We predict novel inter-band physics for bosons in double-well optical lattices (OL). An intrinsic coupling between the s and ps band due to interaction gives rise to larger Mott regions on the phase diagram at even fillings than the ones at odd fillings. On the other hand, the ground state can form various types of condensates, including a mixture of single-particle condensates of both bands, a mixture of a single-particle condensate of one band and a pair-condensate of the other band, and a pair-condensate composed of one particle from one band and one hole from the other band. The predicted phenomena should be observable in current experiments on double-well OL.

I. INTRODUCTION

The last decade has seen many exciting developments in the studies of cold atoms in OL. A number of many-body phases of bosons and fermions have been observed in experiment, showing that cold atoms in OL provide an ideal platform for studying a number of theoretical models in condensed matter physics. For example, bosons in OL have been used to study the single-band Bose-Hubbard model extensively in the past few years.

Despite the fact that single-band models are usually good descriptions for atoms in OL, recent studies have found important influence from the higher bands. The leading-order effect of such inter-band coupling is to renormalize the parameters of the single-band model. For current experimental parameters, the phase boundary is found to change slightly while the structure of the phase diagram remains the same. It is therefore commonly assumed that inter-band coupling only leads to small quantitative changes in the quantum phase diagram of bosons in OL.

A question then naturally arises, whether OL can be used to create many-body systems, which go beyond the description of the renormalized single-band models, i.e., whether situations exist where interaction induced inter-band coupling could give rise to qualitative new quantum phases not conceivable in the single-band picture? It is easy to see that the chemical potential µ needs to be much smaller than the band gap ∆ of between the s and ps band for invalidating the standard single s band description. In this Letter, we propose using a system in which ∆ can be tuned to be comparable with or even smaller than µ. A single-band description for this system is no longer valid, and novel quantum many-body phenomena due to inter-band coupling emerge.

The system we consider is bosons in a double-well lattice. In the literature, there has been studies on bosons in an excited band in double-well OL or standard OL. Here we focus on a new aspect regarding the inter-band physics between the lowest two bands in a double-well lattice. From the experimental side, double-well lattices have recently been realized by several groups with different lattice geometries. We focus on the simplest case, where a second laser is added to a simple cubic optical lattice along the x direction. The physics we discuss here can be easily generalized to other cases. By choosing the wave length of the second laser as half of the first one which creates the cubic lattice, a superlattice forms with a double-well potential. For appropriate choices of the relative positions of the two lattices, the potential is symmetric with respect to the center of each lattice site, as shown in Fig. 1b.

II. HAMILTONIAN

The potential of a double-well lattice in our case can be written as

\[ V(R) = V_L(R_x) + V_y(R_y) + V_z(R_z), \]

where \( V_L(R_x) = V_L \sin^2(\frac{\pi R_x}{d}) - V_S \sin^2(\frac{2\pi R_x}{d}) \), \( V_y(R_y) = V_y \sin^2(\frac{\pi R_y}{d}) \), and \( V_z(R_z) = V_z \sin^2(\frac{\pi R_z}{d}) \). \( V_L \) and \( V_S \) are the amplitude of the long and short lattice along the \( x(=y, z) \) direction, \( d \) is the lattice spacing. For this periodic potential, the single particle energy \( \epsilon_i(\vec{k}) \) and the Wannier wave function \( \psi_i(\vec{R}) \) can be exactly calculated, where \( \sigma \) is the band index for the three dimensional lattice. \( \epsilon_i(\vec{k}) \) can be written as the sum of the corresponding single particle energy \( \epsilon_{i,n}(k_i) \), where \( i = x, y, z \) and \( n \) is the band index, for the one dimensional lattice \( \mathcal{V}_i(R_i) \). Typical band structures for a standard optical lattice and a double-well lattice are shown in Fig. 2. It is clear that in a double-well lattice, \( \epsilon_{s,0}(k_z) \) and \( \epsilon_{s,1}(k_z) \) become very close to each other and are well separated from higher ones. Thus we focus on the lowest two bands for the three dimensional lattice, the energy of which can be written as

\[ \epsilon_{s,0}(\vec{k}) = \epsilon_{s,0}(k_z) + \epsilon_{y,0}(k_y) + \epsilon_{z,0}(k_z), \]

\[ \epsilon_{p,0}(\vec{k}) = \epsilon_{p,0}(k_z) + \epsilon_{y,0}(k_y) + \epsilon_{\sigma,0}(k_z). \]

