Abstract

Regeneration of multiple shoots via callus induction and organogenesis was obtained from young leaf explants of the field grown marigold (Tagetes erecta L.). Callus induction and shoot regeneration at various frequencies were observed using different concentrations and combinations of growth regulators. Highest percentage (90%) of callus formation was observed within two weeks on MS medium supplemented with 5.0 mg/l BAP with 2.5 mg/l NAA. The maximum percentage (80%) of shoot bud formation (10±0.5/callus) was obtained from MS medium containing 1.0 mg/l BAP with 0.5 mg/l kinetin. The regenerated shoots developed highest percentages (90%) of roots on half strength MS medium supplemented with 1.0 mg/l IBA. The plantlets when transferred into potsoil 80% survived. Regenerated plants were morphologically uniform with normal leaf shape and growth pattern.

Keywords: In vitro; Tagetes erecta L.; Callus induction; Regeneration; Acclimatization

Introduction

Marigold (Tagetes erecta L.) is an annual herbaceous medicinal plant of the botanical Family: Compositae and is presently grown in almost all tropical countries including Bangladesh. It is often cultivated in homestead gardens and as pot plants. Besides attractive flower colors, both leaves and flowers are equally important medicinally. The plant is effective against in emmenagogue, piles, rheumatism, colds, bronchitis, kidney troubles and muscular pains (Ghani, 1998). It has been also noticed that Tagetes are highly effective in keeping the population of nematode under control (Khan et al., 1971; Lehman, 1979; Siddiqui and Alam, 1988). The nematocidal effect is attributed to the presence of thiophenes (Chan et al., 1975), which are naturally occurring biocides (Cros et al., 1989, Hulst et al., 1989). Because of its aesthetic, medicinal and commercial values the demand of Tagetes has been steadily increasing.

The plant is generally propagated by seeds and cuttings. Seed germination is unreliable due to its poor rate. Sometimes Tagetes production declines due to incidence of viral and other diseases which may cause a great extent of commercial losses (Sastry et al., 2019). Tissue culture techniques provide a fast and dependable method for production of a large number of disease free, uniform plantlets in a shorter period of time. Several authors have reported about the micro propagation of Tagetes spp. but the reproducibility of the results was not satisfactory (Kothari and Chandra, 1984, 1986; Bespalhok and Hattori, 1998; Misra and Datta, 2001). However, further improvement of the protocol is essential because it is one of the major pre-requisites for genetic manipulation and to improve the quantity and quality of planting material to approach for safe, long-term maintenance of valuable germ plasm, developed through breeding programmes (Vanegas et al., 2002). Thus, the present study was undertaken to develop an improved and easily reproducible protocol for multiplication of T. erecta through organogenesis.

Materials and methods

The experiment was conducted at Biological Research Division, Bangladesh Council of Scientific and Industrial Research (BCSIR), Dhaka, Bangladesh. The apical shoot tips with leaf primordia (2-4 mm) were collected from

*Corresponding author e-mail: john_liton@yahoo.com
2-3 month old field grown T. erecta and used as primary explants. First explants were washed under running tap water for 10-15 min and then surface sterilized with 0.1% HgCl2 for 10 min followed by five to six rinses with sterilized distilled water further. For callus induction the leaf segment of 2-4 mm length were excised and were inoculated in 150 × 25 mm culture tubes containing MS (Murashige and Skoog, 1962) supplemented with various combinations and concentrations of auxins and cytokinins and with 0.6% agar pH 5.7. Six callus induction media (CIM) were used. CIM1 and CIM2 media contained BAP 1.0 and 2.0 mg/l, respectively, CIM3 medium contained BAP 2.5 mg/l with NAA 0.5 mg/l, CIM4 medium contained BAP 5.0 mg/l with NAA 2.5 mg/l. CIM5 medium contained BAP 10 mg/l with NAA 5.0 mg/l and CIM6 medium contained no growth regulators.

In the present protocol, four regeneration media (RM1, RM2, RM3 and RM4) supplemented with kinetin (0.5 mg/l) and different combinations of BAP (0.5, 1.0, 3.0 and 5.0 mg/l) were used as treatment for plant regeneration. Twenty five shoots were used per treatment with three replications. For root induction, >1.0 cm long micro shoots were inoculated in the rooting medium containing half strength MS media with various concentrations of auxin and sucrose for root induction. Inoculated cultures were incubated at 25±2°C under fluorescent tube light with 16 h photoperiod and data were recorded after 3 weeks of culture.

For hardening, the culture tubes containing rooted shoots were kept at room temperature under light for 14 d. Then the rooted shoots were removed from culture tubes, washed thoroughly to free agar from roots and finally transplanted into small pots containing soil. Plantlets were well covered with a piece of polythene sheet for three weeks to ensure high humidity while watering was continued regularly.

