Q$ applies. Thus

$$Q^k(\phi, v) \to Y \quad \text{as } k \to \infty,$$

and hence there must be at least $N < \infty$, such that $Q^N(\phi, v)$ lies on the impact side of $S$. It further follows from section 2 that, since $Q^{N-1}(\phi, v)$ lies on the non-impact side of $S$, $Q^N(\phi, v)$ must lie on the non-impact side (i.e. to the left) of $W$. Finally, we note that, as $(\phi, v)$ lies to the right of $C$, then the local linearisation of $Q$ implies that $Q^k(\phi, v)$ lies to the right of $C$ for all $k > 0$. Hence, $Q^N(\phi, v)$ lies to the left of $W$, the right of $C$ and on the impacting side of $S$. Consequently it lies in the set $E$. □

The set $E$ can now be extended to form the trapping region $H$.

**Lemma 4.5.** Let $a$ and $b$ be the respective points of intersection of $C$ with $S$ and $W$ (so that to leading order in $\epsilon$, $a = (\phi_n, v_n) + (0, a\epsilon)$ and $b = (\phi_n, v_n) + (0, r\epsilon)$). Then

$$Q(a) = b = P^2(a)$$

and $P^2$ takes an arc in $C$ (with end point $a$) diffeomorphically to an arc tangent to $W$ at $b$ which lies to the right of $W$.

**Proof.** By lemma 4.3, $C$ is invariant under $Q$, implying that $Q(a) \in C$, but statement (i) in corollary 4.2 implies that

$$Q(a) \in W$$

and the result follows. The tangential nature of the intersection follows from theorem 2.8, as the subset of $C$ lying between $a$ and $b$ is on the impact side of $S$. □

Now, let be the approximately triangular closed region of 'size' $\epsilon$, bounded by $C$, $P^2(C)$ and $S$, with vertices $a, b, c$ as shown in figure 4.4, so that $E \subseteq \mathcal{D}$. The set

![Figure 4.4](image-url)
\( \mathcal{O} - E \) is small because of the tangency of \( P^2(C) \) to \( W \) and hence the point \( c \) is given approximately by the intersection between \( W \) and \( S \). It therefore follows from our earlier calculation that

\[
e = \epsilon \left( \frac{ar(1-r)}{A(1+r)} \right) + O(\epsilon^2). \tag{4.4}\]

In particular, if we parameterize \( W \) by the scalar \( t \) so that

\[
W = \{(x, y): x = trb, y = t((1 + r)Ab - rc), t \in \mathbb{R}\} \tag{4.5}
\]

then \( c \) is approximately given when

\[
t = \frac{ea(1-r)}{Ab(1+r)}. \tag{4.6}
\]

We note further that \( b \) is given when \( t = 0 \).

Now, the map \( P^2 \) is a diffeomorphism on \( \mathcal{O} \) and hence maps the boundary of \( \mathcal{O} \) to the boundary of \( P^2(\mathcal{O}) \) and the interior of \( \mathcal{O} \) to the interior of \( P^2(\mathcal{O}) \). As \( \mathcal{O} \) intersects \( S \), lies on the impact side of \( S \) and is of size \( \epsilon \), we may apply theorem 2.8, to conclude that \( P^2 \) maps \( \mathcal{O} \) to a set of length \( O(\epsilon^{1/2}) \) and width \( O(\epsilon^{3/2}) \) approximately tangent to \( W \) at \( b \), lying to the right of \( W \) and pointing into the non-impact side of \( S \). The set \( P^2(\mathcal{O}) \) is also illustrated in figure 4.4 and its asymptotic approximation to a one-dimensional set in the limit of \( \epsilon \to 0 \) leads directly to the form of the map \( f(s) \) described in section 3.

Using these results we construct a trapping region for \( P \).

