Perioperative management of geriatric patients for orthopedic surgeries

Bhavya Krishna, Nidhi Pathak*

INTRODUCTION

With increasing life expectancy, both orthopedicians and anesthesiologists now have to deal with is increasing. In this review article, we discuss the case management of three centurions aged 110, 105 and 102 years respectively who underwent lower limb orthopedic surgery under nerve block, general anesthesia and neuraxial blockade, and elaborate on the various issues faced periooperatively by the treating team. The challenges and differences faced in perioperative period in geriatric anesthesia were discussed and literature reviewed for the benefit of the operating surgeons.

METHODS

Case report 1

A 110 year old lady presented to us with neck of femur fracture and was planned for elective bipolar hemiarthroplasty. Appropriate anesthetic assessment was done and there was no positive history of any systemic illness except anemia (hemoglobin (Hb) 9 gm%, hematocrit (HCT) 27%). The rest of the investigations were within normal limits. On examination, she was pale, frail and had a kyphoscoliotic spine with intervertebral spaces not well felt. Her anemia was treated with packed cell transfusion preoperatively to attain Hb of 10 gm% and adequate blood products reserved for surgery. Plan of anesthesia was neuraxial anesthesia combined spinal and epidural (CSE). Several attempts were made to put CSE with changes tried in approach (median or paramedian), position change, provider, space and needle change. Secondary to calcifications, ossifications and kyphoscoliotic spine, neuraxial plan was abandoned and we proceeded with putting nerve blocks instead comprising of femoral and obturator and lateral cutaneous nerve of thigh and sciatic nerve block along with local anesthesia infiltration at proximal site of skin incision. After adequate effect surgery was started which lasted about two hours, with blood loss of 500 ml and was replaced with one unit packed cell transfusion intraoperatively. Patient was discharged in 5 days after
receiving physiotherapy and rehabilitation training and was asked to come for follow up for further management.

Case report 2

A 105 year old gentleman presented to us with shaft of femur fracture in the emergency department. He was a known case of CAD on antiplatelets (clopidogrel 75 mg and aspirin 75 mg), hypertensive on beta blocker (atenolol 50 mg), uncontrolled diabetic with HbA1C of 11% on irregular intake of oral hypoglycemic agents (OHA) with features of autonomic neuropathy (paresis in bilateral foot and postural hypotension). Cardiac consultation was taken with a screening echo showing ejection fraction of 60%. On examination, he was edentulous. Since it was an emergency surgery, with adequate risk assessment and consent, he was taken up for surgery under high risk consent and general anesthesia administered since neuraxial blockade or nerve block couldn’t be given due to the anticoagulated state.3 His international normalized ratio was 1.2 and platelet count 1.5 lacs/mm². After giving judicious amount of opioid (inf fentanyl 1.5 μg/kg iv), titrated dose of etomidate (0.3 mg/kg iv) given followed by atracurium (0.5 mg/kg) muscle relaxant and a proseal laryngeal mask airway placed in a deep plane for mechanical ventilation using sevoflurane and nitrous oxide with oxygen gas mixture for maintenance. Hemodynamics were fluctuating intraoperatively for which appropriate drugs (variable doses of phenylephrine) and fluids were given. Normothermia was maintained. At the end of the surgery, neuromuscular blockade was reversed (inf glycopyrrolate 0.2 mg/kg iv and ing neostigmine 0.5 mg/kg) and patient extubated once he was completely awake. He developed lower respiratory tract infection on post-operative day 3 probably secondary to being immobilised and in view of emergency surgery, there was no time for preoperative optimisation or incentive spirometry. Adequate antibiotics and respiratory care were given following which he recovered and was discharged in 8 days.

Case report 3

A 102 year old lady with neck of femur fracture was planned for open reduction internal fixation. She was hard of hearing. She had no other comorbidities or positive findings, and after taking consent from her and her attendants, she was taken up for surgery under neuraxial blockade (CSE was planned), avoiding parenteral opioids, benzodiazepines, and other anesthetic agents. After noting baseline monitor values, intravenous line secured and co loading was done with ringer lactate fluid. Low dose local anesthetic combined with opioid (2.4 ml of 0.5% hyperbaric bupivacaine with 0.2 ml (10 mcg) fentanyl) was given via paramedian approach through a 27G Quincke needle in the L3-4 intervertebral space (level achieved was dermatome level T10 with modified Bromage score 1 (complete block).4 Pressure point padding was done, efforts to maintain normothermia were taken. As the patient was hard of hearing, it was a challenge to keep counselling her intraoperatively. Although the surgery was uneventful, she developed postoperative cognitive dysfunction (POCD) a few days after surgery, despite taking all possible precautions. She was discharged on the 6th day after maximal optimisation.