The Wannier wave function for each band can be written as

\[ \psi_{s}(\vec{R}) = \psi_{s,0}(R_x)\psi_{y,0}(R_y)\psi_{z,0}(R_z), \]

\[ \psi_{p,s}(\vec{R}) = \psi_{s,1}(R_x)\psi_{y,0}(R_y)\psi_{z,0}(R_z), \]

where \( \psi_{i,n}(R_i) \) is the Wannier wave function for the one dimensional lattice \( \mathcal{V}_i(R_i) \) as shown in Fig. 1b. Because the
lattice potential \( V(\vec{R}) \) respects the inversion symmetry, i.e., \( V(\vec{R}) \) remains unchanged under the transformation \( R_i \to -R_i \), \( \psi_x(\vec{R}) \) has well defined parity. For example, \( \psi_s(R_x, R_y, R_z) = \psi_s(-R_x, R_y, R_z) \) and \( \psi_p(R_x, R_y, R_z) = -\psi_p(-R_x, R_y, R_z) \). Both of them remain unchanged for \( R_y \to -R_y \) or \( R_z \to -R_z \). This is similar to the parity of the usual \( s \) and \( p_x \) bands in a single harmonic oscillator. This is the reason that we denote the lowest two bands as the \( s \) and \( p_x \) bands for simplicity.

The many-body Hamiltonian can be written as

\[
H = \sum_n \left( H_\sigma - \mu_\sigma \bar{N}_\sigma \right) + U_{sp} \sum_{\sigma m} \bar{n}_\sigma \bar{\bar{n}}_{\sigma m} + H_c,
\]

where

\[
H_\sigma = \sum_{\sigma m \vec{r}} t_{\sigma,\vec{r}} (\hat{b}_{\sigma m}^\dagger \hat{b}_{\sigma m+\vec{r}} + c.c.) + \frac{U_\sigma}{2} \sum_{\sigma m} \bar{n}_\sigma \bar{\bar{n}}_{\sigma m} - 1
\]

(1)

is the usual Bose-Hubbard band model for the \( s \) and \( p_x \) bands, and

\[
H_c = \sum_{\vec{m}} \left( W \hat{b}_{\sigma m}^\dagger \hat{b}_{\sigma m+\vec{r}} + c.c. \right)
\]

(2)

is the inter-band paring coupling term. In above two expressions, the band index \( p_x \) has been replaced by \( p \) for simplicity, \( \vec{r} = d\hat{x}, d\hat{y}, d\hat{z} \) represents the unit vector along the \( x, y, z \) directions, \( \hat{b}_{\sigma m, \vec{r}}^\dagger \) creates a particle in the basis of Wannier wave functions at a lattice site \( \vec{m} = d(m_x, m_y, m_z) \) that contains two wells, \( \mu \) the chemical potential, \( \mu_s = \mu \), \( \mu_p = \mu - \Delta_g \), \( \Delta_g \) is the energy difference between the middle of the \( s \) and the \( p_x \) band, which will be referred to as the band gap for simplicity.

For example, \( \psi_R \) is the usual Bose-Hubbard band model for the \( s \) band, and

\[
\epsilon_{x,n}(k_x)/E_R
\]

FIG. 1: (a) Schematic of a double-well lattice along the \( x \) direction, as well as the lowest a few bands marked down in different colors. Contours with an unit cell marked in a red box on the \( x-y \) plane are also shown. Dark region represents the potential minimum. (b) Wannier functions for the one-dimensional lattice \( V_s(R_x) \), where \( V_s = 11E_R, V_L = 4E_R, V_y = V_z = 13E_R \) along the \( x \) direction.

\[
\sum_{\sigma m} \epsilon_\sigma(R_x) + \epsilon_{p,x}(R_x) = \epsilon_{p,x}(R_x) + \epsilon_{p,x}(R_x)
\]

\[
\epsilon_{x,n}(k_x)/E_R
\]