**Results and discussion**

Calli were developed at the cut surfaces of the leaf explants within 8-10 d of inoculation and subsequently covered the entire surfaces within 15-18 d in the callus induction media. Although, callus induction was observed in all media but there was a wide range of variation in percentages of callus formation as well as color and texture of the callus (Table 1). Callus induction was not found in MS medium without growth regulators even after four weeks of culture. The most rapid and prolific callus response was obtained from a combination of 5.0 mg/l BAP with 2.5 mg/l NAA. The highest percentages (90%) of callus formation were observed on this medium compared to other media 10.0 mg/l BAP with 5.0 mg/l NAA (49%), 2.5 mg/l BAP with 0.5 mg/l NAA (58%), 2.5 mg/l BAP (45%) and 1.0 mg/l BAP (25%). Calli were found hard and compact, which were initiated on media supplemented with higher concentrations of hormonal combinations. The results of the present experiment agree with the findings of Kothari and Chandra (1986). They found that a combination of BAP, NAA and GA₃ (gibberellic acid) was suitable for high frequency callus production in Tagetes.

However, Ketel et al. (1985) reported that certain marigold species i.e. T. erecta and T. patula are difficult to culture in vitro due to browning of explants that led to poor callus growth or death of explants. Our results showed that, young leaf of T. erecta provides an excellent material to obtain most rapid and prolific callus formation. This might be due to genotypic variation of explants reinforced by the cultural and environmental conditions.

Table II shows the capacity of shoot bud differentiation and shoot proliferation from leaf derived calli of T. erecta depended on hormonal variation. For shoot formation green nodular compact calli were cultured on MS medium containing different concentration of BAP with Kinetin for shoot formation. The highest percentages of shoot formation were observed in MS medium containing 1.0 mg/l BAP with 0.5 mg/l kinetin. The explants showed shoot initiation after 10-15 days (Fig.1a). In this medium 80% of cultures were found to regenerate shoots and the number of regenerated shoots per explants was 10±0.5. In MS medium

supplemented with BAP (0.5 mg/l) with kinetin (0.5 mg/l), 2-3 shoot developed within 15-20 days (Fig. 1b). Media containing a high level of BAP (3.0-5.0 mg/l) with Kinetin (0.5 mg/l) yielded a few of shoots and decreased with further more increase in BAP concentrations. Kothari and Chandra (1984, 1986) and Vanegas et al. (2002) reported that development of adventitious shoot bud was observed on a medium with different concentrations of BAP with IAA. On the contrast, in the present study, there was a good shoot bud initiation and proliferation response only in the presence of cytokinins (BAP with kinetin). The cytokinins are generally added to a culture media to stimulate cell division, to induce shoot formation and axillary shoot proliferation. Our results showed that, an absolute cytokinin may be required for Tagetes organogenesis from leaf explants. The potential of calli to differentiate was ascribed to a phytohormone effect mediated by differential gene activity (Breteler and Ketel 1993).

For adventitious root formation elongated healthy shoots (3-4 cm in length) were excised and transferred to the half strength MS media supplemented with different concentrations (0.5-2.0 mg/l) of IBA and IAA. In most cases, root initiation started with in 7-10 days of culture

**Fig. 1** (a-e). Different stages of plant regeneration from leaf explants in *Tagetes erecta*

c. Root induction in half strength MS with 1.0 mg/l of IBA  
d. and e. Hardened plantlets transferred to soil
(Fig. 1c). It may be mentioned that, root induction was not observed in MS medium which was free from any hormonal supplement. Best response observed when 1.0 mg/l of IBA was used (Table III). In this medium, 90% shoots rooted within four weeks of culture and each microcutting produced 6-8 roots. Similar effects of IBA were reported in Ocimum americanum L. syn. O. canum Sims and O. sanctum L. (Pattanaik and Chand, 1996). Root developed in medium containing lower concentration IBA or IAA (0.5 mg/l) was poor in quality. On the other hand, medium containing higher concentrations of IBA or IAA (2.0 mg/l) always formed root accompanied with callusing. The proper stage of root development is another criterion for selecting plantlets to be transferred into the soil. In vitro regenerated plantlets were transferred to small pots for future establishment (Fig. 1d). After 10-15 days when the plants were fully acclimated to outdoor conditions, they were then transplanted in the earthen pots (Fig. 1e).

The present report showed that MS medium containing 1.0 mg/l BAP with 0.5 mg/l kinetin proved more effective for multiple shoot formation from the leaf explants derived calli. The technique described here appears to be readily adaptable for large scale propagation of this important medicinal and ornamental plant to earn foreign exchange and also to meet the local demand.

**Conclusion**

Multiple shoots were obtained from young leaf induced callus of *T. erecta*. Our study demonstrated that MS medium with BAP and NAA combination induced highest percentage of callus, whereas BAP with Kinetin produced maximum shoots from callus. Maximum roots were produced in half strength MS medium with IBA. When transferred to soil, 80% plantlets survived. The technique described here is a promising method of micro propagation of *T. erecta* to a larger scale. In order to make it more effective further experiments should be done at the stage of acclimatization using different types of soil media combinations.