DISCUSSION

Management of geriatric patients involves preoperative assessment for risk- stratification, intra operative management of comorbidities and complications and postoperative discharge planning. Even in the absence of a specific organ-based disease process, anaesthesia for the elderly requires an alteration in technique to take account of age-related changes to normal physiology as discussed in Table 1. These changes are even more pronounced in elderly aged above 100 years old.

Pre operative assessment and management

The preoperative management and assessment of a geriatric patient requires several factors to be kept in mind.3 Regular perioperative risk assessment measures may often overlook subtle geriatric-specific syndromes that translate into increased vulnerabilities for older patients. Although old age is not a disease, the age of the patient is the most important factor as there are physiological changes as given in Table 1. Several comorbidities are present in elderly - most commonly hypertension, diabetes, CAD, cancer, and cerebrovascular disease. They should all be tackled individually, polypharmacy and drug interactions to be kept in mind. The extent and duration of surgery, planned technique of anaesthesia, blood products needed, expected postoperative care should all be discussed and adequate arrangements made. The patient’s goals and treatment preferences, health care proxy or surrogate decision-maker should all be confirmed and documented. In patients with existing advance directives, new risks associated with the surgical procedure and an approach for potentially life-threatening problems consistent with the patient’s values and preferences should be discussed. Shortened fluid fast (clear liquids up to two hours before anesthesia) and solid fasting should be considered. Adherence to existing best practices regarding antibiotic and venous thromboembolism prophylaxis should be done. Nonessential medications should be stopped and only essential medications given. Incentive spirometry, deep breathing exercises should be started. Multidisciplinary approach with consultations from physical rehabilitation specialist, occupational therapy and post discharge home needs should be done.

Counselling and consent in geriatric

Cognitive dysfunctions, memory loss, hearing loss, dementia, depression and stroke may all complicate the issues of consent and decision making. Talking about legal standards of competence for consent include- the
abilities to communicate a choice, understand relevant information, appreciate the current situation and its consequences, manipulate the information rationally. The above mentioned features are often not present in elderly patients, making counselling and consent a difficult task in them. In the 3 case reports mentioned above, only one patient had hearing problem but she was explained about the risk, procedure and complications with the help of her relatives and sign language.

Table 1: Physiological changes in geriatric age group.