FIG. 2: (a) The energy spectrum for a standard lattice, where \( V_L = 13E_R, V_S = 0, \Delta_g = 6E_R \). (b) The energy spectrum for a double-well lattice, where \( V_L = 4E_R, V_S = 11E_R, \Delta_g = 1.5E_R \) in 1D along the \( x \) direction. For comparison, the differences between the maximum and the minimum of these two lattices have been chosen to be the same. Red and blue horizontal lines in the upper panel represent the energy level of each Wannier orbitals.

\[
t_{s,p,x} = \sum_\vec{r} \epsilon_\sigma(R_x) e^{i\vec{r}\cdot\vec{r}} / N_s
\]

is the tunneling amplitude between the nearest neighbor sites, where \( N_s \) is the total number of lattice sites. From exact numerical results, we found that tunneling amplitude beyond nearest neighbor sites is at least two orders of magnitude smaller, and thus can be ignored (see Appendix).

The interaction part in the Hamiltonian was obtained by expanding the field operator \( \Psi(\vec{R}) \) in the general expression for the interaction of bosons

\[
\mathcal{U} = \frac{2\pi g^2}{M} \int d^3 R \Psi(\vec{R})^\dagger \Psi(\vec{R})^\dagger \Psi(\vec{R}) \Psi(\vec{R})
\]

\[
\sum_{\sigma m} \psi_\sigma(R_x) - m \bar{n}_{\sigma m}
\]

A straightforward calculation shows that there are three terms for on-site interaction. \( U_s \sum_{\sigma m} \bar{n}_{\sigma m} (n_{\sigma m} - 1) \) is the

\[
|2, 0\rangle
\]

\[
U_s
\]

\[
|0, 2\rangle
\]

\[
U_p
\]

\[
|1, 1\rangle
\]

\[
U_{sp}
\]

FIG. 3: Fock states and the matrix elements between them due to on-site interaction for two particles per site.
intra-band repulsion for each band, where \( U_\sigma = \frac{4\pi^2a^2}{\hbar^2} \int d^3R |\psi_\sigma(R)|^4 \). The second one is the inter-band repulsion, \( U_{sp} = U_{sp} \sum_m \bar{n}_{s,m} \bar{n}_{p,m} \), where \( U_{sp} = \frac{8\pi^2a^2}{\hbar^2} \int d^3R |\psi_s(R)|^2 |\psi_p(R)|^2 \). The last one as shown in Eq. (2) describes the interacting process that scatters two atoms from the s band to the p_x band, where \( W = \frac{2\pi^2a^2}{\hbar^2} \int d^3R |\psi_s(R)|^2 |\psi_p(R)|^2 \). Because of different parities of the s and p_x band, \( \psi_s(R_x, R_y, R_z) = \psi_s(-R_x, R_y, R_z) \), \( \psi_p(R_x, R_y, R_z) = -\psi_p(-R_x, R_y, R_z) \), the Hamiltonian does not contain terms like \( \bar{n}_s \bar{b}_s \bar{b}_p \), where \( \sigma \neq \sigma' \). We have dropped off other terms involving inter-site interaction that are much smaller. The Fock states for two particles per site as well as the matrix elements between them due to on-site interaction are shown in Fig. (3).

The Hamiltonian in Eq. (1) has earlier been considered for standard OL with a fixed band gap at a constant lattice depth in a context different from our interest. Dependences of the parameters of the Hamiltonian in Eq. (1) on \( V_L/E_R \) and \( V_S/E_R \) for a typical double-well lattice are shown in Fig. (4), where \( E_R = \hbar^2/8Md^2 \) is the recoil energy. It is clear that as \( V_S \) increases, \( \Delta_g \) decreases quickly.

III. MEAN-FIELD PHASE DIAGRAM

To solve this problem, the Gutzwiller mean field approach is used. The trial wave function is written as \( |\psi\rangle = \prod_m \sum_{\alpha,\beta} c_{\alpha\beta} |\alpha,\beta\rangle_m \), where \( |\alpha,\beta\rangle_m \) is the on-site Fock state, \( \alpha \) and \( \beta \) are the particle numbers in the s and p_x orbital respectively. The order parameter for each band \( \langle \hat{b}_{s,m} \rangle = \phi_s \) is determined self-consistently, and the phase boundary is obtained from \( |\phi_s| = |\phi_p| = 0 \).