**Lemma 4.6.** For \( \epsilon \) sufficiently small, there exists a finite \( N(\epsilon) > 0 \), such that the set

\[
H := \bigcup_{i=1}^{N+2} P^i(\mathcal{O}),
\]

is a trapping region for \( P \) so that

\[
P(H) \subset H.
\]

**Proof.** Firstly, we prove that every point of \( P^2(\mathcal{O}) \) lying on the impact side of \( S \) in fact lies in \( \mathcal{O} \). As \( \mathcal{O} \) is bounded by \( C, S \) and \( P^2(\mathcal{O}) \), it follows that \( P^2(\mathcal{O}) \) is bounded by \( P^2(C) \), \( W \) and \( P^2(bc) \) (which is a subset of \( P^i(C) \)). Hence, \( P^2(\mathcal{O}) \) must lie in the region bounded by \( P^2(C) \) and \( W \). The intersection of this region with the impact side of \( S \) then necessarily lies in \( \mathcal{O} \). We can be more precise by invoking the local linearization for small \( \epsilon \). Using the approximation (4.4), (4.6) for \( c \) and using the local linearisation of \( Q \) implies that the point \( P^2(c) \) approximately lies on the intersection of \( W^2 \) and \( W \) and is given when

\[
t = r \frac{ea(1-r)}{Ab(1+r)},
\]
Thus, for small $\epsilon$, $P^2(\epsilon)$ lies strictly between $b$ and $c$.

Next we consider those points $x \in P^2(\mathcal{B}) \cap S$ lying on the intersection of $P^2(\mathcal{B})$ and $S$. We know that $P(x) \in \Sigma_0 = \{ (\phi, v) : v = 0 \}$, and that $P^2(x) = Q(x) \in W$. Moreover, $x$ lies between the points $p$ and $c$ on $S$ and thus $P^2(x)$ lies between $P^2(c)$ and $P^2(p)$ on $W$. Consequently, we have $P^2(x) \in \mathcal{B}$.

Finally, we consider those points in $P^2(\mathcal{B})$ lying on the non-impact side of $S$. We now presume that $\epsilon$ is sufficiently small such that points of $O(\epsilon^{1/2})$ distant from the point $y(\epsilon)$ still lie sufficiently close to $y$ to lie within its domain of attraction under the action of the map $Q$. It follows from lemma 4.4 that each such point, $x$, will lie in $E = \mathcal{B}$ after $N(\epsilon; x)$ further iterations. By simple continuity and compactness arguments it follows further that we may take a maximum value of $N$ to be $N(\epsilon)$ as $x$ varies over $P^2(\mathcal{B})$. This completes the proof. 

Thus $H$ is a compact invariant set for $P$. Lemma 2.4 implies that $P$ will be contracting on $H$ and, hence, that $H$ contains a set of zero Lebesgue measure, which is the $\omega$-limit set of all the points in $H$.

In figure 4.5 we indicate the form of the set $H$. The set is, in fact, very close in form to the attractor illustrated in figure 3.5. In particular, the sets $P^2(\mathcal{B}), P^3(\mathcal{B}), \ldots, P^{N+1}(\mathcal{B})$ form the $N$ fingers close to $y$, whilst the set $P(\mathcal{B})$ contains $\mathcal{B}$.

The value of $N(\epsilon)$ in the limit $\epsilon \to 0$ can be estimated from the local linearisation of $Q$. The point on $P^2(\mathcal{B})$ furthest from $\mathcal{B}$ is $P^2(b)$ lying on distance approximately $Ke^{1/2}$ from $y$, where $K$ is essentially independent of $\epsilon$. This point returns to $\mathcal{B}$ when it is $O(\epsilon)$ distant from $y$. From the linearisation it follows that this occurs when

$$Nr^NKe^{1/2} = O(\epsilon) \quad \text{so that} \quad Nr^N = O(\epsilon^{1/2}).$$

![Figure 4.5. The trapping region $H$.](image-url)
This implies that if \( \varepsilon \) is small

\[
N = \frac{1}{2} \log(\varepsilon) - \log \left[ \frac{1}{2} \log(\varepsilon) \right]
\]

giving the result (1.3) stated in the introduction.