| System         | Structural changes                                                                 | Functional changes                                                                 |
|----------------|------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------|
| CNS            | ● ↓ in volume of both gray and white matter                                        | ● Memory decline                                                                    |
|                | ● Shrinkage of subcortical white matter and hippocampus (more with hypertension & vascular disease) | ● ↓ in neurotransmitters like dopamine, acetylcholine, norepinephrine and serotonin |
|                |                                                                                     | ● ↓ in brain reserve leading to functional activity of daily life                   |
|                |                                                                                     | ● ↑ sensitivity to anaesthetic                                                     |
|                |                                                                                     | ● medications                                                                      |
|                |                                                                                     | ● ↑ risk of delirium                                                              |
|                |                                                                                     | ● ↑ risk of postoperative cognitive dysfunction                                     |
| Neuraxial      | ● ↓ in epidural space area                                                           | ● ↓ conduction velocity                                                             |
| changes        | ● ↑ permeability of dura                                                             | All the structural and functional changes leads to                                  |
|                | ● ↓ volume of CSF                                                                   | ↑ sensitivity to neuraxial and peripheral nerve blocks                               |
| Cardiovascular | ● ↓ myocyte number                                                                  |                                                                                                                                 |
| system         | ● ↓ in conduction fiber density and number of sinus node cells                      |                                                                                                                                 |
|                | ● ↓ contractility                                                                   |                                                                                                                                 |
|                | ● ↑ myocardial stiffness and ventricular filling pressure                            |                                                                                                                                 |
|                | ● ↑ central aortic dilatation                                                       |                                                                                                                                 |
|                | ● ↑ thickness of arterial wall                                                      |                                                                                                                                 |
|                | ● Aortic valve sclerosis and annular calcification                                  |                                                                                                                                 |
| Respiratory    | ● ↓ elastic recoil                                                                  | ● ↓ β adrenergic sensitivity                                                       |
| system         | ● Altered surfactant                                                                | ● ↑ in sympathetic nervous system activity                                          |
|                | ● ↑ in lung compliance                                                              | ● ↑ systemic vascular resistance and mechanical stiffening of peripheral vessels    |
|                | ● ↑ in anatomic dead space                                                          |                                                                                                                                 |
|                | ● ↓ diffusing capacity                                                              |                                                                                     |
|                | ● ↑ closing capacity                                                                | ● ↓ maximal heart rate and ↓ peak ejection fraction                                 |
|                | ● Impaired gas exchange                                                             | during exercise and stress which makes heart more susceptible to cardiac failure    |
|                | ● Residual volume ↑ by 5-10% per decade                                              |                                                                                                                                 |
|                | ● Vital capacity↓                                                                  | Diastolic dysfunctionà diastolic heart failure                                      |
|                | ● Functional Residual capacity - unchanged/ slightly ↑                               |                                                                                                                                 |
| Renal          | ● Nephrosclerosis                                                                    | Ventricular response to hypoxia, hypercapnia and mechanical stress impairment secondary to ↓ CNS activity |
|                | ● ↓ renal blood flow- 10% decrease per decade                                        | Respiratory depressant effect of benzodiazepines, opioids and volatile anaesthetics |
| Hepatic        | ● Liver volume decreased by 20-40% with aging                                        | ↑ sensitivity for bronchoconstriction and response to treatment with inhaled β agonist |
|                | ● Hepatic blood flow decreases 10% per decade                                         | ↓ immune response --> ↑ susceptibility to environment exposure and lung injury      |

Intraoperative management

General considerations

Preoperative antibiotics should be given based on procedure, risk factors, and the hospital’s unique pathogen profile within 60 minutes before surgical incision. Consideration of regional techniques to avoid postoperative complications and improve pain control should be taken. There should be a detailed perioperative analgesic plan including taking a directed pain history and plan multi-modal or opioid-sparing techniques with
consideration of regional techniques. Postoperative nausea risk stratification and prevention strategies should be taken. Prevention of postoperative pulmonary complications and hypothermia should be done. Appropriate use of intravenous fluids, restrictive or goal-directed strategies should be preferred over fixed-volume strategies, which can cause fluid overload in an already compromised physiological state in elderly. Appropriate hemodynamic management anticipating the fluctuations. Measures should be taken to ensure proper positioning and padding of bony prominences of elderly patients undergoing elective or nonelective surgery to maintain skin integrity and limit pressure on peripheral nerves and prevention of pressure ulcers. The elderly in particular are predisposed to hypothermia due to altered thermoregulation from decreased muscle mass, metabolic rate, and vascular reactivity. Patient warming with forced air warmers and/or warmed IV fluids should be used in older patients who are undergoing procedures longer than 30 minutes to avoid hypothermia. 

**Blood transfusion**

Orthopedic surgeries often require blood transfusion. There should be proper assessment of hemoglobin before surgery as it is seen that that patients with anemia have more risk of surgical complications and death especially during orthopedic surgeries because of the large quantities of blood loss due to bone trauma and the difficulties of achieving hemostasis in this tissue. If hemoglobin level is less than 6% the risk may increase up to 30%. There occurs dramatic improvement in symptoms with small improvements in hemoglobin and hematocrit. In elective surgeries the recommended hemoglobin level is 11 g%. Talking about replacement, packed red blood cells seems to be most effective both during and after the procedure. But it has been found that infection rates are higher among patients undergoing femoral neck surgery who received transfusions because of decreased immunity.

**ANESTHESIA IN ELDERLY**

**Nerve blocks**

There are several changes that occur in peripheral nervous system with respect to aging like peripheral nerve deterioration; dysfunction of genes responsible for myelin sheath protein components; decreased myelinated nerve fiber conduction velocity; motor and sensory discriminatory changes in the feet; changes in sensation (e.g. pain, touch).