The phase diagram for the parameters \( V_S = 11E_R, V_L = 4E_R \) and \( V_p = V_s = 25E_R \) is shown in Fig. (5). Compared with the usual results for the single-band Bose-Hubbard model, it is clear that the structure of the phase diagram changes dramatically. For the single-band model, the area of the Mott region on the phase diagram monotonically shrinks with increasing filling factor. For our two-band model, there is an “even-odd” effect, namely, the Mott region at an even filling \( 2n_0 \) becomes larger than the one at an odd filling \( 2n_0 - 1 \).

This “even-odd” effect can be first understood intuitively using an extreme case, \( V_L = 0 \) and \( V_S \neq 0 \). For this particular configuration, the Mott regions with odd fillings must vanish, since the lattice spacing has changed to \( d/2 \) and odd fillings in the original basis now correspond to non-integer fillings. However, for any general case \( V_L \neq 0 \), the lattice spacing is still \( d \). The above simple picture does not apply. To fully understand the “odd-even” effect, one needs to consider on-site correlations induced by the inter-band coupling and the competition between the onsite energy and the tunneling energy.

The excitation gap of a Mott insulator can be written as \( \Delta_n = E_{n+1} + E_{n-1} - 2E_n \), where \( E_n \) is the on-site energy of the Fock state with \( n \) particles per site. In a single s-band model, \( E_n^0 = U_s n(n-1)/2 - \mu n \). Consequently, \( \Delta_n^0 = U_s \sim a_s \) does not depend on \( n \), where the superscript 0 represents the results for the single band model. On the other hand, the tunneling energy \( -t_s \langle \hat{b}_{s,m}^\dagger \hat{b}_{s,m+1} \rangle \sim -t_s \sqrt{(n+1)n} \) increases with increasing \( n \) due to bosonic enhancement. As a result, the critical value of \( a_s \), i.e., at the tip of the Mott region, has to increase so as to overcome the increasing kinetic energy with increasing \( n \) and form an insulator.
This is the reason that Mott region monotonically shrinks on the phase diagram of the single band model with increasing \( n \) or \( \mu \). In our two-band model for double-well lattices, \( H_c \) lowers the onsite energy \( E_n \) by coupling the \( s \) and \( p_s \) band, \( E_n = E_n^0 + \delta E_n \), and modulate the nature of the excitation gap \( \Delta_n = \Delta_n^0 + \delta \Delta_n \). For example, \( \delta E_2 = -4W^2/(2\Delta_g + U_p - U_s) + O(W^4) \) and \( \delta E_3 = -12W^2/(2\Delta_g + U_p + 2U_{sp} - 3U_s) + O(W^4) \) because of the formation of the pair \( c_{20}(2,0) + c_{02}(0,2) \) and \( c_{30}(3,0) + c_{12}(1,2) \) respectively, where \( c_{20}, c_{30} \) and \( c_{02}, c_{12} \) have a phase difference of \( \pi \). \( \delta E_2, \delta E_3 \) can be viewed as an effective binding energy induced by the pairing coupling \( H_c \) with respect to \( |2,0\rangle \). On the other hand, \( \delta E_1 = 0 \) as the state \( |1,0\rangle \) or \( |0,1\rangle \) does not couple to any other Fock states. One can easily verify that \( \delta \Delta_1 < \delta \Delta_2 \) if \( U_{sp} > U_s \), where \( \delta \Delta_1 = \delta E_1 < 0 \), \( \delta \Delta_2 = \delta E_2 - 2\delta E_3 \). Thus \( \Delta_1 = U_s + \delta \Delta_1 \) is suppressed and meanwhile \( \Delta_2 = U_s + \delta \Delta_2 \) is either enhanced or reduced less than \( \Delta_1 \), i.e., \( \Delta_1 < \Delta_2 \). As seen from Fig.4(b), \( U_{sp} > U_s \) is satisfied if \( V_S > 2.5E_R \). Moreover, \( U_{sp} - U_s \) increases with increasing \( V_S \), so does \( \Delta_2 - \Delta_1 \). Though populating the \( p_s \) band may increase the kinetic energy for \( n = 2 \) compared with \( n = 1 \), when \( \Delta_1 \ll \Delta_2 \), this kinetic energy increase, as well as the bosonic enhancement, is no longer important, and the critical value of \( \alpha_s \) for \( n = 2 \) Mott insulator becomes even smaller than then one for \( n = 1 \). That is what we see on Fig.5. Similar analysis applies for \( n = 3,4 \), and so on.