We now proceed to construct the (approximately) one-dimensional map \( f(s) \) (and the related map \( F(v) \)) described in section 3.

The set \( P^2(\mathcal{C}) \) is approximately coincident with \( W \) and is divided into \( N \) intervals \( I_k, k = 0 \ldots N, \) defined by

\[
I_k = \{ x \in P^2(\mathcal{C}) : P^k(x) \in \mathcal{D} \}.
\]

If \( 1 \leq k \leq N - 1 \) then \( I_k \) is approximately the interval of points in \( W \) lying between the intersection of \( W \) with the sets \( S^k \) and \( S^{k+1} \). As \( I_1 \) is on the non-impact side of \( S \) it follows that it is bounded below by, and does not include \( S \) and above by, and includes, \( S^2 \). Similarly, \( I_k \) is bounded below by, and does not include, \( S^k \) and is bounded above by, and includes \( S^{k+1} \), whilst \( I_0 \) is the interval lying between the intersections of \( C \) and \( W \) with \( S \). The set \( I_N \) lies in a subinterval, between \( S^N \) and \( S^{N+1} \). Using the local linearization it follows, after some manipulation, that if \( W \) is parameterised by \( t \) as in (4.5) then

\[
I_0 = \left\{ (x, y) \in W : 0 \leq \frac{A b (1 + r)}{a e r} t \leq (r^{-1} - 1) \right\}
\]

\[
I_k = \left\{ (x, y) \in W : \frac{(r^{-k} - 1)}{k} \leq \frac{A b (1 + r)}{a e r} t \leq \frac{(r^{-1} - k - 1)}{(k + 1)} \right\} \quad 1 \leq k \leq N - 1.
\]

The sets \( I_k \) are illustrated in figure 4.6. As \( \varepsilon \) is small they are line segments to a first approximation as they have width \( O(\varepsilon^{3/2}) \) and length \( O(\varepsilon^{1/2}) \).
Considering the image each set $I_k$ for $k > 0$, we define $K_k = P^k(I_k)$. As the points in the set $I_k$ lie close to $W$ it follows that the points in $K_k$ lie close to $W^{k+1}$. Moreover, for $1 \leq k \leq N - 1$ it follows that $K_k$ is close to $\mathcal{D} \cap W^{k+1}$ and is bounded above by, and includes, the set $S$ and is bounded below by, and does not include, the set $W$. The set $K_N$ is close to a subset of $\mathcal{D} \cap W^{N+1}$ and is bounded below by the set $W$ alone. The points where $W$ intersects $K_k$ are computable from the local linearization of $\mathcal{Q}$, so that,

$$K_k \cap W = \left\{(x, y) \in W : \frac{Ab(1 + r)}{ae} t = \frac{(1 - r^k)}{k}\right\}. \quad (4.8)$$

The sets $K_k$ are also illustrated in figure 4.6.

We now consider the action of $P$ approximately triangular set $\mathcal{J}$ given by $P(\mathcal{D})$ which is of length $O(\varepsilon^{1/2})$ and width $O(\varepsilon)$ at the base. For small $\varepsilon$ this very closely approximates a line segment parallel to $W^2$. This set is divided into $N + 1$ sets $J_k$ such that $P(J_k) = I_k$, where each set $J_k$ is a thin trapezium, apart from $J_N$ which is a thin triangle, of width $O(\varepsilon)$ in a direction orthogonal to that of $W^2$. To study the action of $P$ on this set we introduce a coordinate system $(s, u)$ such that for each point $j$ in $\mathcal{J}$