Nerve blocks are considered safe in the elderly and are shown to have benefits in terms of faster post operative mobility as compared to epidural analgesia for lower limb surgeries. They also play an important role as a part of multi modal analgesia. Adequate pain management is of utmost importance in the elderly as enhances faster recovery by improving mobility, lesser postoperative respiratory complications, and lesser delirium.

**General anesthesia**

General anesthesia involves airway manipulation as well as administration of a cocktail of drugs, all of which are affected in the elderly. Elderly patients are prone to structural and functional changes surrounding the airway, including, but not limited to, an edentulous mouth, oropharyngeal tumors, atrophy of the glottic muscles, and decreased neck range of movements as compared to a young adult making bag mask ventilation (BMV) and intubation more difficult. In case report 2, the 105 year old adult was edentulous and had difficult BMV for which we used a gauze pack to cover the hollow cheeks. Laryngeal mask airway placement was however done without any difficulties. In addition, age-related comorbidities such as chronic obstructive pulmonary disease, gastroesophageal reflux disease, and diabetes increase the risk of aspiration pneumonia. Desaturation occurs faster in older patients hence preoxygenation should be done religiously. The time to peak relaxation following neuromuscular blockade is delayed with increasing age and the elderly are more prone to have a cardiac event from desaturation.

The pharmacokinetics and pharmacodynamics of drugs are also altered in geriatrics. The ED 50 equivalent for inhalational anesthetics falls linearly with age therefore, the dosage of drugs affecting central nervous system (CNS) need be reduced. Hypotension is very common so the dosages of agents like propofol, opioids, benzodiazepines, thiopeptone etc. should be titrated as shown in Table 2.

Short acting drugs should be selected. Peak effects of drugs administered is delayed: midazolam 5 mins, fentanyl 6 to 8 min, and for propofol 10 minutes. Autonomic neuropathy of diabetes, diminished gut motility and diminished hepatic functions makes geriatric patients vulnerable to side-effects of opioids and anaesthetic drugs. Aging of the autonomic nervous system shows limited adaptability to stress; decreased basal activity of the parasympathetic nervous system and overall net activation of the sympathetic nervous system; decreased baroreflex sensitivity; slowing and weakening of homeostatic functions. The increase in sympathetic tone in older patients should also be considered when choosing an anesthetic with sympathomimetic properties, as such anesthetics may be poorly tolerated by some individuals with cardiovascular disease.

**Neuraxial anesthesia**

Not only are there anatomical changes which affect neuraxial blockade in elderly, there are also several physiological factors. Age has no effect on duration of motor blockade with bupivacaine spinal anaesthesia.
although the time of onset is decreased. The LA spread is more extensive with hyperbaric bupivacaine because of the physiologic changes described in Table 1. Studies have not revealed any effect of age on duration of epidural anesthesia.6

Table 2: Clinical pharmacology of anesthetic agents in elderly.6

| Drug              | Brain sensitivity | Pharmacokinetics                                      | Dose       |
|-------------------|-------------------|-------------------------------------------------------|------------|
| Inhalational agents |                   |                                                       |            |
| Thiopentone       | ↔                 | Decreased initial volume of distribution               | Decreased  |
| Etomidate         | ↔                 | Decreased initial volume of distribution               | Decreased  |
| Propofol          | Increased         | Decreased clearance                                   | Decreased  |
| Midazolam         | Increased         | Decreased clearance                                   | Decreased  |

Table 3: Recommendations for anesthesia in some specific orthopedic surgeries.5

| Type of surgery         | Technique of anesthesia                                                                 | Advantages of regional anesthesia                                                                 |
|-------------------------|----------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------|
| Hip fracture repair     | Discuss about the risk and benefit with the patient and decide about regional or general anesthesia!! | • Reduced mortality                                                              |
|                         |                                                                                       | • Reduced requirement of sedatives                                                             |
|                         |                                                                                       | • Avoids airway instrumentation                                                               |
|                         |                                                                                       | • Decreased blood loss                                                                       |
|                         |                                                                                       | • Decreased risk of thrombosis                                                                |
|                         |                                                                                       | • Decreased POCD                                                                             |
| Elective hip and knee arthroplasty | Consider regional anesthesia                                                           | • Reduced mortality                                                              |
|                         |                                                                                       | • Better pain scores with decreased sedation                                                |
|                         |                                                                                       | • Reduced systemic infection and less use of critical care                                    |