This “even-odd” effect can be directly observed from in-situ images of the density of trapped bosons in a double-well lattice. With increasing interaction, the Mott plateau with two atoms per site would first emerge when \( V_S \) is sufficiently high. The above discussion can be generalized to arbitrary orbital numbers \( n^o \) in each lattice site. When there are strong pairing couplings similar to \( H_c \), between different orbitals, the Mott region on the phase diagram for \( (n \mathrm{mod} n^o) = 0 \) will be larger than the one for \( (n \mathrm{mod} n^o) = 1, 2, \ldots n^o - 1 \). Similar phenomenon also happens for a model containing two or three \( p \) bands in standard OL29.

IV. CONDENSATE PHASES

Now we turn to the condensate phases. Because of more than one orbital in each single site, there are multiple choices for the bosons to form condensate phases. (1) When \( |\langle \hat{b}^\dagger_{sm}\rangle| \neq 0 \) and \( |\langle \hat{b}^\dagger_{sm}\rangle| \neq 0 \), we call it a (C1) condensate, which is a coherent mixture of single-particle condensates of both bands. (2) When one of the single-particle condensates vanishes, we call it a (C2) condensate, i.e., \( |\langle \hat{b}^\dagger_{sm}\rangle| = 0 \) and \( |\langle \hat{b}^\dagger_{sm'}\rangle| \neq 0 \), we call it a (C2) condensate. (3) When \( |\langle \hat{b}^\dagger_{sm}\rangle| = |\langle \hat{b}^\dagger_{pm}\rangle| = 0 \), the interband coupling induces a paired-condensate \( |\langle \hat{b}^\dagger_{sm}\hat{b}^\dagger_{pm}\rangle| 
eq 0 \) under certain conditions.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{condensate.png}
\caption{(a) \( n_s + n_p \) (brown dash-dotted), \( n_s \) (red solid) and \( n_p \) (blue dashed) versus \( \mu \) at \( \alpha_s/d = 0.081 \) for Fig.5. (b) \( \langle \hat{b}_s \rangle \) (red solid), \( \langle \hat{b}_s\hat{b}_p \rangle \) (black dash-dotted), \( \langle \hat{b}_p \rangle \) (brown dashed) and \( \langle \hat{b}_p \rangle = 0 \) for same parameters as (a).}
\end{figure}

A. (C1) condensate

For a (C1) condensate to emerge, the chemical potential \( \mu \) needs to be larger than a critical value \( \mu_c \). We write down the energy density for the excited band in the mean field approach as \( E_p = -(\mu - \Delta_g + 2\sum_{\mathbf{r}_p}\phi_{\mathbf{r}_p}^\dagger\phi_{\mathbf{r}_p})^2 + U_{sp}\phi_{\mathbf{r}_s}^\dagger\phi_{\mathbf{r}_p}^\dagger\phi_{\mathbf{r}_p}\phi_{\mathbf{r}_s}^\dagger + 2W|\phi_{\mathbf{r}_p}|^2 \). Based on Landau’s criteria, \( \mu_c = \Delta_g - 2\sum_{\mathbf{r}_p}\phi_{\mathbf{r}_p}^\dagger U_{sp}\phi_{\mathbf{r}_s}^\dagger + 2W|\phi_{\mathbf{r}_p}|^2 \) and \( |\phi_{\mathbf{r}_p}| \neq 0 \) for \( \mu > \mu_c \). In the parameter regime considered in Fig.4, the very large \( U_{sp} \) has largely increased the value of \( \mu_c \). Thus, the ground state forms a (C2) condensate with \( \langle \hat{b}_{sm} \rangle \neq 0 \), \( \langle \hat{b}_{pm} \rangle = 0 \) and \( \langle \hat{b}_{pm}\hat{b}_{pm} \rangle \neq 0 \). At lower lattice depths, i.e., \( V_L = 4E_R \) and \( V_S = 1E_R \), \( U_{sp} \) is small enough and (C1) condensates can emerge, i.e., for about four atoms per site26.