$$j = w + sa + ub$$

where $w = W^2 \cap S_0$, $a = (1, A_1)^T$, $b = (-r, A_1)$ and $A_1$ is the acceleration at $w$. It follows from theorem 2.8 that the vector $a$ is approximately parallel to $\mathcal{J}$, and that the map $P$ has an approximately zero stretching rate in the direction $b$ and an approximately constant stretching rate in the direction $a$. Thus we may consider the action of $P$ on $\mathcal{J}$ to be a map on the single coordinate $s$. As a first consequence we may estimate the length (and the corresponding value of $s$) of each set $J_k$ along $W^2$ by rescaling the values of $t$ corresponding to the intervals $I_k$. We conclude that there is a constant $J$ such that

$$|J_0| \approx J(r^{-1} - 1) \quad |J_k| \approx J\left[\frac{r^{-k-1} - 1}{(k + 1)} - \frac{r^{-k} - 1}{k}\right]. \quad (4.9)$$

Points in each set $J_k$ are mapped by $P$ through $I_k$ and $D$ to return to $P(\mathcal{D})$ in $k + 2$ iterations. We now consider the behaviour of the iterates of $P$ on each $J_k$. Each set $J_k$ is bounded below, and does not include, the set $L_k = S^{k+1} \cap P(\mathcal{D})$. It follows immediately that all points in $L_k$ have the same coordinate $s = a_k$. Similarly, $J_k$ is bounded above, and includes, the set $L_{k+1} = S^{k+2} \cap P(\mathcal{D})$ for which $s = a_{k+1}$. Following $k + 1$ iterations of $P$, $J_k$ is mapped into the approximate line segment $K_k$, the points on $L_k$ lie on $K_k \cap W$ and those points in a neighbourhood of $L_{k+1}$ are mapped to points in a neighbourhood of $K_k \cap S$. Because the map $P^{k+1}$ has an approximately uniform stretching rate throughout the set $J_k$ it follows that there is an approximately linear map between $J_k$ and $K_k$. As $K_j$ lies on the impact side of $S$ and is always close to $S$ we may now apply the result of theorem 2.8 to deduce the behaviour of the points in $K_k$ under the stretching action of $P$. To do this we note that each $K_k$ is approximately a line segment and it is clear from figure 4.6 that the 'length' of $K_k$ increases with $k$ if $k \gg 1$ and is bounded above, although we may have $|K_0| > |K_1|$ and $K_k$ is approximated by all or part of the line segment joining $s_k$ to $w_k$. 
where $s_k = S \cap W^{k+1}$ and $w_k = W \cap W^{k+1}$ ($w_0 = W \cap C$). (Note that $w_{k+1} = P^2(s_k) = Q(s_k)$.) The set $K_k$ can thus be parameterized in terms of the scalar $\lambda$ so that

$$K_k = s_k + \lambda(w_k - s_k)$$

where $0 \leq \lambda < 1$ if $k < N$, or $\lambda^* \leq \lambda < 1$ if $k = N$ for some $\lambda^* > 0$.

Invoking theorem 2.8 it now follows that the image of under $P$ of a point parameterised by $\lambda$ lies on a line segment interior to $\mathcal{J}$ such that

$$P(s_k + \lambda(w_k - s_k)) = P(s_k) + \lambda^{1/2} f_k$$

where $P(s_k) \in \Sigma_0$ lies on the 'base' of $P(\mathcal{D})$ and $f_k = P(w_k) - P(s_k)$ is a point near the 'peak' of $P(\mathcal{D})$. The sets $J_k$ and the corresponding image sets $P(K_k)$ are illustrated in figure 4.7.