The anatomical changes pose as challenges for neuraxial blockade technique.14 It is not uncommon to find dorsal kyphosis, osteoarthritic and rheumatoid arthritis changes limiting range of motion of the spine, osteoporosis further decreasing mobility and difficult needle placement. There is difficulty in positioning due to above mentioned reasons along with degenerative changes of intervertebral disc and vertebrae and compression of intervertebral and epidural spaces. There occurs calcification of ligamentum flavum and other ligaments making needle placement more challenging. Osteophytes decrease the size of the intervertebral space, which limits access to the subarachnoid space. By using lateral or paramedian needle approach, we can avoid calcified vertebral midline ligament and distortion of dorsal vertebrae. The L5-S1 interspace, the largest intervertebral space can ease the blockade in severe osteoarthritis patients.

General vs regional anesthesia

There is no clear cut evidence of which type of anesthesia is preferred in elderly. Both types have their own pros and cons. Memtsoudis et al have said that regional anaesthesia has advantages of reduced blood loss during surgery and decreased need for transfusion and related hazards, decreased incidence of deep-vein thrombosis and pulmonary embolism, better postoperative analgesia and lesser costs, all important considerations during geriatric anaesthesia.15

Whereas Waesbergh et al have said that they could not detect any difference in the 30-day mortality in patients undergoing hip fracture surgery. However, in their study, the length of hospital stay and the in-hospital mortality were significantly shorter in the neuraxial anaesthesia group. The incidence of myocardial infarction and respiratory failure was significant lower in the neuraxial anaesthesia group and there was no difference in the incidence of pneumonia between the two groups. They also found that spinal anaesthesia may be associated with significantly reduced early mortality, fewer incidents of deep vein thrombosis, less acute postoperative confusion, a tendency to fewer myocardial infarction, fewer cases of pneumonia, fatal pulmonary embolism and postoperative hypoxia. In their meta-analysis they did not observe any difference in the 30-day mortality rate between neuraxial and general anaesthesia although length of hospital stay and the in-hospital mortality was shorter in the neuraxial anaesthesia group.16

As per the American Geriatric Society guidelines, in Table 3 we see the recommendations for technique of
anesthesia in some specific orthopedic surgeries and the advantages of regional anesthesia.\(^5\)

There is evidence that the use of regional techniques allows for the minimization or elimination of the negative side effect profiles of other systemic pain management options, such as bowel and bladder dysfunction, hemodynamic derangements, and cognitive effects often experienced with opiates and other analgesic adjuncts and sedative or hypnotics, to which older patients are often more sensitive.\(^6\) The type of anesthesia should be decided by a multidisciplinary approach, patient, attendants, type of surgery, comorbidities and weighing the risk versus benefit ratio. Further studies are still required to decide which type is better.

**Post operative management**

In elderly patients postsurgical stress, both physical and psychological leads to an imbalance in autonomic, endocrine, metabolic, and immune functions. Depending on the patient’s preoperative physiologic reserve and comorbid conditions, additional clinical challenges may impose further alterations in the stress response and the recovery trajectory.\(^17\) Common postoperative complications in elderly include delirium, pulmonary complications, falls, undernutrition, urinary tract infection, pressure ulcers, and functional decline.

**Postoperative cognitive dysfunction and delirium**

Postoperative cognitive dysfunction (POCD) refers to a deterioration in cognition temporally associated with surgery as quantified by neuropsychological tests. Although all orthopedic surgeries in elderly are a risk factor for development of POCD or delirium, patients with hip fractures have a high incidence of post-operative delirium of 32 to 53.3% due to physiological and psychological stress from injury, pain, analgesia and surgery.\(^16\) Anesthetic technique is a potentially adjustable risk factor for postoperative delirium. Unfortunately, most studies have been unable to detect a consistent difference in postoperative delirium between regional and general anesthesia.\(^18-20\) Marcantonio and colleagues developed a risk factor criteria for development of POCD in general, orthopaedic, and gynaecology surgery.\(^21\) The risk factors were: age>70 yr, alcohol abuse, poor cognitive status, poor functional status, markedly abnormal sodium, potassium, or glucose, non-cardiac thoracic surgery, aortic aneurysm surgery, with one point given to each risk factor. 0 points, <1%; 1 point, 8%; 2 points, 19%; and 3 points, 45%.