B. (C2) condensate

In double-well lattices, a (C2) condensate has a unique property: when \( \langle \hat{b}_{sm} \rangle \neq 0 \), \( \langle \hat{b}_{sm}\hat{b}_{sm} \rangle \) must be finite (see Fig.6). We can view the (C2) condensate as a coherent mixture of a single-particle condensate of one band and a two-particle condensate in the other band. A non-zero \( \langle \hat{b}_{pm}\hat{b}_{pm} \rangle \) despite a vanishing \( \langle \hat{b}_{pm} \rangle \) results from the interband coupling \( H_c \). Once \( \langle \hat{b}_{sm} \rangle \neq 0 \), the ground state includes Fock states \( |\alpha, \beta\rangle_{m} \) and \( |\alpha \pm \nu, \beta\rangle_{m} \), where
\(\nu\) is an integer. On the other hand, the coupling term \(H_c\) provides a matrix element between \(|\alpha+2\nu, \beta\rangle_m\) and \(|\alpha, \beta \pm 2\nu\rangle_m\). The expectation value for \(\hat{b}_{\nu,m}\hat{b}_{\nu,m}\) then must be finite, since the ground state includes both \(|\alpha, \beta\rangle_m\) and \(|\alpha, \beta \pm 2\nu\rangle_m\), though it does not include Fock states \(|\alpha, \beta \pm (2\nu+1)\rangle_m\), i.e., \(\langle \hat{b} \rangle = 0\). This is very different from a single-band model, where \(\langle \hat{b} \rangle\) and \(\langle \hat{b} \hat{b} \rangle\) must vanish at the same time. Here, \(\langle \hat{b}_{\nu,m}\hat{b}_{\nu,m}\rangle\) can be induced by a finite \(\langle \hat{b}_{\nu,m}\rangle\) in a different band. For standard OL, a \((C2)\) condensate also exists but the amplitude of \(\langle \hat{b}_{\nu,m}\rangle\) is rather small because of the very large band gap. Our double-well lattices significantly reduce the band gap and make \((C2)\) condensate observable in experiments.

A \((C2)\) condensate can be probed in Time-Of-Flight(TOF) experiments with a band mapping technique, which maps the crystal momentum distributions in different bands, i.e., \(\langle \hat{n}_{p,k} \rangle\) and \(\langle \hat{n}_{p,k} \hat{n}_{p,k} \rangle\), separately to the first and second Brillouin Zone after expansion. Since there is no single-particle condensate in the \(p\) band, i.e., \(\langle \hat{b}_{\nu,m} \rangle = 0\), no singular feature is present in \(\langle \hat{n}_{p,k} \rangle\). On the other hand, a finite \(\langle \hat{b}_{\nu,m}\hat{b}_{\nu,m} \rangle\) induces a novel structure in the momentum correlation function \(I_p(k_1,k_2) = \langle \hat{n}_{p,k_1}\hat{n}_{p,k_2} \rangle - \langle \hat{n}_{p,k_1} \rangle \langle \hat{n}_{p,k_2} \rangle\). A straightforward calculation shows, \(I_p(k_1,k_2) = I_1 + I_2\), where \(I_1 = \sum_{m} \langle \hat{n}_{m} \rangle e^{i(k_1-k_2)\cdot m} [1 - \sum_{m} \langle \hat{n}_{m} \rangle^2] + I_2 = \sum_{m} \langle \hat{n}_{m} \rangle^2 e^{i(k_1-k_2)\cdot m} - \sum_{m} \langle \hat{n}_{m} \rangle^2 \rangle^2\). As a function of \(k_1\) and \(k_2\), \(I_2\) has singular points at \(k_1 + k_2 = qK\), where \(q\) is an integer, and \(K = \frac{2\pi}{\sqrt{3}}(\hat{x}, \hat{y}, \hat{z})\) is the reciprocal lattice vector. By measuring the amplitude of \(I_p(Q,-Q)\), where \(Q\) is an arbitrary momentum in the second Brillouin Zone, the strength of \(\langle \hat{b}_{p,m}\hat{b}_{p,m} \rangle\) can be probed.

It is worthwhile to mention that, to observe \((C2)\) condensates discussed above, the temperature of the atoms needs to satisfy \(T < t_s, W\). For a typical recoil energy \(E_R \sim 100nK\), it can be seen that \(t_s\) and \(W\) are of the order of \(nK\). It is therefore quite promising to observe \((C2)\) condensates and the novel structure of the phase diagram in current experiments.