We may now construct the (approximately) one-dimensional map $f(s): \mathcal{J} \rightarrow \mathcal{J}$. Each point in $\mathcal{J}$ has coordinates $s$ and $u$ but because of the zero stretching of $P$ in the direction $b$ the image of such a point is to a very good approximation determined only by the value of $s$. A typical point in a set $J_k$ has a coordinate $s$ lying in the interval $[a_k, a_{k+1})$ and is mapped, by $P^k$ into the set $K_k$ and then by $P$ into the set $\mathcal{J}$ to give a new value of $s$. This defines the map $f(s)$. Now the map $P^k$ is approximately linear in $J_k$ and hence the value of $\lambda$ corresponding to $s$ is given approximately by

$$\lambda \approx (s - a_k)/(a_{k+1} - a_k).$$

If we combine this approximation with the square-root map in (4.10) we see that $f(s)$ is given approximately by

$$f(s) = a_k(a_{k+1} - s)^{1/2}/(a_{k+1} - a_k)^{1/2}, s \in (a_k, a_{k+1}]$$

where (apart from $a_0$) the values of $a_k$ increase with $k$ and are bounded above.
Here we note that on $J_N$ the description of $f(s)$ only applies to a subset of the interval $[a_N, a_{N+1}]$. This description of $f(s)$ combined with the explicit calculation of $a_k$ from the length of $J_k$ is that given in section 3 and illustrated in figure 3.7.

The approximation of $f(s)$ as a one-dimensional map relies on the result, immediately following from theorem 2.8, that two points $p_1, p_2$ with the same coordinate $s$ and with coordinates $u_1$ and $u_2$ with $|u_1 - u_2| = O(\epsilon)$ will be mapped to two points $q_1$ and $q_2$ with $|q_1 - q_2| = O(\epsilon^2)$. Thus the approximation of $f(s)$ as a one-dimensional map becomes increasingly accurate as $\epsilon \to 0$. (We note further that it can be shown that $|u_1 - u_2| = O((1-r)\epsilon)$ and hence this approximation is even more accurate if $r$ is close to 1.)

In figure 1.4 we displayed a map $F(v) : \mathcal{J} \to \mathcal{J}$ mapping one low velocity impact to the next. There are difficulties in extending $f(s)$ to such a map because of the non zero width of $O(\epsilon)$ of $\mathcal{I}$ implies that two points with the same velocity may correspond to different values of $s$. However, the numerical values given in figure 1.4 strongly imply that this is possible. The numerical observations follow, in fact, from the nonuniform measure on the attractor of the intermittent motion. It is not unreasonable to assume, and the numerical evidence strongly implies, that the distribution of the points within each individual $K_k$ is uniform, that is given that $x \in K_k$, the probability that the parameter $\lambda$ corresponding to $x$ is less than $\Lambda$ is just $\Lambda$. This in turn implies, after applying the map $P$, that the probability that a point $p(x) \in \mathcal{J}$ has velocity less than $V$ is proportional to $V^2$. This again agrees with the numerical evidence. Hence, by far the greatest number of points will be concentrated in the sets $J_k$ where $k$ is close to $N$ and these will be mapped to the line segments $P(K_k)$ where $k$ is also close to $N$. It follows from our earlier description of $K_k$ that for $N$ large these line segments are very close to $P(C)$. The figure 1.4 obtained by plotting points on the attractor is therefore essentially just the map of the single line segment $P(C)$ into $\mathcal{J}$ and is necessarily one-dimensional. (We can also see from this figure that the points are concentrated into the sets $J_k$ for large $k$.)

5. Global features of the bifurcation diagram

In this section, we study in more detail the features of the bifurcation diagrams presented in figure 1.5 which can effectively be regarded as a bifurcation diagram for the map $f(s)$ when $r = 0.8$. The discussions in this section will be necessarily more approximate and heuristic than those presented in section 4 as we consider the dynamics of the impact oscillator for larger values of $\epsilon$.

There are three features of figure 1.5 which cannot be explained by the local analysis developed in section 4, and which depend on global features of the impact oscillator which have not yet been considered. These features as follows.