To prevent POCD or delirium post operatively, we should provide adequate pain control, optimize physical environment (for example, sleep hygiene, sleep protocol, minimize tethers, encourage family at bedside), make vision and hearing aids accessible, remove catheters, minimize psychoactive medications, and avoid potentially inappropriate medications.\(^22\)

**Respiratory complications**

Older adult patients are at risk for postoperative pulmonary complications, including atelectasis, hospital acquired pneumonia, and acute respiratory failure. These kinds of complications increase the risk of long-term mortality following surgery. Additionally, older age may be an independent predictor of postoperative pneumonia, after adjustment for comorbidity burden.\(^23\) To avoid postoperative respiratory complications several measures can be taken. Epidural analgesia techniques should be used whenever possible. Intermediate (like cisatracurium, rocuronium, vecuronium) and long acting neuromuscular blocking agents (like pancuronium) should be avoided. When neuromuscular blockade is used, adequate recovery of neuromuscular function prior to extubation should be ensured. Preoperative incentive spirometry and deep breathing exercises should be started as already mentioned. Early mobilization and ambulation should be done and aspiration precautions should be taken.

**Thromboembolism**

Increasing age is a known risk factor for thromboembolism.\(^2\) Other risk factors which may add up to the list are surgery, trauma, immobility, lower extremity paresis all of which may be found in orthopedic patients. Prophylaxis to prevent venous thromboembolism (VTE) should be taken whenever possible. The elderly should be put on intermittent pneumatic compression devices on a priority basis during and after prolonged orthopedic surgeries.

In case 2, the patient was on aspirin and clopidogrel. As per the American Society for Regional Anesthesia (ASRA) guidelines for aspirin—“in patients receiving these medications, we do not identify specific concerns as to the timing of single-injection or catheter techniques in relationship to the dosing of NSAIDs, postoperative monitoring, or the timing of neuraxial catheter removal”.\(^3\) The ASRA guidelines for clopidogrel “based on labeling and surgical/procedural experience, the recommended time interval between discontinuation of thienopyridine therapy and neuraxial blockade is 5-7 days for clopidogrel”.\(^1\) Since it was an emergency case, we opted for general anesthesia rather than regional anesthesia to bypass the waiting time required to give neuraxial blockade.

**TO PERFORM SURGERY OR NOT?**

Following are some of the studies which force us to think that “do we need surgery or not?”

Most hip fractures in patients over 100 years of age are pertrochanteric. Patients with 2 or more major background diseases have an increased risk for dying in the first 6 months after the operation. Most patients having operations in this age group had a postoperative reduction in mobility status and in performing basic
activities of daily living. A significantly higher 30-day and 1-year mortality was revealed in nonoperatively treated hip fracture patients. Operating on patients older than 100 years carries an acceptable mortality rate. Age alone should not preclude centenarians from undergoing operative treatment for hip fractures. The ability to remain independent is vital to many elderly patients as highlighted in a study by Salkeld et al, where 80% of elderly female patients stated that they would rather die than lose their independence and be admitted to a nursing home establishment.

A multitude of factors influence the surgical outcomes in older patients, such as the type, duration, and invasiveness of an operation, coexisting medical or mental status dysfunction, and the skill and expertise of both the anesthesiologist and surgeon hence eventually it has to be a combined decision of the patient, attendants, the concerned physician, orthopedic surgeon and the anaesthesiologists to weigh the risk vs benefit ratio of whether the patient should be managed conservatively, where possible, or to go ahead with surgery.

CONCLUSION

A multidisciplinary approach is required for perioperative management of geriatric orthopaedic cases. As our population continues to age, anaesthesiologists and surgeons are tasked with identifying anesthetic techniques that minimize morbidity and mortality and postoperative cognitive disorders in the older patient, in our case we discussed three patients over the age of 100 years. To conclude we would say that age is just a number and every patient needs to be individualised according to the comorbidities, type and duration of surgery, expected complications thus deciding about the anesthesia technique hoping for the best but preparing for the worst. As of the year 2020, if you are not a pediatric, you are a geriatric specialist!