C. \((C3)\) condensate

The Fock space in each single site can be divided into two subspaces, \(\{S_1\} : \{|n-2l, 2l\rangle_m\}\) and \(\{S_2\} : \{|n-2l-1, 2l+1\rangle_m\}\), where \(l = 0, 1, 2, ...\), since \(H_o\) only mixes states within each subspace. For \(n\) particles per site, we can denote the ground state of each subspace as \(|\Psi_{n1}\rangle_m\) and \(|\Psi_{n2}\rangle_m\) and the ground state energy as \(E_{n1}\) and \(E_{n2}\). Both \(E_{n1}\) and \(E_{n2}\) are dependent on \(a_{s}\) and the lattice configuration. For the parameters in Fig.5, \(E_{n1} \ll E_{n2}\). On the other hand, under certain conditions, \(E_{n1} \approx E_{n2}\). For example, for \(V_S = 1E_x\), \(V_z = 14E_x\), \(V_y = 80E_x\), which is essentially an one dimensional system, \(E_{n1} \approx E_{n2}\) is satisfied for \(n = 3(5)\) around \(a_{s}/d = 0.18(0.123)\). Under this situation, by taking into account higher order correlations between nearest neighboring sites, an exotic \((C3)\) condensate arises.

We apply a spin-1/2 representation for the system, \(|\uparrow_m\rangle = |\Psi_{n1}\rangle_m\) and \(|\downarrow_m\rangle = |\Psi_{n2}\rangle_m\). The spin operators are defined as \(S_{\alpha m} = \frac{1}{2}(\uparrow \downarrow \uparrow | \uparrow \downarrow \downarrow \downarrow | \uparrow \uparrow \uparrow \downarrow | \uparrow \uparrow \downarrow \uparrow |)\), \(S_{\alpha m} = | \uparrow \downarrow \downarrow \downarrow \downarrow | \uparrow , S_{\alpha m} = | \downarrow \uparrow \uparrow \uparrow \uparrow |\downarrow , \downarrow |\), which satisfy the commutation relations, \([S_{\alpha m}^+ | S_{\beta m}^-] = 2S_{\gamma m}\delta_{\gamma m,m}, [S_{\alpha m}^- | S_{\beta m}^+] = -S_{\alpha m}^- | S_{\beta m}^+, S_{\alpha m}^- | S_{\beta m}^+ = S_{\alpha m}^- | S_{\beta m}^-.\) A spin-1/2 model can be obtained by applying second order perturbation theory (see Fig.7), \(H_{spin} = \sum_{m, \alpha} J_{\alpha}(S_{\alpha m}^+ S_{\alpha m}^- + c.c.) + \sum_{m, \alpha} \Delta_{J_{\alpha}}(S_{\alpha m}^+ S_{\alpha m}^- + c.c.) + \sum_{m, \alpha} J_{\alpha} S_{\alpha m}^+ S_{\alpha m}^- - h \sum_{m, \alpha} S_{\alpha m}^+ \rangle = \langle S_{\alpha m}^- | J_{\alpha} \Delta_{J_{\alpha}} \approx t_{s, p} \langle E^{ex}_m - E_{n1} - E_{n2} \rangle + t_{p, p} \langle E^{ex}_m - E_{n1} - E_{n2} \rangle, h \approx E_{n2} - E_{n1} \) and \(E^{ex}_{\alpha} = E^{ex}_{\alpha} + E^{ex}_{\alpha, \alpha}\). It is easy to verify that when \(|J_{\alpha}| + |\Delta_{J_{\alpha}}| > |J_{\alpha}|/2\) is satisfied, there is a critical value \(h_c = |J_{\alpha}| + |\Delta_{J_{\alpha}}| - |J_{\alpha}|/2\). If \(|h| < h_c\), the value of \(\theta\) to minimize \(H_{spin}\) is no longer zero or \(\pi\), and there is a projection of the spin on the \(x - y\) plane with a preference on the
direction. i.e., $\varphi = \pm \pi/2$ for $\Delta_t > 0$ or $\varphi = 0, \pi$ for $\Delta_t < 0$. Similar results can also be obtained for other signs of $J_T, J'_T$.