(i) The maximum impact velocity $v_{\text{max}}^B$ of the high velocity impacts in the chaotic motion grows like $\epsilon^{1/2}$ for small values of $\epsilon$, in accordance with the local theory, but at $\epsilon = 0.003$ (for $r = 0.8$), $v_{\text{max}}^B$ is asymptotic to an approximate value of

$$v_{\text{max}}^B = 2.5.$$ 

The maximum impact velocity, $v_{\text{max}}^A$, of the low velocity impacts, continues to grow
Intermittency in impact oscillators

like $\epsilon^{1/2}$, even for these larger values of $\epsilon$. The bifurcation diagram for the low velocity impacts is presented in figure 5.1.

(ii) There are a sequence of windows in the bifurcation diagram in which periodic rather than chaotic behaviour is observed. As $\epsilon$ tends to zero, the number of impacts observed in the successive windows increases monotonically by one reaching a maximum finite number $N_{\text{max}}$. For $\epsilon$ close to zero, only chaos is observed. If $\epsilon_k$ is the greatest value of $\epsilon$ such that a $k$-impact orbit is observed then

$$\frac{\epsilon_{k+1}}{\epsilon_k} \approx r.$$

(iii) In each window there is a short period doubling cascade in which the $k$ impact orbit loses stability as $\epsilon$ is decreased to a succession of $2^k$-impact orbits. However, after a finite number of these bifurcations the stable $2^k$-impact orbit is destroyed in a saddle-node bifurcation and the system becomes chaotic. An example of this is given in figure 5.2 which shows a close up of the bifurcation diagram for $-0.3372 < \sigma < -0.3367$.

(iv) In figure 5.3 we present a bifurcation diagram for a grazing bifurcation when $r = 0.3$ in which we see a similar picture to that in figure 1.5 but in which the windows of periodic motion are larger and also, although there is a chaotic region for quite small values of $\epsilon$, the motion ultimately stays periodic as $\epsilon \to 0$.

We can explain these features heuristically in terms of the features of the one-dimensional map $f(s)$ and global features of the flow. (An alternative explanation is given by Nusse et al 1993 in terms of a single map with discontinuous first derivative.)

As we have seen, when $\epsilon$ is small, the map $f(s)$ comprises a sequence of approximately parabolic curves on the intervals $J_k = (a_k, a_{k+1}]$, each of which intersects the line $f(s) = s$. These fixed points correspond to a $(k + 1, k)$ periodic orbit of the impact oscillator. The modulus of the slope of $f(s)$ at the points of intersection decreases as $k$ increases and is bounded below by $|f''(a_n)|$ giving an
estimate for the stability of any potential fixed point of the map $f(s)$. On the final interval $(a_N, a_{N+1}]$, $f(s)$ takes the approximate form

$$f(s) = a_{N+1} \cdot \left( \frac{b_{N+1} - s}{b_{N+1} - a_N} \right)^{1/2}$$

and thus

$$f'(a_N) \approx \frac{1}{2} \cdot \frac{a_{N+1}}{b_{N+1} - a_N}$$

Now, for large $N$, it follows from (4.9) that $b_{N+1} - a_N \approx (1 - r)a_{N+1}$ and hence

$$f'(a_N) \approx \frac{1}{2} \cdot \frac{1}{(1 - r)}$$

which is greater than 1 if $r > 1/2$. Thus, for small $\epsilon$ the fixed points of the map $f(s)$
Intermittency in impact oscillators

will always be unstable if $r > \frac{1}{2}$. This explains why we observe an immediate bifurcation into chaos if $r = 0.8$ but not so if $r = 0.3$. This accounts for observation (iv).