We now go back to the boson representation $(G) = \prod_m \left( (\cos \frac{\theta}{2})^2 |\Psi_{n1}\rangle \sigma_{m} + (\sin \frac{\theta}{2})^2 e^{i\varphi}|\Psi_{n2}\rangle \sigma_{m} \right)$. As $|\Psi_{n1}\rangle = \sum_{l} c_{l1}|n-2l, 2l\rangle_m$ and $|\Psi_{n2}\rangle = \sum_{l} c_{l2}|n-2l-1, 2l+1\rangle_m$, it can be seen that $(S^+_{m}) \neq 0$ implies $(b^+_{p,m}b_{p,m}) \neq 0$. We refer to this state as a $(C\beta)$ condensate that emerges when $|h| < h_c$. It is a pair-condensate composed of one particle from one band and one hole from the other band. $(C\beta)$ condensates have also been found in a model describing two component bosons in a lattice, however, due to different underlying physics. We have shown that the band gap between the $s$ and $d$ bands can be easily tuned in a double-well lattice. This tunable band gap gives rise to novel condensate phases in double-well OL. Our studies indicate the strong possibility of realizing novel condensate phases in double-well OL. Our studies can be generalized to the cases that more than one higher band is tuned to be very closed to the lowest band, where very rich physics is expected.

VII. APPENDIX

The kinetic energy in the momentum space can be written as $K = \sum_{\sigma k} \epsilon_{\sigma k} a_{\sigma k}^\dagger a_{\sigma k}$, where $a_{\sigma k}^\dagger (a_{\sigma k})$ creates (annihilates) a particle in the basis of Bloch wave functions $\hat{\phi}_{\sigma k}(\vec{R})$. Define $b_{\sigma m}^\dagger = \sum_{\vec{k}} a_{\sigma \vec{k}}^\dagger e^{i\vec{k}\cdot\vec{m}}/\sqrt{N_\sigma}$, where $N_\sigma$ is the total number of lattice sites, which creates a particle in the basis of Wannier functions $\psi_{\sigma m}(\vec{R})$ at site $m$, $K = \sum_{\sigma m\vec{k}} t_{\sigma,\vec{r},l}(b_{\sigma m\vec{k}}^\dagger b_{\sigma m\vec{k}+\vec{r}+c.c}$), where $l$ is an positive integer, $\vec{r} = dx, dy, dz$ represents the unit vector along the $x, y, z$ directions, and tunneling constants $t_{\sigma,\vec{r},l} = \sum_{\vec{k}} \epsilon_{\sigma k} e^{i\vec{k}\cdot\vec{r}}/N_\sigma$. Because the single particle energy is already diagonal with band indices, there is no crossing term involving tunneling between orbitals with different index $\sigma$. It can also be shown from a straightforward calculation that $t_{\sigma,\vec{r},l}$ corresponds to the overlap integral of the Wannier wave functions $\psi_{\sigma m}(\vec{R})$ and $\psi_{\sigma m}(\vec{R} - \vec{m} - i\vec{r})$, i.e., $t_{\sigma,\vec{r},l} = \int d^2R \psi_{\sigma m}(\vec{R} - \vec{m})^* (e^{i\vec{k}\cdot\vec{r}} + V(\vec{R})) \psi_{\sigma m}(\vec{R} - \vec{m} + i\vec{r})$. From the exact band structure $\epsilon_{\sigma k}$, we found that the tunneling amplitude between the nearest neighbor sites along any direction is always much larger than other ones. For example, for $V_L = 4E_R$, $V_S = 11E_R$, the one for the next nearest neighbor sites $t_{\sigma,\vec{r},l} = 5%/2%$ of $t_{\sigma,\vec{r},l}$. We thus keep only the tunneling between the nearest neighbor sites in the Hamiltonian. On the other hand, we have verified that introducing such a small correction from the tunneling between the next nearest neighbor sites does not change the qualitative feature of the phase diagram.

There are also interaction terms for particles at different sites besides on-site ones. These terms, however, depend on overlap integrals of Wannier wave functions at different sites, either in the same or different bands. Those integrals are always much weaker than the onsite interaction. For example, we have verified from exact numerical results that the largest nearest neighbor interaction is one or two orders of magnitude smaller than the onsite interaction for the parameters regime we considered. Thus we kept only onsite interaction in the Hamiltonian.