The computations illustrated in figures 1.5 and 5.1 show, in contrast to the above, that for $n \leq N_{\text{max}} = 21$, there are windows of values $\epsilon_n^s$ of $\epsilon$, $\epsilon_n^T \in (\epsilon_n, \epsilon_{n+1})$, such that for $\epsilon \in (\epsilon_n, \epsilon_n^s)$ the fixed points are stable. The explanation for this behaviour lies in the change of the global behaviour of the set $P^2(D)$ as $\epsilon$ is increased. Providing that $\epsilon$ is not too large, the set $D$ continues to be approximately triangular with sides of length proportional to $\epsilon$. Moreover, the set $P$ continues to approximate a subset of $W^2$ and has length proportional to $\epsilon^{1/2}$. This is in accord with the numerical observations recorded in figure 5.1 that $v_\text{max}^4$ is proportional to $\epsilon^{1/2}$ for a wide range of values of $\epsilon$. The set $P(\mathcal{J})$ then continues to closely approximate a subset $W^3$. For very small $\epsilon$ this subset of $W^3$ is approximately a straight line segment nearly tangent to $W$. In figure 5.4 we show the global form of the set $W^3$ in which is initially tangent to $W$ but which eventually curves round to intersect $W$ again transversely. The maximum value of $v$ taken by points lying in $W^3$ is approximately 1.46. This maximum point is in turn mapped by $P$ to a local maximum point on each of the sets $W^k$. When $k = 4$ or 5 this point is in fact a global maximum value for $v$ during the iteration of $P$ and this global maximum is equal to $v_\text{max}^g$. This effectively sets a limit on the maximum value of $v$ on $P^2(D)$ and hence also on $H$, providing an explanation for observation (i).

To explain the appearance of the periodic orbits discussed in observation (ii), we consider the effect of the global geometry of the set $W^3$ on the function $f(s)$, assuming that $\epsilon$ is now sufficiently large for $P^2(D)$ to be mapped onto the curved section of this set. We presume that the set $W^3$ is intersected by the sets $S^1, \ldots, S^N$, where $N$ decreases as $\epsilon$ increases, and that the curvature of $W^3$ implies that it will intersect the set $S^N$ (and possibly the sets $S^i$ for $j$ close to $N$) more than once. If $\epsilon$ is not too small, then the set $J$ will be sufficiently large for part of it to be mapped under $P$ onto the curved part of $W^3$. Indeed, $P(\mathcal{J})$ may intersect $S^N$, or equivalently,
the set \( \mathcal{J} \) may intersect \( S^{N+1} \), more than once. This is also indicated in figure 5.4. The global effect of the curvature of \( W^3 \) on the subset \( P(\mathcal{J}) \) means that, the velocity of the image of a point \((\phi, v)\) in \( \mathcal{J} \) will increase with \( v \) if \( v \) is small, and will decrease with \( v \) for the larger values of \( v \). As a consequence, the set \( P^{N+1}(\mathcal{J}) \) lying in \( D \) will also be curved and the image of this set in \( \mathcal{J} \) will retain this curvature. The effect on the map \( f(s) \) is for it to have a lower gradient or indeed a local minimum in the set \( J_N \). This is clearly evident in figure 3.8 showing the related map \( F(v) \) for \( \sigma = -0.3375 \). The reduced gradient of \( f(s) \) in this subset means that it is now possible for a fixed point to be stable, and this is indeed what we observe. The windows of periodic behavior and the decrease in the number of impacts in these windows as \( \varepsilon \) increases can both be explained in terms of values of \( \varepsilon \) for which the curve \( S^k \) intersects the local maximum of \( W^3 \), as the behaviour of the system must change qualitatively at such points. If we assume (very approximately indeed but consistently with the numerical observations!), that the maximum point of \( W^3 \) lies on an extension of \( W \) obtained from the parameterization (4.2) and let \( r_{\text{max}} \) denote the value of \( r \) at this point and if we assume further that the points of intersection of \( S^k \) with \( W \) are described (again approximately) by the formula 4.3, then the critical values of \( \varepsilon = \varepsilon_k \) at which the behaviour changes are given by

\[
\varepsilon_k (r^{\frac{k}{k}} - 1)/k
\]

so that \( \varepsilon_{k+1}/\varepsilon_k = r \) if \( k \) is not too small. This is in agreement with the numerical observations. This roughly accounts for the numerical observations (ii) and the observations (iii) can be explained in terms of the usual behaviour of continuous dynamical systems.
